The waves that appear in nature are complex. Nevertheless, our work on harmonic waves is relevant because most elastic media that undergo small displacements in response to forces exhibit **linearity**. Linearity means that if two waves can travel through a medium, then a third wave whose form is the algebraic sum of these waves is possible. Thus if a stretched rope supports two different waves in the form $z_1(x, t)$ and $z_2(x, t)$, then it can also support the wave that is described by $z(x, t) = z_1(x, t) + z_2(x, t)$. In other words, *the sum of two solutions of the wave equation for the system is also a solution*. When linearity applies, the sum of any number of waves can add to form another wave, and a wave multiplied by any constant is also an allowed wave. Of course, when we say the "sum" or "multiple" of waves, we are talking about the displacement involved, the quantity we have often called z that describes the wave. This could be a transverse displacement on a rope, a longitudinal displacement in a solid, or the pressure change or density change in a gas. This fact is known as the **superposition principle**.

Let us see how a sum of two solutions of the wave equation can also be a solution to that equation. We saw in Chapter 14 that for transverse waves on a string the wave equation reads [Eq. (14–10)]

$$\frac{\partial^2 z}{\partial x^2} = \frac{1}{v^2}\frac{\partial^2 z}{\partial t^2}, \tag{15–1}$$

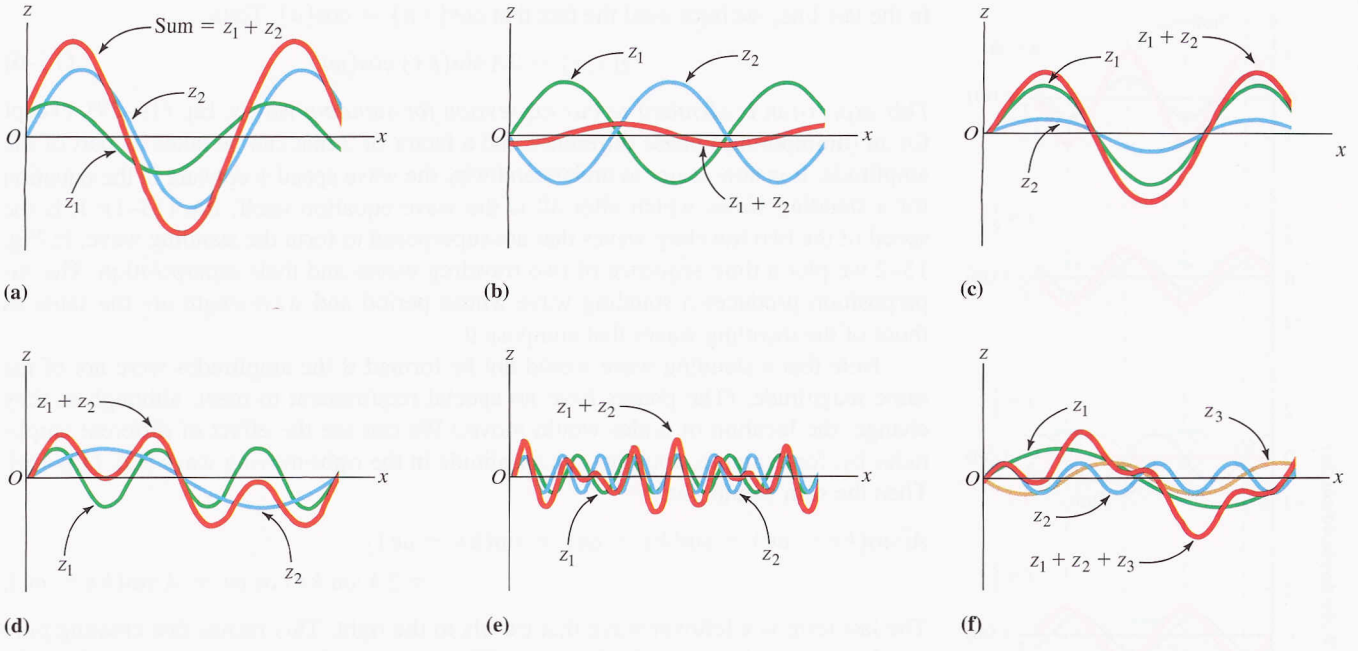
where x is the distance along the string and $z(x, t)$ is the transverse displacement of the string at point x and time t. Equation (15–1) is *linear* because the function z appears linearly; that is, as z rather than as z^2 or as z to some other power. If $z_1(x, t)$ and $z_2(x, t)$ are two different solutions satisfying some linear equation such as the wave equation, then the sum $z_1(x, t) + z_2(x, t)$ also satisfies that equation. Superposition works only for waves of small amplitude because when a medium is stretched or distorted too far, the restoring force is no longer purely springlike, and the dynamical equation becomes nonlinear.

Interference

The superposition principle allows us to add sinusoidal waves of different amplitudes, wavelengths, and frequencies, each of them moving in different directions. These sums are *algebraic* sums, complete with the possibilities of algebraic cancellations (Fig. 15–1). This cancellation is known as **interference**, and the result of the interference is a rich palette of patterns called **interference phenomena**.

A simple and striking example of interference is the case of two transverse harmonic waves that each travel to the right on a rope. Let the waves have the same amplitude and be 180° (π rad) out of phase. The two waves have the respective forms

$$z_1(x, t) = z_0 \sin(kx - \omega t) \tag{15–2}$$



and

$$z_2(x, t) = z_0 \sin(kx - \omega t + \pi) = -z_0 \sin(kx - \omega t). \tag{15–3}$$

The superposition of these two transverse waves adds to zero! This is an extreme case of **destructive interference**, which is interference that occurs at any point where two waves have the opposite sign. Although interference may be *fully* destructive (waves adding to zero at a given point), keep in mind that less than total cancellation is possible. **Constructive interference** occurs when the waves add in such a way that they reinforce. If, for example, our two waves z_1 and z_2 had exactly the same phase, we would find a summed solution with the same x- and t-dependence of either wave but with amplitude $2z_0$. Here too, less than maximal levels of constructive interference are possible.

Coherence

What conditions are necessary for waves from two different sources (for example, the sound waves coming from two loudspeakers) to exhibit an interference pattern? If the two sources put out a series of waves with different frequencies and with phases that change randomly, then there is no *consistent* interference pattern. Any pattern would change so

▲ **FIGURE 15–1** The superposition of (a) two waves of the same frequency, with a slight phase difference between them; (b) two waves of the same amplitude and frequency, with a phase difference of nearly 180° between them; (c) two waves of the same frequency and phase but different amplitudes; (d) two waves of the same amplitude but frequencies that differ by a factor of 3; (e) two waves of the same amplitude but slightly different frequencies, resulting in beats; (f) three waves of different amplitudes and frequencies.

rapidly that we could not recognize it. *An interference pattern occurs only when the waves have a definite, stable relation between their frequencies and phases.* The waves are then said to be **coherent**. When, in contrast, we have waves without a definite, stable relation between their frequencies and phases, the waves are **incoherent**. Sources such as piano strings or lightbulbs or the human voice that are not point sources are generally incoherent with other sources such as other piano strings or other voices. If the form of vibration of the piano string is complex, as it generally is, even waves coming from different parts of the string will not generally be coherent with each other. You won't observe interference by listening to a rock band! This is discussed further at the end of Section 15–4.

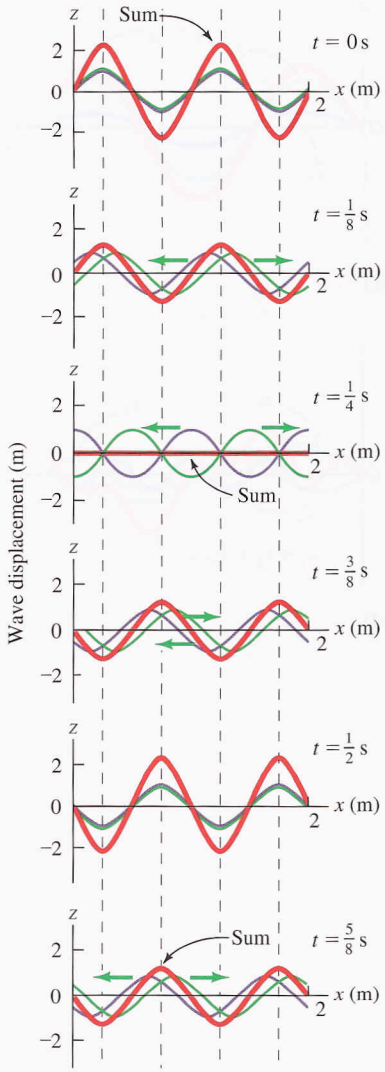
15–2 Standing Waves Through Interference

Standing waves can be viewed as the result of the superposition of traveling waves moving in opposite directions. Imagine a very long string with two waves that move in opposite directions but are otherwise identical, each a solution of the wave equation:

$$\text{for the left-moving wave: } z_l(x,t) = A\sin(kx + \omega t); \qquad (15\text{–}4a)$$

$$\text{for the right-moving wave: } z_r(x,t) = A\sin(kx - \omega t). \qquad (15\text{–}4b)$$

We have taken the wavelengths, frequencies, phases, and amplitudes to be equal. (You may want to review the meaning and relations between these quantities at this point; see Section 14–3.) According to the principle of superposition, the resultant displacement is



$$z_1(x,t) = z_r(x,t) + z_l(x,t) = A[\sin(kx - \omega t) + \sin(kx + \omega t)]. \qquad (15\text{–}5)$$

If we use the trigonometric identity 5.3 of Appendix IV–4, with $a = kx - \omega t$ and $b = kx + \omega t$, then we obtain

$$\sin(kx - \omega t) + \sin(kx + \omega t)$$

$$= 2\sin\left[\frac{(kx - \omega t) + (kx + \omega t)}{2}\right]\cos\left[\frac{(kx - \omega t) - (kx + \omega t)}{2}\right]$$

$$= 2\sin(kx)\cos(\omega t).$$

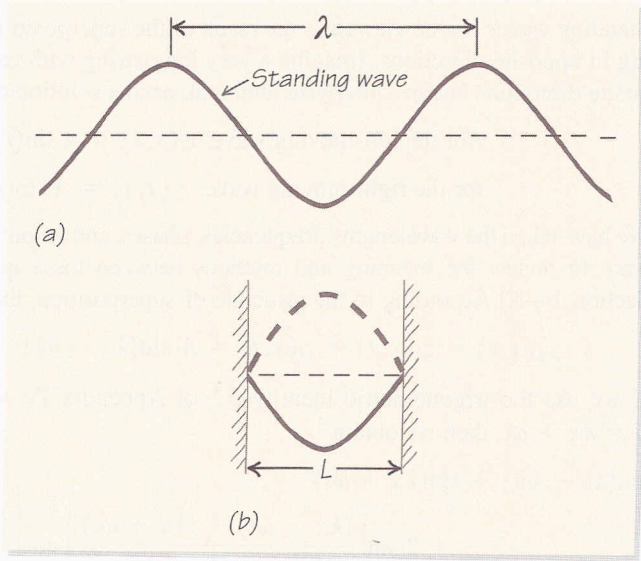
In the last line, we have used the fact that $\cos(-a) = \cos(a)$. Thus

$$z(x, t) = 2A \sin(kx) \cos(\omega t). \tag{15–6}$$

This expression is identical to our expression for standing waves, Eq. (14–39), except for an (unimportant) phase difference and a factor of 2 that can be taken as part of the amplitude. It is now easier to understand why the wave speed v appears in the equation for a standing wave, which after all is the wave equation itself, Eq. (15–1): It is the speed of the two traveling waves that are superposed to form the standing wave. In Fig. 15–2 we plot a time sequence of two traveling waves and their superposition. The superposition produces a standing wave whose period and wavelength are the same as those of the traveling waves that compose it.

Note that a standing wave would not be formed if the amplitudes were not of the same magnitude. (The phases have no special requirement to meet, although as they change, the location of nodes would move.) We can see the effect of different amplitudes by, for example, doubling the amplitude in the right-moving wave [Eq. (15–4b)]. Then the sum would give

$$A[\sin(kx - \omega t) + \sin(kx - \omega t) + \sin(kx + \omega t)]$$
$$= 2A \sin kx \cos \omega t + A \sin(kx - \omega t).$$



The last term is a leftover wave that travels to the right. This means that creating pure standing waves is not a trivial matter. Of course, standing waves are created on the strings of musical instruments all the time—this is because, as we'll see below, in the reflection of waves from a place where the string is fixed, such as a fret, the conditions for a standing wave are automatically satisfied.

◀ **FIGURE 15–2** Superposition of two traveling waves produces a standing wave, plotted in red. Shown are the waves $\sin(kx - \omega t)$, moving rightward, and $\sin(kx + \omega t)$, moving leftward. The amplitude of each wave is 1 m, the wavelength is 1 m, and the period is 1 s. Thus, $k = 2\pi$ m^{-1} and $\omega = 2\pi$ rad/s. Arrows indicate the direction of motion of the two traveling waves. Time progresses in $\frac{1}{8}$-s intervals starting at $t = 0$ s and ending at $t = \frac{5}{8}$ s. Note that the peaks of the standing wave remain at exactly the same x-values.

EXAMPLE 15–1 Two traveling waves move in opposite directions in a one-dimensional medium and form a standing wave. The angular frequency of that standing wave is 2.9 rad/s, and the velocity of each of the traveling waves is 1.8 m/s. For comparison purposes you also have a string attached tightly to two walls whose separation can be adjusted. In particular, they are adjusted so that the largest wavelength of the standing waves (lowest mode) that can be supported on your string is the same as the wavelength of the superposition of the two traveling waves. What is that separation?

Setting It Up The medium with the traveling waves is not specified, but we can imagine it too is a string. This system and the comparison string are both shown in Fig. 15–3. We are given the angular frequency ω as well as the speed v of the traveling waves that form the standing wave in the medium. The wavelength λ, which is labeled in the figure, is unknown; we can find the wall separation L in terms of it.

Strategy We first must find the wavelength of the standing wave set up within the medium, given that we know the angular frequency and the wave speed. For this we can use the relation $v = f\lambda = (\omega/2\pi)\lambda$. We then want to adjust the separation L of the walls so that the lowest, or fundamental, mode (longest wavelength) of the string connected to the walls has wavelength λ. For that we need only recall that the longest wavelength on a string connected at its two ends is twice the string length, Eq. (14–42) with $n = 1$. Thus we set $L = \lambda/2$.

▲ **FIGURE 15–3** Part (a) shows the standing wave on the one-dimensional system, while (b) shows the string attached to walls.

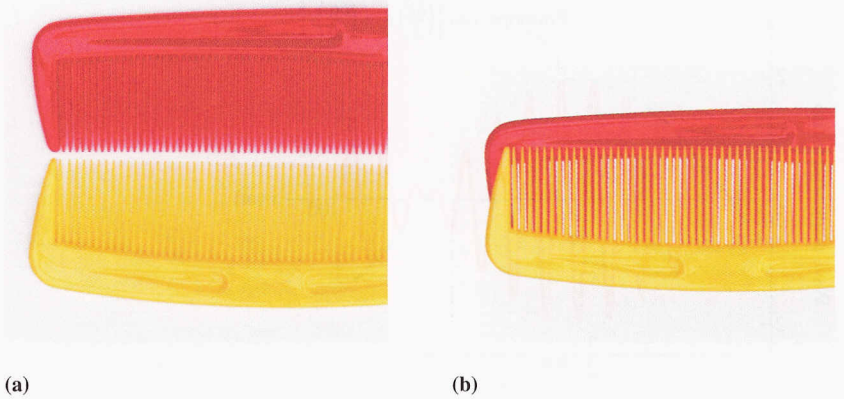
Working It Out We find

$$\lambda = 2\pi v/\omega = (2\pi)(1.8 \text{ m/s})/(2.9 \text{ rad/s}) = 3.9 \text{ m}.$$

In turn,

$$L = \lambda/2 = 2.0 \text{ m}.$$

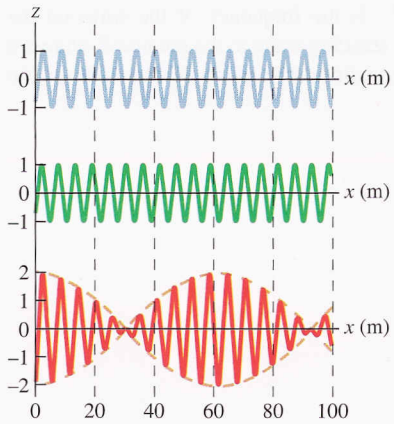
What Do You Think? Is the frequency of the wave on the string necessarily that of the standing wave in the medium? *Answers to **What Do You Think?** questions are given in the back of the book.*



Interference of Incident and Reflected Waves

In order to understand the production of standing waves, it is helpful to consider an *incident*, or incoming, harmonic traveling wave that encounters a wall. To carry this wave, we can stretch a long rope aligned with the x-axis attached to a wall at the point $x = 0$ and extending to the left. Since the string is tied to the wall at that point, the displacement $z(x, t)$ is always zero at $x = 0$. A harmonic incident wave is initiated somewhere on the far left and arrives at $x = 0$. When the wave arrives at the wall it is *reflected*. The energy initially carried to the right bounces back and travels back down the string to the left as a reflected wave. The reflected wave has the same frequency f as the incoming wave, as you can see by thinking about the reflection process: A peak of the incident wave will produce a peak of the reflected wave, and it will take the same period for the reflected wave to produce its next peak as it did for the next peak of the incident wave to arrive at the wall. Also, the rigid wall absorbs no energy, so the reflected wave must have the same amplitude as the incident wave. Finally, the reflected wave moves with the same speed as the original incident wave because the wave speed v is a property of the string. These are just the conditions that give us Eq. (15–5), and they lead to Eq. (15–6): The reflected wave interferes with the rightward-moving incident wave to produce a standing wave with the same frequency and wavelength. This is why the idea that a standing wave on a string is a superposition of traveling waves is more than merely a mathematical construct.

One feature of the reflection that creates a standing wave deserves special notice. The standing wave formed on the string must have a node at the fixed end $x = 0$. This means that the incident wave and its reflection must *cancel* at $x = 0$ (and hence form a node at that point). This requires that *the sinusoidal wave that reflects from a fixed end has a displacement with a sign opposite to that of the incoming wave and is therefore inverted*. Whether reflected waves are inverted or not is an interesting subject and one that we'll take up again in Section 15–5.



15–3 Beats

Beats occur when two waves of nearly the same frequency are superposed; a long-wavelength (low-frequency) interference pattern is produced. Musicians use beats to tune their instruments, and the phenomenon is of scientific importance because it provides a sensitive technique for measuring frequency (or period) differences. A simple visual analogue to beats can be constructed with the help of two combs with slightly different tooth spacings; the slightly different spacings are analogous to slightly different periods. In Fig. 15–4b, two combs are superposed. Where the teeth lie directly on

(a) (b)

◀ **FIGURE 15–4** An analogy indicating beats. (a) Two combs have slightly different spacings. (b) When superposed, the combs produce an interference pattern known as a moiré pattern.

▲ **FIGURE 15–5** Two traveling waves of identical amplitude, $z_0 = 1$ m, and nearly the same frequency and wavelength, at $t = 1$ s. The blue traveling wave has $\omega = 1$ rad/s and $k_1 = 1\ \text{m}^{-1}$. The green traveling wave has $\omega_2 = 0.9$ rad/s and $k_1 = 1.1\ \text{m}^{-1}$. Beats are visible in their superposition (the red wave), formed by the envelope shown as a dashed line. The vertical lines trace the regions of constructive and destructive interference.

top of one another, the spaces are visible. Some distance away, the teeth will lie out of phase and no spaces are visible, farther still and the spaces will once again be visible. The superposed combs exhibit a pattern that repeats over a much greater distance than the separation of the teeth. The large spacing of the pattern observed when the two combs are superposed is equivalent to the large period of the interference pattern observed when waves with two slightly different periods are superposed.

Consider two traveling waves of slightly different frequencies, as in the blue and green waves in Fig. 15–5. The two waves have equal amplitudes of 1 m. The first wave has $\omega_1 = 1.00$ rad/s and $k_1 = 1.00\ \text{m}^{-1}$, and the second has $\omega_2 = 0.90$ rad/s and $k_2 = (1/0.90)\ \text{m}^{-1} = 1.11\ \text{m}^{-1}$. To the eye, the two waves are barely distinguishable from each other. Yet their superposition has a striking visual signature: *A very different wave—one with a long wavelength—is formed* (the red wave in Fig. 15–5 and the close-up view of Fig. 15–6).

Here is how this pattern is formed: Both waves start out together at $x = 0$ m, in phase, and hence interfere constructively. The amplitude of the superposed wave is therefore large at this point. Because the wavelengths of the two waves differ slightly, they begin to develop a phase difference as we move along x, and at some point along x (at about 30 m), they are almost perfectly out of phase. Whereas they started out with maximum on maximum or minimum on minimum, they now are such that the maximum of one is at the same point as the minimum of the other. At this point they interfere destructively, and the amplitude of the superposed wave is small. The cycle repeats itself as the waves slowly come together to interfere constructively again, at about 63 m, as for the combs of Fig. 15–4.

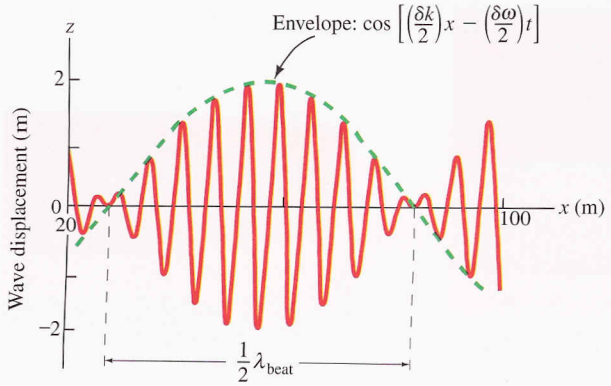
Calculation of the Beat Frequency

To analyze this situation more quantitatively, start with the two waves

$$z_1(x, t) = z_0 \sin(k_1 x - \omega_1 t) \quad \text{and} \quad z_2(x, t) = z_0 \sin(k_2 x - \omega_2 t). \tag{15–7}$$

The angular frequencies and wave numbers differ a little. A convenient way to account for this fact is to deal with the sum and the difference of the frequencies. The frequency difference will be a small quantity. If $\omega_1 > \omega_2$, and $k_1 > k_2$, we define

$$\delta\omega \equiv (\omega_1 - \omega_2) \quad \text{and} \quad \Omega \equiv \frac{1}{2}(\omega_1 + \omega_2), \tag{15–8}$$



and similarly,

$$\delta k \equiv (k_1 - k_2) \quad \text{and} \quad K \equiv \frac{1}{2}(k_1 + k_2). \tag{15–9}$$

It is easy to show that the ratios $\delta\omega/\delta k$ and Ω/K are given by the wave speed $v = \omega_1/k_1 = \omega_2/k_2$ in the medium. Both $\delta\omega$ and δk are positive and small.

We can now reexpress the original frequencies and wave numbers in terms of their sums and differences:

$$\omega_1 = \Omega + \frac{1}{2}\delta\omega \quad \text{and} \quad \omega_2 = \Omega - \frac{1}{2}\delta\omega, \tag{15–10}$$

▶ **FIGURE 15–6** An enlarged look at the superposition of the red wave of Fig. 15–5. The dashed envelope is a traveling wave of wavelength $\lambda_{\text{beat}} = 126$ m.

$$k_1 = K + \frac{1}{2}\delta k \quad \text{and} \quad k_2 = K - \frac{1}{2}\delta k. \tag{15–11}$$

When Eqs. (15–10) and (15–11) are substituted into the waves of Eq. (15–7), we find that

$$\begin{aligned} z_1(x,t) &= z_0 \sin\left[\left(K + \frac{\delta k}{2}\right)x - \left(\Omega + \frac{\delta\omega}{2}\right)t\right] \\ &= z_0 \sin\left\{(Kx - \Omega t) + \frac{1}{2}[(\delta k)x - (\delta\omega)t]\right\}, \end{aligned} \tag{15–12}$$

$$\begin{aligned} z_2(x,t) &= z_0 \sin\left[\left(K - \frac{\delta k}{2}\right)x - \left(\Omega - \frac{\delta\omega}{2}\right)t\right] \\ &= z_0 \sin\left\{(Kx - \Omega t) - \frac{1}{2}[(\delta k)x - (\delta\omega)t]\right\}. \end{aligned} \tag{15–13}$$

To sum these two terms and find the resultant superposition, we expand the trigonometric functions with identity 5.3 of Appendix IV–4, and we use the fact that $\cos(-a) = \cos(a)$. The result is

$$z(x,t) = z_1(x,t) + z_2(x,t) = 2z_0 \sin(Kx - \Omega t)\cos\left[\left(\frac{\delta k}{2}\right)x - \left(\frac{\delta\omega}{2}\right)t\right]. \tag{15–14}$$

Equation (15–14) states that the sum of the original two waves can be reformulated as a *product* of two traveling waves. The wavelength and frequency of the first of these traveling waves, which is the sine term in Eq. (15–14), are given by the *average* of the corresponding quantities for the original two waves. The envelope formed by the second traveling wave is the dashed curve in Fig. 15–5. This envelope is a wave traveling with the same speed as the sine wave but with a much longer wavelength. The envelope wave is called a *beat* of the original two waves. The coefficient of x in the cosine factor in Eq. (15–14), $\delta k/2$, gives the wave number of the beats, whereas the coefficient of the time, $\delta\omega/2$, gives the angular frequency. In turn, we can use Eqs. (15–8) and (15–9) to find the wavelength and frequency of the beats:

$$\frac{1}{\lambda_{\text{beat}}} = \frac{k_{\text{beat}}}{2\pi} = \frac{k_1 - k_2}{4\pi} = \frac{1}{2}\left(\frac{1}{\lambda_1} - \frac{1}{\lambda_2}\right); \tag{15–15}$$

$$f_{\text{beat}} = \omega_{\text{beat}}/2\pi = (\omega_1 - \omega_2)/4\pi = \tfrac{1}{2}(f_1 - f_2). \tag{15–16}$$

BEAT WAVELENGTH AND FREQUENCY

The beat has a wave number and frequency that are one half the *differences* of the original wave numbers and frequencies. Because this difference is small by assumption, the wave number of the envelope is small and the wavelength is *large*. Similarly, the frequency of the beat is *small*. In deriving this result, we tacitly assumed $f_1 > f_2$, so that f_{beat} was positive. Note, however, that the beat factor in Eq. (15–14) is a cosine factor, and the cosine is unchanged if its argument changes sign. This means that if $f_2 > f_1$, f_{beat} would be given by $(f_2 - f_1)/2$ rather than $(f_1 - f_2)/2$: The beat frequency is always positive.

Figure 15–6 is an enlarged version of the superposed waves plotted in Fig. 15–5. Recall that the original two waves have $k_1 = 1.0\ \text{m}^{-1}$ and $k_2 = 1.1\ \text{m}^{-1}$. From Eq. (15–15), the beat wavelength is then

$$\lambda_{\text{beat}} = \frac{4\pi}{|(k_1 - k_2)|} = \frac{4\pi}{|(1.00\ \text{m}^{-1} - 1.10\ \text{m}^{-1})|} = 126\ \text{m}.$$

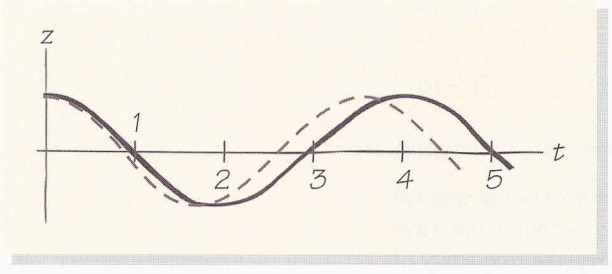
Only a little over half a wavelength is plotted in Fig. 15–6, and we can indeed see that $\lambda_{\text{beat}}/2 \cong 63$ m. The frequency of the beat is, in this case,

$$f_{\text{beat}} = (\omega_1 - \omega_2)/4\pi = (1.00\ \text{rad/s} - 0.90\ \text{rad/s})/4\pi = 0.0080\ \text{Hz}.$$

Beats in Sound: When we hear beats of sound, the combination of ear and brain has a definite physiological response. In addition to the note of average frequency, we hear

a second note with the pitch of the beat frequency if the beat frequency exceeds 25 Hz or so. If the beat frequency is less than this, however, we hear regular pulses in amplitude. Because the ear interprets loudness as proportional to the wave intensity, which is in turn proportional to the amplitude squared, the ear hears a pulse every time the beat passes through either a maximum or minimum. The result of this is that *the frequency of the perceived pulse is twice the beat frequency.*

CONCEPTUAL EXAMPLE 15–2 Two tuning forks labeled as identical actually differ in frequency by approximately 0.5%. By determining the beat frequency, can you determine precisely the difference in frequencies? Can you determine which tuning fork has the higher frequency? Suppose you had some electrical tape. Knowing that winding the tape around the upper end of the prongs of a tuning fork reduces the frequency, could you then determine which tuning fork has the higher frequency?



Answer Since the beat frequency is one half of the frequency difference, an accurate measurement of the beat frequency determines the frequency difference accurately. However, the beat frequency only determines the absolute value of the frequency difference, so that this measurement alone cannot determine which tuning fork has the higher frequency.

The tape can be used to determine which tuning fork has the higher frequency. Suppose the two tuning forks are distinguished by color, say blue and green. Suppose we put the electrical tape on the blue one. If the blue one has the lower frequency, then the tape lowers it further, and the beat frequency increases. If the blue one has the higher frequency, then the tape reduces the difference and that will be noticed in a measurement of the beat frequency.

What Do You Think? Why would putting electrical tape on the end of the tuning fork prongs reduce the frequency?

EXAMPLE 15–3 Two sinusoidal waves traveling along a string with equal amplitudes and with periods of 19 and 20 seconds, respectively, are observed to have a maximum displacement at a particular point and time (say $x = 0$ and $t = 0$). After how many seconds will the resultant displacement be zero at $x = 0$? When will this occur for the second time?

Setting It Up We sketch the two waves as a function of time at the fixed point $x = 0$ (Fig. 15–7). They coincide at $t = 0$, where they are each a maximum. The sketch extends to beyond $t = 5$ s, the time when the wave with 20-s period crosses the axis, while the wave with 19-s period will have crossed it at $t = 4.75$ s.

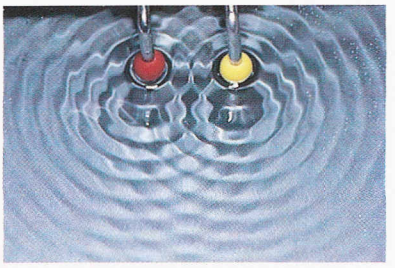
▲ **FIGURE 15–7** Two traveling waves have the same amplitude, but slightly different frequencies.

Strategy We deal at a given space point ($x = 0$) with the superposition of two traveling waves with slightly different periods and equal amplitudes. The first step is to write expressions for the two waves at $x = 0$, taking into account the fact that they are both at their maximum at $t = 0$. We then add the two waves and use trigonometric identities to express the sum as a product of single waves, one involving a beat frequency and one involving an "average" frequency, just as in the text above. Because the oscillation in the "average" frequency is faster, we expect that it is the average frequency term that will vanish first. At that point it is a matter of numerically identifying the time when the harmonic function involving the average frequency is zero. We then need to convert periods to angular frequencies ω and then work out the details.

Working It Out A harmonic wave at a particular point is a function only of t. If it takes its maximum value at $t = 0$, it must be proportional to $\cos \omega t$. We have two waves, and since their amplitudes are equal, we describe them by $A \cos \omega_1 t$ and $A \cos \omega_2 t$, respectively.

Now we work out the sum, breaking out sums and differences of the frequencies:

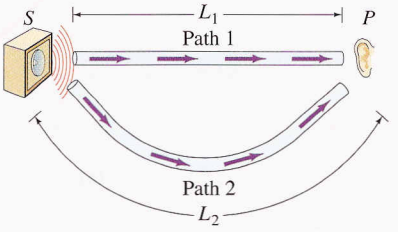
$$A(\cos \omega_1 t + \cos \omega_2 t) = A\left[\cos\left(\frac{\omega_1 + \omega_2}{2}t + \frac{\omega_1 - \omega_2}{2}t\right) + \cos\left(\frac{\omega_1 + \omega_2}{2}t - \frac{\omega_1 - \omega_2}{2}t\right)\right]$$
$$= 2A\cos\left(\frac{\omega_1 + \omega_2}{2}t\right)\cos\left(\frac{\omega_1 - \omega_2}{2}t\right).$$



The first cosine term contains the average frequency, the second the beat. Our expression will be zero when either $\frac{\omega_1 + \omega_2}{2}t = \frac{\pi}{2}$ or $\frac{\omega_1 - \omega_2}{2}t = \frac{\pi}{2}$, whichever happens earlier. These correspond respectively to $t_{1,\text{av}} = \frac{\pi}{\omega_1 + \omega_2}$ or $t_{1,\text{beat}} = \frac{\pi}{\omega_1 - \omega_2}$. As must be the case, $t_{1,\text{av}}$ is smaller. The sum of the two waves will again be zero at *either* $t_{1,\text{beat}}$ or at the second zero of the average frequency factor $t_{2,\text{av}}$, whichever occurs first. We have $\frac{\omega_1 + \omega_2}{2}t_{2,\text{av}} = \frac{3\pi}{2}$ or $t_{2,\text{av}} = \frac{3\pi}{\omega_1 + \omega_2}$. We will find which occurs first numerically, but since the frequencies of the two waves are almost the same, we might expect the beat period to be very large, and $t_{2,\text{av}}$ to be first.

We start with the relation $\omega = 2\pi f = 2\pi/T$ to calculate $\omega_1 = 2\pi/(19\text{ s}) = 0.33$ rad/s and $\omega_2 = 2\pi/(20\text{ s}) = 0.31$ rad/s. We substitute these into our expressions for $t_{1,\text{av}}$, $t_{2,\text{av}}$, and $t_{1,\text{beat}}$. We find that these are, respectively, 4.9 s, 15 s, and 1.6×10^2, and the beat period is much larger than the times associated with the "average" wave.

What Do You Think? Would these results be changed if at $x = 0$ each wave had their maxima at $t = 5$ s rather than 0 s? Would they change if each wave had a $t = 0$ maximum at a different space point than $x = 0$?



15–4 Spatial Interference Phenomena

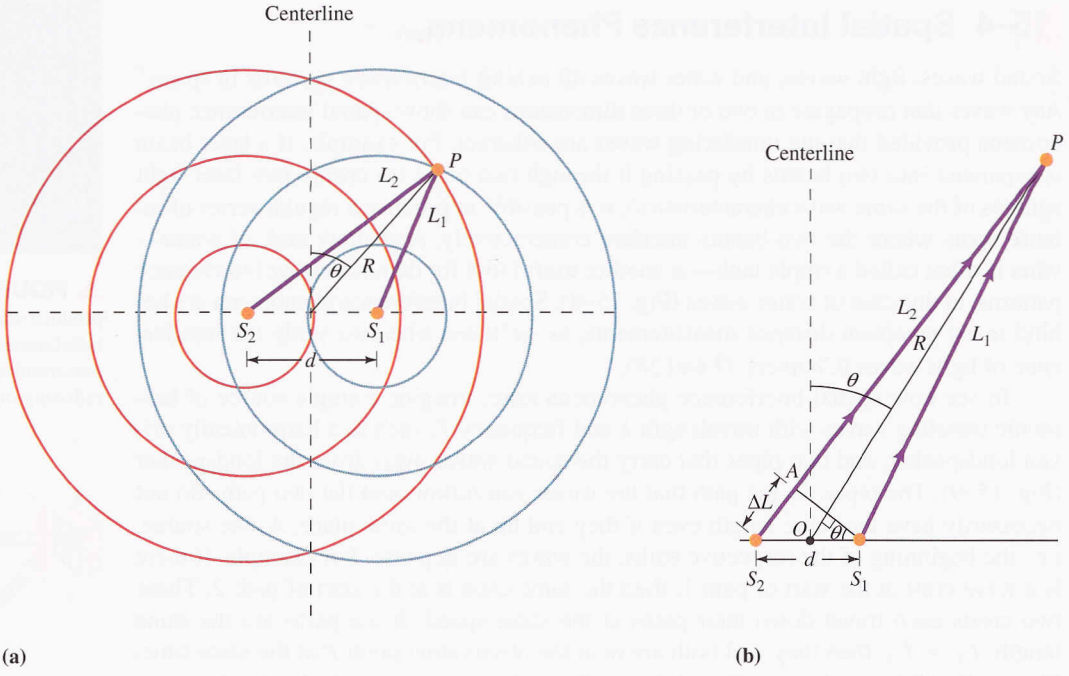
Sound waves, light waves, and water waves all exhibit *interference patterns* in space.[†] *Any* waves that propagate in two or three dimensions can show spatial interference phenomena provided that the interfering waves are coherent. For example, if a laser beam is separated into two beams by passing it through two holes (to ensure two laser light sources of the same wave characteristics), it is possible to produce a regular series of intense spots where the two beams interfere constructively. A shallow tank of water—what is often called a ripple tank—is another useful tool for demonstrating interference patterns, in this case of water waves (Fig. 15–8). Spatial interference phenomena are behind many precision distance measurements, as we'll see when we study the interference of light waves (Chapters 37 and 38).

▲ **FIGURE 15–8** Two sources that produce waves in a ripple tank form an interference pattern, visible as regions of constructive and destructive interference radiating out from the sources.

To see how spatial interference phenomena arise, imagine a single source of harmonic traveling waves with wavelength λ and frequency f, such as a harmonically driven loudspeaker, and two pipes that carry the sound waves away from the loudspeaker (Fig. 15–9). The pipes fix the path that the waves can follow, and the two paths do not necessarily have the same length even if they end up at the same place. At the source, i.e., the beginning of the respective paths, the waves are in phase. For example, if there is a wave crest at the start of path 1, then the same crest is at the start of path 2. These two crests each travel down their paths at the same speed. If the paths are the same length, $L_1 = L_2$, then they will both arrive at the observation point P at the same time. They will still be in phase at P, and they will interfere constructively. Under these circumstances, the adjacent troughs will arrive together, as will the next crests, and so forth. The interference will always be constructive.

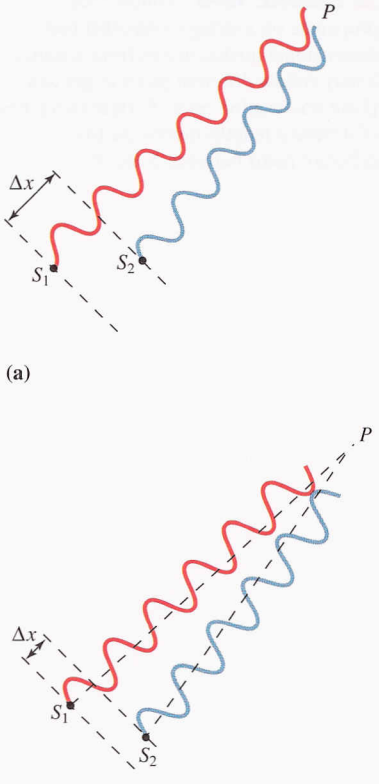
▲ **FIGURE 15–9** Unless they propagate on a string or on other one-dimensional media, waves from a source S may follow different paths to get to a given observation point P. Here two pipes of different lengths determine two different paths between S and P.

If the path lengths are different, however, then these same crests will not arrive at the same time. Whether the interference is constructive or destructive depends on the *difference* in path length, $\Delta L = L_2 - L_1$. Suppose path 2 is longer, so that ΔL is positive. If ΔL is one full wavelength, $\Delta L = \lambda$, then the second crest will arrive at P along path 1 just when the first crest arrives at P along path 2. The two waves will be in phase and the interference will be constructive. If $\Delta L = \lambda/2$, then when the crest arrives at P from path 2, it meets a trough from path 1. In this case the interference is destructive, and no disturbance is recorded at P. The situation can be summed up as follows:



$$\text{for constructive interference: } \Delta L = n\lambda,\ n = 0, \pm 1, \pm 2, \ldots \qquad (15\text{–}17)$$

$$\text{for destructive interference: } \Delta L = (n + \tfrac{1}{2})\lambda,\ n = 0, \pm 1, \pm 2, \ldots. \qquad (15\text{–}18)$$

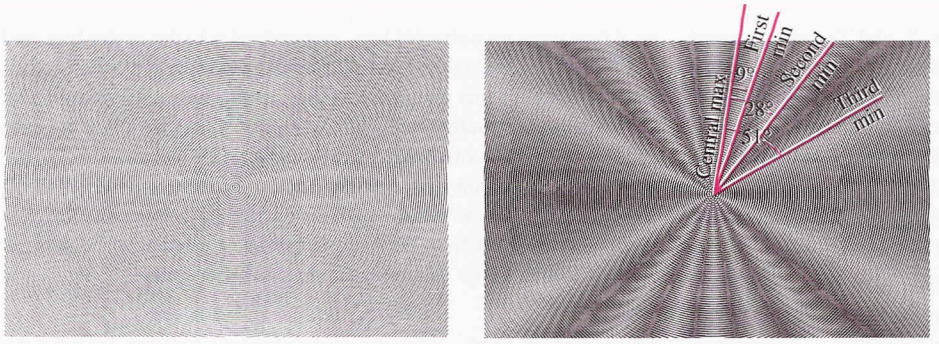


CONDITIONS FOR INTERFERENCE

The effect just described also occurs with two sources at different distances from an observation point. Imagine two separate sources emitting harmonic waves of the same wavelength in a given medium. We could for example make the same rhythmic disturbance at two different points on a water surface. At each point, a series of spreading ripples is created that interfere with one another. In Fig. 15–10, we have two separated sources, S_1 and S_2, each producing waves with the same wavelength λ and frequency f. We assume that these waves are *in phase*; that is, a crest always emerges from S_1 at the same moment that a crest emerges from S_2. These waves are coherent. An observation point P is located a distance L_i from source S_i; the path difference is $\Delta L = L_2 - L_1$. The conditions for constructive interference are simply that the crests, or the troughs, of the waves from the two sources arrive at P together. For this two-source situation, the same conditions respectively apply for constructive and destructive interference as before; namely, Eqs. (15–17) and (15–18). Since different places in space are different distances from the sources, there will be constructive interference at some points in space and destructive interference at others.

[†]Not to be confused with beats, in which we are primarily interested in time dependence at a particular point.

▲ **FIGURE 15–10** (a) The water waves generated by two coherent sources in phase spread away in circles from these sources. Whether the interference is constructive or destructive at observation point P depends on the difference in path lengths. The circles are (arbitrarily) drawn on the wave crests. (b) The geometry necessary to determine the path difference $\Delta L = L_2 - L_1$ and hence for the pattern of interference maxima and minima. The observation point P is far away compared to the separation of the two sources, d.



▲ **FIGURE 15–11** The conditions for maxima and minima in the interference of coherent waves of the same wavelength emitted by two sources. (a) Maxima correspond to the difference in path length equal to an integer multiple of λ, while (b) minima occur when the path difference is an integral multiple of λ plus $\lambda/2$.

Locations of Maxima and Minima

The observation point P can be anywhere that the waves propagate. Some locations will have constructive interference, some destructive, and some points will have an intermediate level of interference, depending only on the distances from the sources. The locations where the interference is constructive are said to exhibit interference *maxima*, and the locations where the interference is destructive exhibit interference *minima*. Finding the spatial pattern of the maxima and minima is an exercise in geometry—of the type sketched out in Fig. 15–11.

We can get a sense of patterns of this type with a visual analogue to wave interference. Figure 15–12a shows a set of finely spaced gray concentric circles around a point representing a wave source. Think of the gray circles as simplified crests and the clear areas between the circles as simplified troughs. When two such wave sources are present, as they are in Fig. 15–12b (too closely spaced to see easily in that figure), we can think of constructive interference as an overlap of the gray areas (crests) with themselves, giving very dark areas, or of the clear areas (troughs) with themselves, leaving a clear area; we can think of destructive interference as a uniform gray where the gray areas and the clear areas overlap. In fact, bands of maxima and minima are clearly visible in the figure, even if the centers of the waves are not.

To find the patterns of maxima or of minima defined by Eqs. (15–17) and (15–18), the necessary geometric information is the wavelength, λ, and the separation of the two sources, d. The geometry is shown in Fig. 15–10. We have put an origin, O, midway between the sources and measured the distance R from point P to the origin, as well as the angle θ between the center line and the line from the origin to P. The center line is the line perpendicular to and bisecting the line of the sources. Note that at the angle $\theta = 0$, where $L_1 = L_2$, we have $\Delta L = 0$; *there is a maximum everywhere along the center line*. The regions of the other maxima and minima are simple to see when $R \gg d$; that is, when P is very far from the pair of sources. This case is illustrated in Fig. 15–10b, which shows, to a good approximation, that all three lines—the line from S_1 to P (S_1P), the line from the origin to P, and the line from S_2

(a) (b)

◀ **FIGURE 15–12** (a) Concentric circles representing waves propagating out from a source. (b) Overlay of the circles that spread from two adjacent sources. Regions of constructive and destructive interference, marked as max (maxima) and min (minima), are clearly visible. We have measured $\lambda = 5$ mm and $d = 16$ mm on the original of this reproduction, so the ratio $\lambda/d = 0.32$. The first minimum should occur at $\sin\theta_1 = \lambda/2d = 0.16$, or $\theta_1 = 9°$, and this is the value of the angle found in the figure.

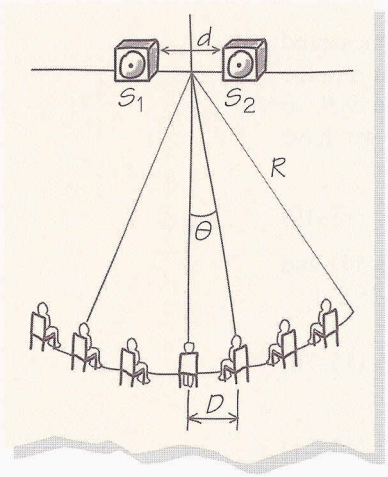
to P (S_2P)—make the same angle θ with the center line. Then ΔL can be measured by drawing a line from S_1 perpendicular to S_2P. This line meets S_2P at point A in the figure. S_2S_1 is perpendicular to the center line, and AS_1 is perpendicular to S_2P, so the angle formed by lines AS_1 and S_2S_1 is θ. Because $AP = S_1P$, we have $\Delta L = L_2 - L_1 = S_2A$, and $\sin\theta = \Delta L/d$, or

$$\Delta L = d\sin\theta. \tag{15–19}$$

As a result of this approximation, for $R \gg d$ we can restate Eqs. (15–17) and (15–18) for the maxima and minima in terms of the angle θ by using Eq. (15–19):

$$\text{for maxima: } \sin\theta = n\frac{\lambda}{d},\ n = 0, \pm1, \pm2, \ldots; \tag{15–20}$$

$$\text{for minima: } \sin\theta = \left(n + \frac{1}{2}\right)\frac{\lambda}{d},\ n = 0, \pm1, \pm2, \ldots. \tag{15–21}$$



These equations determine a set of angles for which there are interference maxima and minima. Positive θ values are to the right of the center line and negative values are to the left. The array of angles is symmetric about the center line, so we can concentrate on one side. On the right side $n = 0$ is a maximum at $\theta = 0$, which is along the center line itself. As we increase θ, the first minimum occurs at $\sin\theta = \lambda/2d$. The second maximum is at $\sin\theta = \lambda/d$, the second minimum at $3\lambda/2d$, and so forth. In Fig. 15–12b these angles are marked on the pattern made by overlaying two sets of concentric circles, one set slightly displaced from the other. In the situation shown here $\lambda = 5$ mm and $d = 16$ mm. The first three minima should then be at $\sin\theta_1 = 0.16$, $\sin\theta_2 = 0.47$, and $\sin\theta_3 = 0.78$, or $\theta_1 = 9°$, $\theta_2 = 28°$, and $\theta_3 = 51°$, in agreement with Fig. 15–12b.

Any unchanging phase difference between two harmonic waves—coherent waves—will lead to an interference pattern. Above, the two sources have the same frequency and no phase difference between them. But suppose we change things a little. Source S_1 could consist of a sharp object dipping into water with some fixed frequency, and S_2 consists of a similar object dipping into the water with the same frequency but a time interval τ later. This changes the relative phase of the two waves (by $\omega\tau$), but the relative phase is still fixed, so that we still have coherence. Let us now change source S_2 as follows. Its frequency is still the same as that of S_1, but the sharp object dips into the water in different positions around what was previously the fixed position of S_2. This means that for each wave, the interval ΔL is slightly different. If ΔL were much smaller than the wavelengths involved, then there would still be an interference pattern, but a blurred one. If ΔL is of the order of the wavelength or more, then the interference pattern is gone: There are still points of total constructive or destructive interference, but these vary from wave to wave, and no steady pattern of the type seen in Fig. 15–8 will appear. This is an example of incoherence—no interference pattern appears when incoherent waves superpose.

Example 15–4 describes the interference pattern that occurs when two waves of the same wavelength have phases differing by π.

EXAMPLE 15–4 Two loudspeakers, S_1 and S_2, are separated by 0.50 m. These speakers form sound waves of the same amplitude at a frequency of 4400 Hz. The amplifier emits the two waves 180° out of phase. A set of chairs is arranged in a semicircle 30.0 m from the midpoint of the two speakers. Find the amplitude of the wave at the chair on the perpendicular bisector (center line) of the line between the speakers. At what distance to the right of this central chair is there a first maximum in sound intensity?

Setting It Up The situation is sketched in Figure 15–13. We have marked on the figure the known speaker separation d and the radius R of the semicircle of chairs surrounding them. The speakers emit with known frequency f. The unknown distance D where a maximum occurs is also marked.

▲ **FIGURE 15–13** The geometry is the same as that illustrated in Fig. 15–10b.

Strategy The first step is a geometrical one, the calculation of the difference in the lengths of the paths from the two speakers to a point on the semicircle. This can be done exactly, but in the approximation that $(d/R)^2 \ll 1$ we can treat the chairs not far from the center line *as if* they were on a straight line, perpendicular to the center line, and we can approximate the sine of the small angle θ by θ alone. We then need to translate that difference in path length into a statement about destructive/constructive interference. Because the two speakers emit the waves 180° out of phase, the rules in Eqs. (15–20) and (15–21) are interchanged: *Minima become maxima* and vice versa. Thus, along the center line, for which the path difference ΔL is zero, the interference is now destructive. We want the smallest angle θ for which ΔL implies constructive interference, and that translates geometrically into D.

Working It Out With the phase change taken into account, the rules are

$$\text{for minima:}\quad \sin\theta = n\frac{\lambda}{d},\ n = 0, \pm1, \pm2, \ldots;$$

$$\text{for maxima:}\quad \sin\theta = \left(n + \tfrac{1}{2}\right)\frac{\lambda}{d},\ n = 0, \pm1, \pm2, \ldots.$$

The first maximum ($n = 0$) is at an angle given by

$$\sin\theta = \frac{\lambda}{2d}.$$

If the semicircle of chairs is a distance R from the speakers, then $\theta = D/R$. For small θ, $\sin\theta \cong \theta$, and the value of D for which the first maximum occurs is

$$\sin\theta = D/R = \lambda/2d, \quad \text{or} \quad D = (\lambda/2d)R = (v/2fd)R.$$

We have used the relation $\lambda f = v$, where v is the wave speed. The speed of sound is roughly 330 m/s, so

$$D = \frac{(330\ \text{m/s})}{2(4400\ \text{Hz})(0.50\ \text{m})}(30.0\ \text{m}) = 2.3\ \text{m}.$$

We see that $D \ll R$, so our small-angle approximation is justified.

What Do You Think? Suppose the listener in the chair at which the first maximum is heard rolls radially away from the midpoint of the speakers at a rate of 3 m/s. What properties of the sound will have changed when he reaches a distance of 60 m?

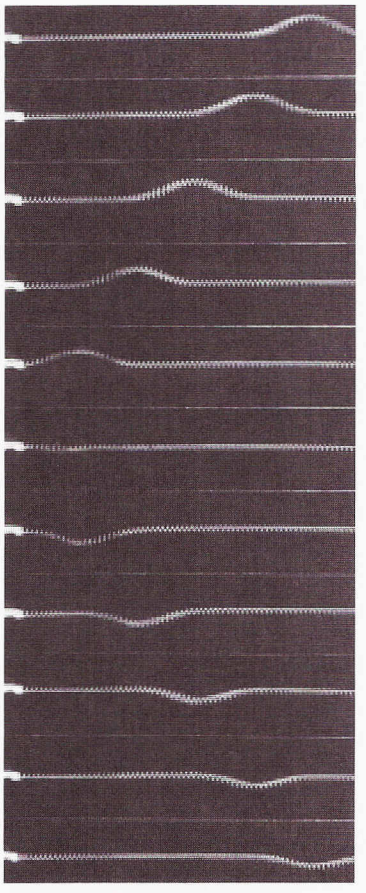
CONCEPTUAL EXAMPLE 15–5 The spatial interference pattern of maxima and minima that we have studied forms lines corresponding to particular angles from a center line. These angles depend on the wavelength λ of the interfering waves and the separation d of the sources. When these angles are small, we say the pattern is *narrow*; when the angles are large, we say the pattern is *broad*. If you had a particular pattern and you wanted to make it broader, and you could control both λ and d, what would you do?

Answer The angular distance between adjacent angles is given by $\sin\theta_{n+1} - \sin\theta_n = (\lambda/d)$. Thus increasing λ and/or decreasing the source separation d make this distance increase. We say that the pattern *spreads* (or is broadened). The pattern *shrinks*, or *narrows*, as λ decreases and/or d increases. For example, as the separation of our two loudspeakers decreases, the pattern of interference maxima and minima spreads in angle.

What Do You Think? By how much can the pattern spread?

15–5 Pulses

When an incident ocean wave meets a wall, the wave rebounds and forms a reflected wave that moves back toward the sea. If the wall is low, then part of the incident wave can pass over the top of it and continue as a transmitted wave. This demonstrates that waves can both reflect from, and be transmitted across, boundaries. A simple lecture demonstration of reflection is obtained by attaching a long rope to a wall and holding the other end fairly taut flipping the wrist. The result is a bump traveling to the wall and



THINK ABOUT THIS . . .

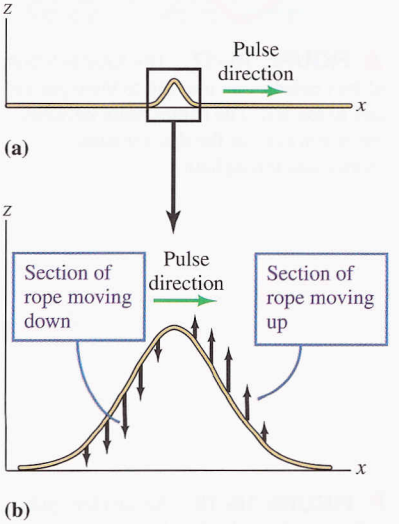
HOW DO NOISE-CANCELING HEADPHONES WORK?

The noise-canceling headphones worn by workers in helicopters or in other very noisy environments (Fig. 15–14) make use of the interference phenomena. They contain both speakers and a microphone located close to the entrance of the ears. Sound received at the microphone is amplified and supplied to the speaker with a phase difference, such that the sound from the speaker cancels the original signal as completely as possible. Maximum cancellation is set to occur within the ear, nominally at the surface of the eardrum. Communication from the radio or intercom of the aircraft is not subject to cancellation and is therefore audible to the crew members.

▶ **FIGURE 15–14** An electronic noise cancellation headset such as this one can reduce noise in the low-frequency range by some 10–15 dB over conventional headsets.

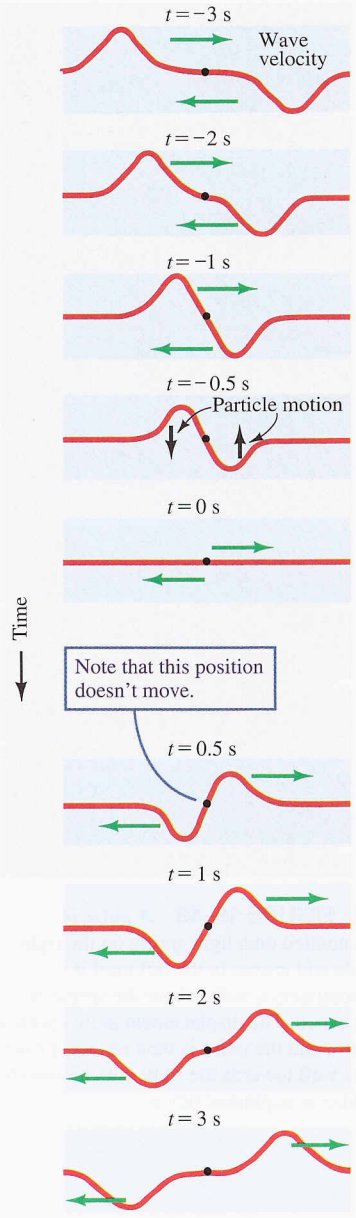
▲ **FIGURE 15–15** A pulse is generated on a light spring on the right side and moves to the left until it encounters a wall, where the spring is attached. The displacement at this point is zero, and the pulse is then reflected from the wall towards the right with an inverted pulse as explained below.

then traveling back to the other end (Fig. 15–15). If the held rope is connected to another rope of different mass density, with the second rope connected to the wall, then both the reflection and transmission are visible at the two-rope boundary.



The bump generated in the ropes is a **pulse**, and the discussion of reflection and transmission is somewhat easier to visualize in terms of pulses. What are pulses? Pure harmonic waves (cosines or sines), or any truly periodic waves, are idealizations in that they are infinitely long. Pulses are disturbances that have a beginning and an end, whether short or not. For us to be able to deal with pulses we need only be sure that they obey the wave equation. This is not much of a limitation, basically only requiring for us that the amplitudes involved are not too great. Aside from that, we saw in Chapter 14 that *any* function of the form $F(x \pm vt)$ satisfies the wave equation. The wave equation is *linear*, i.e., the sum of two solutions is also a solution. So the sum of two pulses is another acceptable pulse.

We are interested in pulses because they are the way waves occur in the physical world. Communication of any kind—the passage of information—is by means of pulses. The sound of a drum, a flash of light, and a ripple caused by a pebble dropped into a pond are all pulses. In Section 15–6 we will see that pulses are formed from the superposition of harmonic waves, but in this section we will use the superposition of pulses to provide us with insight into wave interference.

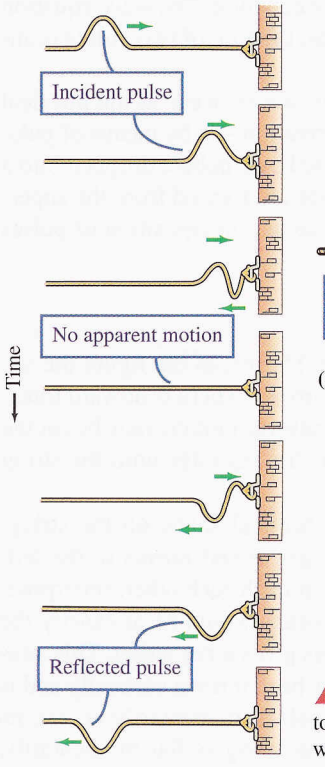


Collisions Between Pulses

Consider a pulse moving to the right along a string (Fig. 15–16). In the figure the velocity of the transverse motion is represented by vertical arrows. There is upward transverse motion along the leading edge of the pulse. The transverse motion vanishes at the peak, and there is downward transverse motion along the trailing edge until the string again comes to rest after the pulse has passed.

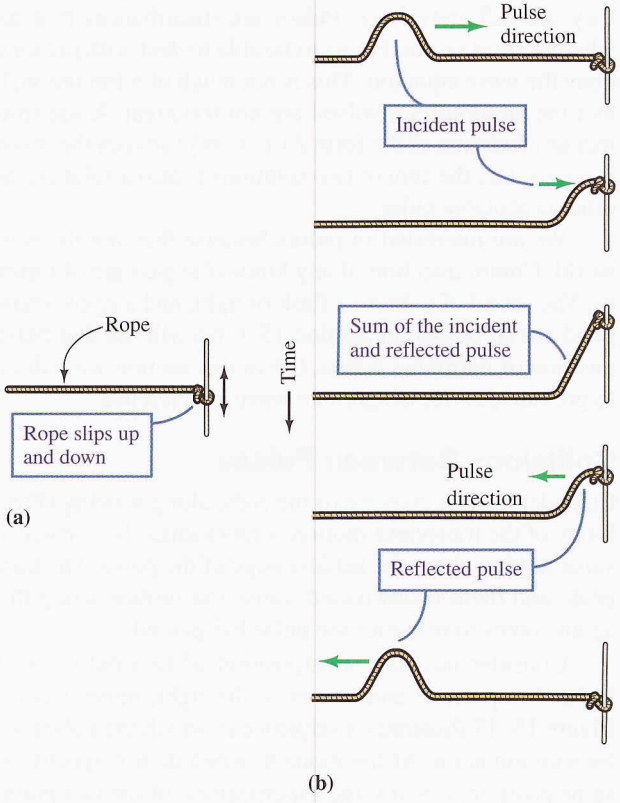
Consider next the superposition of two pulses of identical shape on the string: Pulse 1 is positive and moves to the right; pulse 2 is negative and moves to the left. Figure 15–17 illustrates a sequence in which the pulses approach each other, superpose, then continue on. At the moment when their respective peaks would be at exactly the same position, $t = 0$ s, the superposition of the two pulses gives a flat string. This situation is in fact no more peculiar than that of a ball that has been thrown vertically and is momentarily at rest at the peak of its flight. Even if the ball is momentarily at rest, its acceleration remains constant. Similarly, even though the string is flat momentarily,

▲ **FIGURE 15–16** A pulse moving to the right (horizontal arrow) on a string. The vertical arrows indicate the velocities of elements of the string.



▲ **FIGURE 15–17** The superposition of two pulses, one moving to the right and one to the left. The center point between the two waves, at the dot, remains motionless throughout.

it may still be moving. Not only do the displacements of the pulses superpose but so do their time derivatives, which measure their transverse velocities. The velocities of the string are indicated in sequence in Fig. 15–17. When the peaks superpose, the leading edge of pulse 1 is superposed on the trailing edge of pulse 2. Both edges are moving upward, so there is a region just right of the center of the superposed peaks moving upward rapidly. Similarly, the region just left of the center of the superposed peaks, consisting of the trailing edge of pulse 1 and the leading edge of pulse 2, is moving downward rapidly. Even though the string is flat for a brief moment, it is not at rest!



Reflection

In our discussion of two pulses of opposite sign that meet and interfere, the central point between the two pulses—marked on Fig. 15–17 by a dot—never moves at all. It is clear that the colliding pulses must be of opposite sign and equal magnitude in order to leave a central point undisplaced. Recall now that there is also a single point that remains undisplaced when an incident wave or pulse reflects from the fixed end of a string (or rope). The stationary point there is the point fixed to the wall. Because only pulses of opposite sign can lead to this fixed point, we then argue that the pulse that reflects from a fixed wall is inverted. To phrase all this in another way, we think of the reflection of a pulse as the meeting of two pulses, with one pulse coming from the other side of the wall. The string and the inverted pulse or wave on the other side of the wall are purely imaginary, just an aid to picturing the form of the reflected wave. Figure 15–18 shows a sequence of a pulse reflecting from the fixed end of a string. The pulse moving away from the boundary is the *reflected* pulse.

Suppose that instead of being fixed at the wall, the end of a rope under tension is *free to move in the vertical direction*. This could be arranged by fixing the rope to a support that allows it to slide freely, as in Fig. 15–19a. The analogous sequence of reflection is shown in Fig. 15–19b. As before, the reflected pulse matches the incident pulse

▶ **FIGURE 15–18** An incident pulse reflecting from the fixed end of a string is inverted. If the pulse is symmetric, then at some point the string is flat, because the reflected pulse cancels the incoming pulse by destructive interference.

▲ **FIGURE 15–19** (a) The right-hand end of a string that is free to slide vertically. (b) The reflection of an incident pulse is upright when the end of the string is free.

in shape. This time, however, the reflected pulse must be right-side up rather than inverted because the end of the string has been thrown upward by the incident pulse. In this case, we can also visualize an (imaginary) traveling wave on the far side of the slide support moving to the left. We see from the sketch that when the two pulses meet and combine at the slide support, the pulse height at the support is twice as high as the original amplitude. (What has happened here is that the free end gets a vertical impulse when the pulse arrives. Because there is no mass to be accelerated farther down the string—there is no string to the right of the spot—the end can move an additional amount.) Just as the fixed end of the string was an argument that the reflected wave was inverted, the large size of the displacement at the end of the string in this case is an argument that when the end of the string is not fixed, the reflected wave is right-side up. This is easily confirmed by experiment.

The conclusions we have drawn about whether reflected pulses are inverted or not can also be used to establish the form of reflected harmonic waves, as we see in the following example.

EXAMPLE 15–6 A harmonic sound wave travels in the $+x$-direction. We can describe this wave by using the quantity z that measures the longitudinal displacement of a layer of air from its equilibrium position. z will be a function of the longitudinal position x and will take the form $z_i = A_i \cos(kx - \omega t)$. (We have managed to set the clock so that there is no additional phase here.) The wave encounters a brick wall at $x = 0$, and because no air can cross the brick wall, the boundary condition $z = 0$ at $x = 0$ holds. What is the form of the reflected wave, and what is the form of the superposition of the incident and reflected waves?

Strategy First of all, we need to construct a generic form of the reflected wave. This will have a form similar to the incident wave, with the change from $(kx - \omega t)$ to $(kx + \omega t)$, with a different amplitude A_r and with an unknown phase. We next impose the condition that $z = 0$ at $x = 0$. The expectation is that this condition, which must hold *at all times*, will fix the reflected amplitude and phase. Once we have established the form of the reflected wave, we can study how it adds to the incident wave.

Working It Out The reflected wave has form $z_r = A_r \cos(kx + \omega + \phi_r)$. The boundary condition stipulates that the superposition of the two waves (the net wave) must be zero at $x = 0$: $z_i + z_r = 0$ at $x = 0$ or, for all t,

$$A_i \cos(k \times 0 - \omega t) + A_r \cos(k \times 0 + \omega t + \phi_r) = A_i \cos(-\omega t) + A_r \cos(\omega t + \phi_r) = 0.$$

We can expand the second cosine by using the identities in Appendix IV–4—here, $\cos(\omega t + \phi) = \cos \omega t \cos \phi - \sin \omega t \sin \phi$. Then we separate the coefficients of $\sin \omega t$ and $\cos \omega t$ that result:

$$(A_i + A_r \cos \phi_r) \cos \omega t + (-A_r \sin \phi_r) \sin \omega t = 0.$$

If this equation is to hold for all t, the coefficients of both $\sin \omega t$ and $\cos \omega t$ must be zero. For example, if the expression is to be zero at $t = 0$, where $\sin \omega t$ is zero automatically, the coefficient of $\cos \omega t$ must be zero; if the expression is to be zero at $t = \pi/2\omega$, where $\cos \omega t$ is zero automatically, the coefficient of $\sin \omega t$ must be zero. Thus

$$A_i = -A_r \cos \phi_r \quad \text{and} \quad 0 = A_r \sin \phi_r.$$

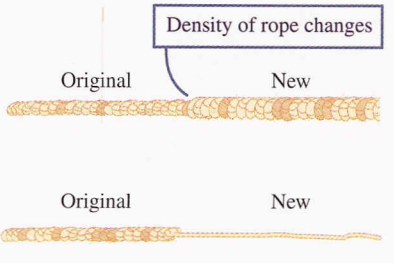
The second equation has as its most interesting solution that $\phi_r = 0$. Then the first equation will give $A_r = -A_i$.

Pulling things together, the reflected wave takes the form

$$-A_i \cos(kx + \omega t).$$

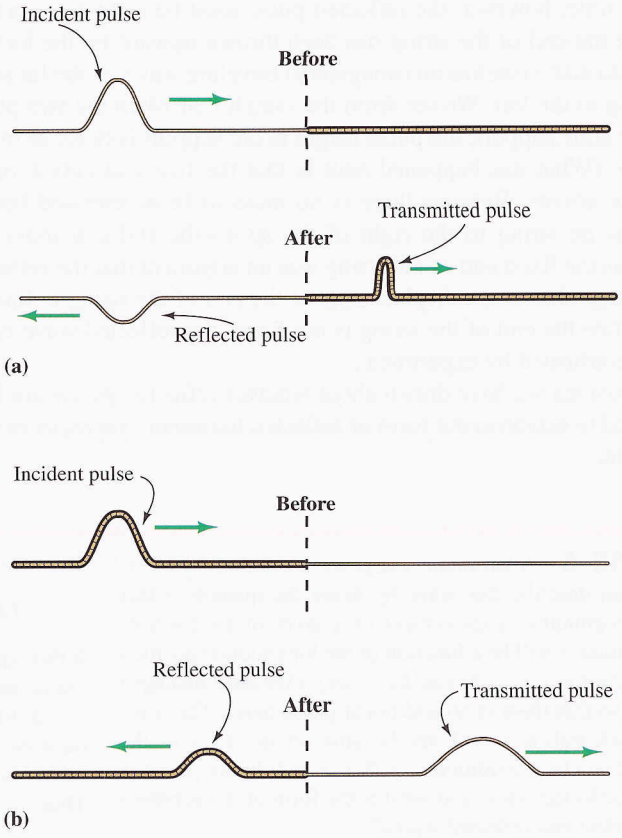
This is like the incident wave, except propagating to the left and inverted. The sum of the incident and reflected wave is therefore

$$z_{\text{total}} = z_i + z_r = A_i[\cos(kx - \omega t) - \cos(kx + \omega t)] = 2A_i \sin kx \sin \omega t.$$



The important results to note are that (a) $z = 0$ at $x = 0$, as required, and (b) the conditions that determine the reflected amplitude and phase *do not depend on the value of* ω.

What Do You Think? How is this wave different, if at all, from the standing waves we saw in Chapter 14?



Transmission

Reflections of waves and pulses are familiar to us through sound echoes and the bouncing of water waves from boundaries. Less familiar, but equally important, is the passage of waves and pulses through boundaries that separate different media. This is the process of *transmission*. The transmission of waves occurs when sound waves penetrate from one medium to another—for example, from water to air, and when light waves pass between air and glass (Chapter 35).

In this chapter we will discuss transmission in terms of harmonic waves or pulses moving along strings. Up to this point, we have supposed that one end of a string was either tightly fixed or completely free. Imagine instead that our string is attached to a new string that is heavier or lighter than the original one (Fig. 15–20). If the new string is sufficiently heavy, then it acts like the wall; if the new string is sufficiently light, then

▲ **FIGURE 15–20** A string is attached to a heavier string (top) and to a lighter string (bottom).

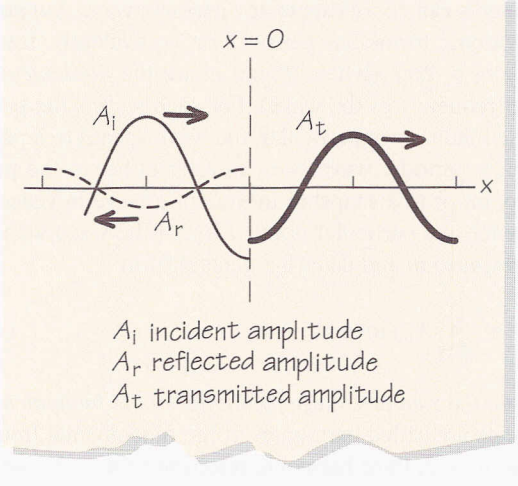
▲ **FIGURE 15–21** (a) A pulse is incident on a heavy string from a lighter one. The reflected pulse is reduced in amplitude and inverted. The transmitted pulse has an amplitude less than that of the incident pulse and moves more slowly than either the incident or reflected pulse. (b) A pulse is incident on a light string from a heavier one. The reflected pulse is reduced in amplitude and right-side up. The transmitted pulse has an amplitude less than that of the incident pulse and moves more rapidly than either the incident or reflected pulses.

it serves as a device that allows the end of the original string to move freely. The situations in Fig. 15–21 are between these extremes, and there we observe both a wave reflected back along the original string and a transmitted wave carried by the new string. We can most easily understand this by considering a pulse traveling along the first string toward the boundary.

The Amplitudes of Reflected and Transmitted Pulses: Figure 15–21a shows what happens when a pulse is incident on a heavier string and Fig. 15–21b shows what happens when a pulse is incident on a lighter string. Consider first the *reflected* pulse. In view of our discussion of the string with fixed or free ends, it is not surprising that when the new string is heavier than the original string, the reflected pulse is inverted, whereas when the new string is lighter, the reflected pulse is right-side up. The amplitude of the reflected pulse decreases to zero in the limit where the new string has a mass density equivalent to that of the original string because, in that case, there is no boundary. This behavior is both smooth and reasonable. What can we say about the transmitted pulse other than that it has the same sign as that of the incident pulse? To say more, we use energy conservation.

Consequences of the Conservation of Energy: If we have an incident pulse that is partly reflected and partly transmitted, then the sum of the energies in these two pulses equals the energy of the incident pulse. If there is no transmitted pulse, as is the case when the new string is either infinitely heavy or infinitely light, then the energy in the reflected pulse matches the energy in the incoming pulse. The transmitted and reflected waves must share the energy of the incident wave and each therefore has an amplitude reduced from that of the incident wave. We'll illustrate the quantitative consequences in Example 15–7.

The Change in Velocity with a Change in Medium: Consider again two different strings attached to each other. The tension throughout the two strings is uniform, as there is no horizontal acceleration. The speed, however, is not uniform. With $v = \sqrt{T/\mu}$, where μ is the mass density of the string, we see that when the new string is heavier (per unit length), the velocity of a harmonic wave is smaller; when it is lighter, the velocity is larger.



We'll state without proof that if the wave speed in the medium containing the incident wave is greater than the wave speed in the medium containing the transmitted wave, then the reflected wave is inverted but is otherwise similar in shape to the incident wave. The transmitted wave is always right-side up, but its shape will be stretched if the wave speed is higher in the second medium and compressed if the wave speed is lower in the second medium (Fig. 15–21). This information is further summarized in Table 15–1.

TABLE 15–1 • Properties of Reflected Waves and Transmitted Waves†

A Wave in Medium 1 Is Incident on a Boundary That Separates Medium 1 from Medium 2	Reflected Wave	Transmitted Wave
Medium 1 is less dense than medium 2 (wave speed in 1 is higher than in 2)	Inverted	Right-side up, Compressed
Medium 1 is denser than medium 2 (wave speed in 1 is lower than in 2)	Right-side up	Right-side up, Stretched

† *See Fig. 15–21.*

EXAMPLE 15–7 A string with mass density μ_1 is attached at $x = 0$ to a second string, with mass density μ_2. The strings are under a common tension T. An incident harmonic traveling wave of amplitude A_i arrives on the first string. A reflected harmonic wave of amplitude A_r results on the first string, and a transmitted harmonic wave of amplitude A_t results on the second string (Fig. 15–22). The strings behave elastically so there is no mechanism for energy loss. Use the fact that energy is conserved to relate the three amplitudes.

▲ **FIGURE 15–22**

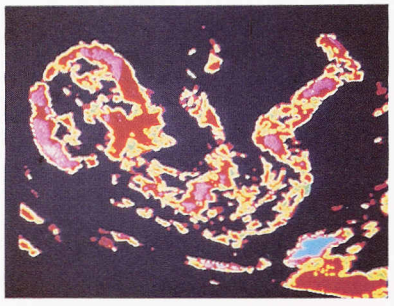
Setting It Up Figure 15–22 labels the amplitudes of the incident, reflected, and transmitted wave. The reflected wave is drawn as having changed sign, which is appropriate if $\mu_2 > \mu_1$, but nothing in what follows depends on that.

Strategy We can solve this using energy conservation alone. However, we can equally well deal with the energy carried per unit time by the three waves—that is, the power—and as we know how to write expressions for the average power in a traveling wave, Eq. (14–37), this is an effective way to proceed. We will therefore write down expressions for the incident, reflected, and transmitted power. Generically the average power is given by $P = \mu\omega^2 A^2 v/2$, where μ is the mass density, ω the angular frequency, A the amplitude, and v the velocity of the harmonic wave. The statement of energy conservation is equivalent to the statement that the incident power is equal to the sum of the reflected and the transmitted power. We also need to use the condition that the frequencies are the same for all three waves—they are the same because they simply represent a counting of the rate at which crests reach and leave the boundary. (If the frequency changed, wave crests would be lost or would pile up somewhere.) When we apply the energy conservation condition, we find a relation for the amplitudes.

Working It Out The statement that the average incident power is equal to the sum of the average reflected and transmitted power is

$$\frac{\mu_1\omega_i^2 A_i^2 v_1}{2} = \frac{\mu_1\omega_r^2 A_r^2 v_1}{2} + \frac{\mu_2\omega_t^2 A_t^2 v_2}{2}.$$

Here we have noted that the speed of both the incident and reflected waves is v_1, whereas the speed of the transmitted wave is v_2. In particular, $v_1 = \sqrt{T/\mu_1}$ and $v_2 = \sqrt{T/\mu_2}$. The (identical) frequencies and the factors of $\sqrt{T}$ and of $\frac{1}{2}$ cancel, and we are left with the relation between the three amplitudes:

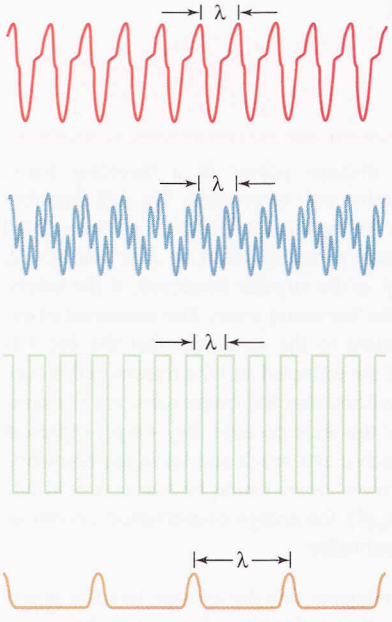


$$\sqrt{\mu_1}A_i^2 = \sqrt{\mu_1}A_r^2 + \sqrt{\mu_2}A_t^2.$$

Note that when there is no transmitted amplitude—either because there is a wall at $x = 0$ or because the end of the first string is free—then the relation is $A_i^2 = A_r^2$. Because this relation depends on the *squares* of the amplitudes, it tells us nothing about whether the reflected wave is right-side up (positive A_r) or inverted (negative A_r).

What Do You Think? What other conditions do you think would be available for the determination of the amplitudes?

THINK ABOUT THIS . . .



HOW ARE REFLECTED AND TRANSMITTED WAVES OF USE TO US?

▲ **FIGURE 15–23** The colors in this ultrasound image of a human fetus are the result of computer processing of the waves that reflect back to the source/receiver.

Our eyes primarily detect light reflected from the objects around us, and it is with the information in these reflected light waves that we interpret the world around us. The light arrives at Earth's surface having traveled through space from the Sun and having been transmitted into the atmosphere. Many technologies use the phenomena of reflection and transmission. For example, geophysicists use sound waves to explore Earth's interior (see the Chapter 14 "Think About This . . . How do we know what's inside Earth?"). We can emphasize here the important role of reflection and transmission across rock boundaries. Doctors use ultrasound (sound of very high frequencies) to make interior images of the human body (Fig. 15–23), and the same techniques are used for investigating imperfections in materials. Radar and sonar devices emit electromagnetic waves or sound waves, then detect the arrival of their reflections, allowing us to learn about the reflecting object. Finally, Doppler shifts of reflected waves tell us about the speed of the reflecting object.

*15–6 Fourier Decomposition of Waves

▲ **FIGURE 15–24** Some nonharmonic periodic waves.

We have studied two types of waves: single pulses, which are not periodic phenomena, and harmonic (or sinusoidal) waves, which are. In another important category we might put periodic waves that are not harmonic (Fig. 15–24). The superposition principle, together with a remarkable mathematical result called *Fourier's theorem*, shows that the waves in these three categories are very closely related. The substance of the theorem is (1) *any periodic (not necessarily sinusoidal) wave can be approximated by a superposition of purely harmonic (or sinusoidal) waves with different frequencies in the form of a sum*, and (2) *any pulse can be approximated by a superposition of purely harmonic waves in the form of an integral.*

Fourier's theorem does more than just state a possibility; it also lays out the rules for finding what the harmonic components are that make up a wave and the relative weights of these components—what we call the *decomposition* of the wave. Even better, it shows how only a few harmonic components can approximate any periodic wave. Suppose that the wave we wish to fit with harmonic forms has period T or, equivalently, frequency $f = 1/T$, and angular frequency $\omega = 2\pi f$ (where f and ω are the *fundamental* frequency and *fundamental* angular frequency of the wave). For such waves, the period in time is related by properties of the medium (in particular, the wave speed) to a period in space—the wavelength. Thus, for a periodic wave, we can refer either to the periodic time dependence at a particular point or to a snapshot in time of a wave in space. Let's look at the periodic time dependence at a particular point, $f(t)$, of the wave we want to fit. The fit is known as a *Fourier expansion* and takes the general form

$$f(t) = \sum_{n=1}^{\infty} A_n \sin(n\omega t + \phi_n). \tag{15–22}$$

The only frequencies that enter into the sum are integer multiples of the fundamental frequency, $f_n = nf$. These frequencies are called harmonics of the fundamental frequency, with second harmonic referring to $n = 2$, third harmonic referring to $n = 3$, and so on.

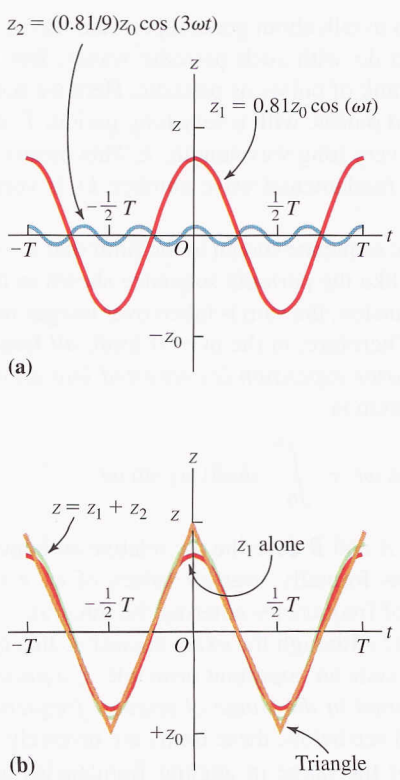
If, instead of concentrating on the time dependence, we take a snapshot of a periodic wave $g(x)$ in space, then that wave, however complex in form, has a fundamental wavelength λ or a fundamental wave number $k = 2\pi/\lambda$. The Fourier expansion of our wave takes the form

$$g(x) = \sum_{n=1}^{\infty} A'_n \sin(nkx + \theta_n). \tag{15–23}$$

Here, the higher harmonics have wave numbers that are integer multiples of the fundamental wave number. The Fourier expansion tells exactly how to calculate the constants

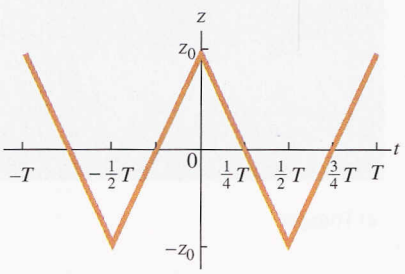
in Eqs. (15–22) and (15–23) with a set of rules. While we won't detail the expansion rules here, we do emphasize that these rules are not at all ambiguous.

If the infinite sum in Eq. (15–22) or (15–23) is truncated (cut off), the resulting finite sum forms an approximation to the original waveform. Such approximations are quite useful. We may want to learn about the important frequencies in a particular waveform so that we can suppress or enhance certain modes. For example, in electronic sound equipment, we may want to boost or suppress certain components of a note without changing its pitch, thus changing the quality of the sound.



Fourier Decomposition of a Triangular Wave

To demonstrate Fourier decomposition, let's try to fit the triangular wave illustrated in Fig. 15–25 with harmonic functions. (Such waves might be used in electronics applications where they are generated precisely by the superposition of harmonic waves.) The triangular wave has a period T and an angular frequency $\omega = 2\pi/T$. The rules for the constants that appear in the expansion require the phases ϕ_n to equal $\pi/2$. This means that only cosines appear in the expansion. This is reasonable because the triangular waveform is symmetric about $t = 0$, and the cosine also has this symmetry. The cosine is thus a "natural" expansion function for the triangular wave. Cosines that reach negative maxima at $t = \pm T/2$ would make it easy to build the sharp negative trough of the triangular wave at these points. This feature is shared by $\cos(\omega t)$, $\cos(3\omega t)$, $\cos(5\omega t)$, and so forth, but *not* by $\cos(2\omega t)$, $\cos(4\omega t)$, and so on. The calculation of A_n bears this out: $A_2, A_4, \ldots$ all turn out to be zero. When the expansion rules are applied, the exact Fourier expansion of our wave is

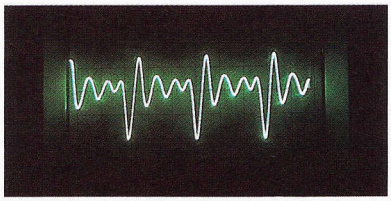


$$z(t) = \frac{8}{\pi^2} z_0 \sum_{n=\text{odd}} \frac{1}{n^2} \cos(n\omega t)$$

$$= 0.81 z_0 \left[\cos(\omega t) + \frac{1}{9}\cos(3\omega t) + \frac{1}{25}\cos(5\omega t) + \cdots \right]. \quad (15\text{–}24)$$

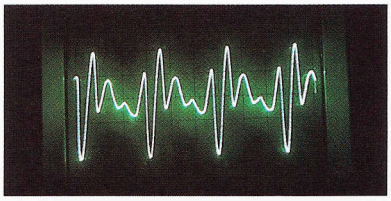
Figure 15–26 illustrates this Fourier expansion. Figure 15–26a shows the individual terms $z_1 = 0.81 z_0 \cos(\omega t)$ and $z_2 = (0.81/9) z_0 \cos(3\omega t)$. Figure 15–26b shows how first one term and then two terms of Eq. (15–24) match the triangular wave.

◀ **FIGURE 15–26** Fourier analysis of the triangular waveform of Fig. 15–25. (a) The first two contributing harmonics, $z_1 = 0.81\ z_0 \cos(\omega t)$ and $z_1 = (0.81/9)\ z_0 \cos(3\omega t)$. (b) The triangular waveform, the expression z_1 alone, and an approximation containing the first two terms of Eq. (15–24). The approximation with z_1 alone is already a good one, and the two-term expression is an even better one.



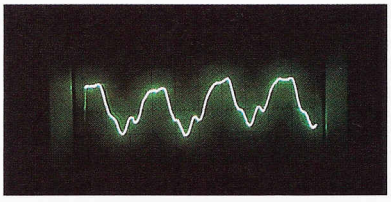
▲ **FIGURE 15–25** A triangular wave of period T. The time dependence of the transverse displacement z of a string is plotted at some fixed point in space.

The $\cos(\omega t)$ term alone does reasonably well in approximating the triangular wave. By the time the second term is included, the approximation is at worst good to 10%.

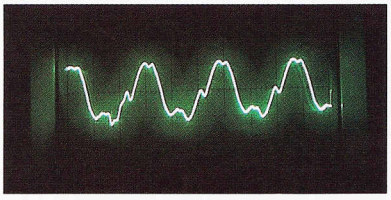


The Fourier theorem is of great importance in engineering and physics because of its relevance to the solution of many different problems. In addition to the applications in vibrations and wave motion that are simply sketched out here, heat-flow problems and the solutions of a great class of problems in electricity and magnetism across the entire gamut of electrical engineering require the Fourier expansion.

Fourier Analysis and the Ear



Our ears work very well as Fourier analysis devices. When the note A is produced by an electronic "tuning fork," a pure harmonic wave of period $T = 1/(440\ \text{Hz}) = 2.27 \times 10^{-3}$ s emerges. The same note played on a piano, a violin, a trombone, an oboe, or a saxophone contains a harmonic wave of the same fundamental frequency. But each instrument emits its own complicated waveform (Fig. 15–27). In the language of Fourier analysis, this means that a note played by any of those instruments contains vast numbers of differing harmonic components. The ear is capable of picking out the fundamental frequency; we can all agree when the same note is played by a piano and an electric guitar. It is the higher components by which the ear differentiates between different instruments or between different voices. Even different violins have very different higher harmonic contents, a very subtle but important matter in the construction of violins. Although the physical differences between Stradivarius violins and others of lesser value are so slight that attempts to duplicate "Strads" fail, the sounds of Strads are generally more appealing than those of ordinary violins. A Fourier analysis shows that better violins have a far greater content of higher harmonics. Our ears can even distinguish between individual violins made by the same master!



(a) Trumpet

(b) Synthesized trumpet

(c) Guitar

(d) Synthesized guitar

▲ **FIGURE 15–27** The characteristic sounds of different instruments are associated with frequencies above that of the sound of the "note" being played. These higher frequencies are known as overtones, and their presence makes the waveform of the sound different than the purely harmonic sine or cosine form. A synthesizer electronically generates the characteristic pattern of overtones to trick the ear. Shown in Figs. (a) to (d) is the note of F, played, by a trumpet, a synthesized trumpet, a guitar, and a synthesized guitar, respectively.

*15–7 Pulses and the Uncertainty Principle

When we treat pulses with Fourier's theorem, we discover a fundamental relation between the width of the pulse and the frequencies of the periodic waves of which it is composed. This relation is known as the **uncertainty principle**.

The Fourier Decomposition of Pulses

In Section 15–6 we used Fourier's theorem to talk about general periodic waves. At first sight, pulses would seem to have little to do with such periodic waves. But the last drawing in Fig. 15–24 suggests a way to think of pulses as periodic. Here we see a periodic wave that is a series of short, repeated pulses, with a very long period, T, between the pulses or, equivalently, separated by a very long wavelength, λ. This means that the fundamental angular frequency, ω (or the fundamental wave number, k), is very small, because $\omega = 2\pi/T$ (or $k = 2\pi/\lambda$).

A true pulse in time is like the periodic sequence shown in the limit that $T \to \infty$, or $\omega \to 0$. Similarly, a true pulse in space is like the periodic sequence shown in the limit that $\lambda \to \infty$, or $k \to 0$. In the Fourier expansion, the sum is taken over integer multiples of angular frequencies (wave numbers). Therefore, in the $\omega \to 0$ limit, *all* frequencies enter into the sum and *the sum in the Fourier expansion is converted into an integral.* More concretely, the statement of the theorem is

$$P(t) = \int_0^\infty d\omega A(\omega) \cos \omega t + \int_0^\infty d\omega B(\omega) \sin \omega t$$

for any pulse function $P(t)$. The functions A and B describe the relative amounts of different frequencies. While the integral runs formally over all values of ω, it is really $A(\omega)$ and $B(\omega)$ that determine the range of frequencies entering the integral.

Just what can we say about this range? Although the exact answer to this question depends on the shape of the pulse, we can state an important principle. *If a pulse is limited in time (or space), then it is also limited in the range of angular frequencies (or wave numbers) that enter into it.* (As we'll see below, these limits are inversely related; the narrower the range in time, the larger the range in angular frequencies and vice

versa.) In other words, the angular frequencies that contribute are in a narrow range, and we can estimate that range by the following argument. The different frequencies that contribute to a pulse interfere constructively in the region where the pulse is strong and interfere destructively in the region where the pulse drops to zero. Suppose that a pulse lasts a time Δt; we say it has a **width** in time of Δt. Suppose also that the contributing frequencies go from a minimum angular frequency ω_{min} to a maximum ω_{max}, with $\Delta\omega = \omega_{\text{max}} - \omega_{\text{min}}$. We want these waves to be out of phase at the beginning of the pulse, to be in phase at the center of the pulse, and then to be out of phase once more at the end of the pulse. If in time span Δt the number of periods of the waves of frequency ω_{max} differs by just one from the number of periods of the waves of frequency ω_{min}, then waves that are out of phase at the beginning of the pulse will be in phase at the center and out of phase at the end. Now the number of periods of a wave of angular frequency ω contained in a time span Δt is

$$\frac{\Delta t}{T} = \Delta t \frac{\omega}{2\pi}.$$

Our condition is then $\frac{\Delta t}{2\pi}(\omega_{\text{max}} - \omega_{\text{min}}) \cong 1$, or $(\Delta t)(\Delta\omega) \cong 2\pi$. In fact, this approximate equality holds for some pulses, and a more detailed mathematical study shows that for others it is an inequality that is usually stated as

$$(\Delta t)(\Delta\omega) \geq 2\pi. \tag{15–25}$$

This equation is a **reciprocal relation**; if Δt is large, $\Delta\omega$ is small, and vice versa. A very sharp pulse in time contains a very broad range of harmonic components. Similarly, a pulse that is very broad in time will have only a limited range of angular frequencies.

A more commonly used reciprocal relation follows if we use the frequency $f = \omega/2\pi$ in place of the angular frequency, ω:

$$(\Delta t)(\Delta f) \geq 1. \tag{15–26}$$

RECIPROCAL RELATION FOR TIME AND FREQUENCY

It is also worthwhile to see how the reciprocal relation works when we study a pulse in space rather than time. Here, the breakdown of the pulse is in terms of a continuous range of wave numbers (or wavelengths) rather than angular frequencies. Suppose that the pulse has width Δx in space. Then the same method of estimating the range of wavelengths, $\Delta\lambda$ of the contributing harmonic waves, can be used. The condition would then be

$$\Delta x\left(\frac{1}{\lambda_{\text{min}}} - \frac{1}{\lambda_{\text{max}}}\right) \cong 1$$

or, in terms of the wave number, $k = 2\pi/\lambda$, $(\Delta x)(\Delta k) \cong 2\pi$. Again, the approximate equality is actually an inequality,

$$(\Delta x)(\Delta k) \geq 2\pi. \tag{15–27}$$

RECIPROCAL RELATION FOR SPACE AND WAVE NUMBER

Here, $\Delta k = k_{\text{max}} - k_{\text{min}}$ is the range of wave numbers that must enter into the construction of a pulse whose width in space is Δx. Again, the smaller Δx is (i.e., the narrower the pulse), the larger the range of wave numbers.

Uncertainty Relations

In the context of the microscopic world of atoms, the reciprocal relations we have discussed are called **uncertainty relations**; the fact that such relations come into play is the *uncertainty principle*. In atomic physics quantum mechanics is important, and the key idea in quantum mechanics is that all matter has wavelike characteristics. Although the words "uncertainty principle" are often used only in connection with quantum

mechanics, the principle really applies to any wavelike phenomenon. The trade-off in the context of quantum mechanics involves the position and speed of microscopic particles. If you measure the position of a particle at any given time with high precision, then you can know the speed—or the momentum—only with poor precision, and vice versa. The momentum is closely related to a wave number in quantum mechanics, which we'll discuss further in Chapter 40.

THINK ABOUT THIS . . .

DOES THE RECIPROCAL RELATION HAVE PRACTICAL CONSEQUENCES?

There is a very real place where the reciprocal relation is relevant: communication by signal construction. Pure harmonic waves cannot convey information, because they have neither a beginning nor an end. Signals and information transfer are necessarily in the form of pulses. For example, all movement of information within and between computers is done with sequences of pulses in binary form. Rapid communication of information requires that the pulses carrying the information be very narrow. If not and, in particular, if pulses overlap to make wider pulses, information is lost in the confusion between the pulses. According to the reciprocal relation, this means that a very broad spectrum of frequencies must go into the construction of these narrow pulses: The narrower the pulse, the broader the range of frequencies must be. But this costs money—in a very literal sense. The energy density and power in harmonic waves of frequency ω are proportional to ω^2, as discussed in Section 14–5. The reciprocal relation forces a trade-off: A sharper pulse, which is more effective in transferring information, is more expensive.

Summary

The algebraic sum, or superposition, of two solutions of the wave equation is also a solution. The collection of physical phenomena that follow from this fact fall under the general heading of wave interference. When two waves that are superposed have opposite algebraic signs at a particular point or a particular moment of time, they interfere destructively. When they have the same sign, they interfere constructively.

Standing waves can be considered to be the result of the superposition of traveling waves moving in opposite directions. Standing waves on a string can be decomposed into the superposition of traveling waves with their own reflections from the ends.

When two waves with nearly equal frequencies, f_1 and f_2, are superposed, the result is that the original wave is modulated by a wave of much smaller frequency and larger wavelength called a beat. The beat frequency is

$$f_{\text{beat}} = \tfrac{1}{2}(f_1 - f_2). \tag{15–16}$$

Two waves of the same wavelength are coherent if there is a constant phase difference between them. If the distances that the waves travel differ by ΔL, an interference pattern that depends only on ΔL and on the phase difference is traced out. If the phase difference at the source is zero, the interference pattern is

$$\text{for constructive interference: } \Delta L = n\lambda,\ n = 0, \pm 1, \pm 2, \ldots; \tag{15–17}$$

$$\text{for destructive interference: } \Delta L = \left(n + \tfrac{1}{2}\right)\lambda,\ n = 0, \pm 1, \pm 2, \ldots. \tag{15–18}$$

Suppose that two coherent wave sources of wavelength λ and zero phase difference are separated by a distance d that is much smaller than the distance to the observation point. Then there is an interference pattern that is a function of the angle θ made with the perpendicular bisector of the line separating the wave sources:

$$\text{for maxima: } \sin\theta = n\frac{\lambda}{d},\ n = 0, \pm 1, \pm 2, \ldots; \tag{15–20}$$

$$\text{for minima: } \sin\theta = \left(n + \frac{1}{2}\right)\frac{\lambda}{d},\ n = 0, \pm 1, \pm 2, \ldots. \tag{15–21}$$

The pattern described by these equations broadens (the angle θ corresponding to a particular minimum or maximum increases) as the wavelengths involved increase and/or the separation between the sources decreases. This is a very general feature of interference patterns.

Waves reflect from boundaries and are transmitted past boundaries that separate one wave-carrying medium from another. A reflected wave is either inverted or right-side up, compared to the original wave, according to whether the medium from which the wave reflects is denser or less dense than the original medium.

Fourier's theorem shows that any wave, both periodic and nonperiodic (pulses), can be approximated as closely as we like by a superposition of purely harmonic waves with different frequencies. This result allows for the construction of arbitrary waveforms from harmonic waves and for the analysis of physical systems in terms of harmonic waves.

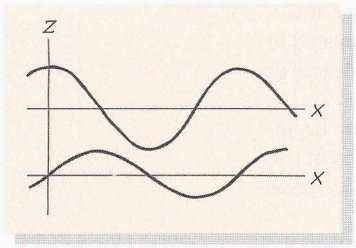
A pulse can also be treated by Fourier analysis. If a pulse has a time span of Δt, then the range of frequencies, Δf, that comprise that pulse is limited:

$$(\Delta t)(\Delta f) \geq 1. \tag{15–26}$$

There is a similar relation between the spatial extent of the pulse, Δx, and the range in wave numbers, Δk, that enter into the pulse's decomposition:

$$(\Delta x)(\Delta k) \geq 2\pi. \tag{15–27}$$

These relations hold whenever wave phenomena are present and explain why sharp information-carrying signals are expensive to generate.



Understanding the Concepts

1. A standing wave on a string can be constructed from two traveling waves that move in opposite directions. Can a traveling wave be constructed from the sum of two standing waves?
2. When transverse positive and negative pulses that have the same symmetric shape and size but travel in opposite directions meet, is it necessary that there be a moment when the string or wire on which they move is flat? If so, how do the pulses "know" to continue moving on the string?
3. Two people on each end of a long rope send off a wave pulse. If both wave pulses are on the same side of the rope, describe what happens when the pulses meet. What about when the pulses are on opposite sides? What happens when one pulse is oriented at a 90° angle to the second pulse?
4. If a higher harmonic than the fundamental one is excited on the string attached between the two walls, will it be the frequency or the velocity that changes?
5. Listening to the beat frequency between an unknown and a standard (known) tuning fork tells you only about the difference between the two frequencies. The unknown frequency could be larger or smaller than the known frequency. With a piece of chewing gum at your disposal, can you devise a method to determine the unknown frequency?
6. A wave with truly sharp edges, such as the triangular wave discussed in Section 15–7, can never exist on a string in nature. What might limit how sharp the changes can be?
7. Consider a sinusoidal traveling wave that moves down a sequence of successively lighter strings tied together end to end. The wave starts at the end containing the heaviest string. Qualitatively describe what happens to the frequency and wavelength of the wave by the time it reaches the lightest end of the system.
8. We saw what interference pattern two speakers close to one another make near the line perpendicular to and bisecting the line that connects the speakers. Will there be an interference pattern even far from this center line, where the small angle approximation that we used to derive the pattern is not valid?
9. A pebble dropped into still water produces a pulse. The speed of water waves of different wavelengths differ from one another. Why does a dropped pebble produce a series of spreading concentric waves rather than a single wave front?
10. How do you reconcile the principle of conservation of energy with the observation that, in one region, the wave medium is not in motion when waves interfere destructively?
11. In Section 15–1 we referred to two waves that move to the right and cancel; they give no wave at all. Yet each wave alone has an energy density. What happens to the energy? [*Hint*: What are the implications of the superposition principle for the energy density?]
12. Musicians often use beats to tune to some standard, such as an oboe. Can a trumpet player tell from the beat frequency whether one particular note is sharp (at a higher frequency) or flat (at a lower frequency) compared to the same note played on the oboe?

Problems

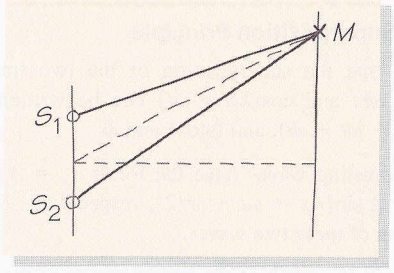
15–1 The Superposition Principle

1. (I) Show that the superposition of the two traveling waves $\sin(kx - \omega t)$ and $\cos(kx - \omega t)$ can be written in the form $A\sin(kx - \omega t + \phi)$, and find A and ϕ.
2. (I) Two traveling waves have the forms $z_1 = A\sin(kx - \omega t)$ and $z_2 = A\sin(kx - \omega t + \pi/2)$, respectively. Sketch the superposition of these two waves.
3. (I) Work out the result of the superposition of the two waves of Problem 2 in the form $z = z_1 + z_2 = A\sin(kx - \omega t + \delta)$.
4. (II) Consider the superposition of two harmonic waves, $\psi(x, t) = A\sin(kx - \omega t) + 3A\cos(kx - \omega t + \theta)$. (a) For what values of θ will this superposition result in the maximum constructive interference? (b) the maximum destructive interference? (c) If this superposition is written in the form $B\sin(kx - \omega t + \alpha)$, express B and α in terms of A and θ.
5. (II) Two sinusoidal waves with the same frequency travel down a long rope (Fig. 15–28, see next page). The waves have amplitudes 3 cm and 2 cm, respectively, but the second wave trails the first wave by a phase of $\pi/2$. Determine the amplitude of the resultant motion.

▲ **FIGURE 15–28** Problem 5.

6. (II) Four sinusoidal waves have the same frequency, but the first two waves have amplitudes twice that of the other two waves. The phases of the four waves are 0, $\pi/2$, π, and $3\pi/2$, respectively. Plot the resulting superposed wave, and describe its motion.
7. (II) Two sine waves, $A\sin(\omega t + kx)$ and $A\sin(\omega t + kx + \delta)$, combine to form a sine wave with the same amplitude A. For what values of δ of the second wave is this possible?

15–2 Standing Waves Through Interference

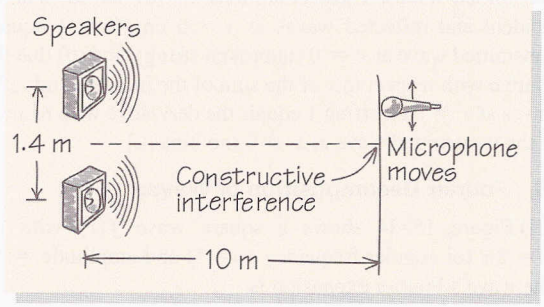


8. (I) Two waves are described by $\psi_1 = (2.5\text{ cm})\sin(kx - \omega t)$ and $\psi_2 = (2.5\text{ cm})\sin(kx + \omega t)$, where $k = 3\pi/2\text{ cm}^{-1}$ and $\omega = 2\pi\text{ s}^{-1}$. (a) Show that the addition of the two waves produces a standing wave. (b) Determine the amplitude and frequency of the resulting standing wave.
9. (I) Consider traveling waves moving in opposite directions: one has the form $z_r(x,t) = z_0\sin(kx - \omega t)$ and the other has the form $z_l(x,t) = z_0\cos(kx + \omega t)$. Do these waves add to a standing wave? If so, what is the expression for the standing wave, and what are the locations of the nodes? Note that $\cos\theta$ can be written as $\sin[\theta + (\pi/2)]$.
10. (II) Show by a specific construction that two standing waves can add up to give a traveling wave. What standing wave would you have to add to $A(\cos kx)(\cos\omega t)$ to get a wave traveling to the left?
11. (II) Two traveling waves that move in opposite directions along the x-axis interfere to produce a standing wave of the form $6\sin kx\cos\omega t$, where $k = 3\pi\text{ m}^{-1}$ and $\omega = 22\pi\text{ s}^{-1}$. (a) What are the frequencies and speeds of the traveling waves? (b) What are the forms of the traveling waves?
12. (II) One harmonic of an organ pipe has a single node at 3/4 of the length of the pipe and an antinode at the open end (see Fig. 14–26). Write an expression to describe this mode as a standing wave. Find two traveling waves that produce the same result. The length of the pipe is 0.80 m and the speed of sound is 330 m/s.
13. (II) Show that the sum of a wave that travels to the right and a wave that travels to the left with the same amplitude, wave number, and frequency is a standing wave, independent of phase. [*Hint*: Consider $\psi(x,t) = A\sin(kx - \omega t) + A\sin(kx + \omega t + \theta)$; define $u \equiv kx + \theta/2$ and $v \equiv \omega t + \theta/2$, and use the appropriate identities.]
14. (II) The most general forms of two traveling waves that move in opposite directions along the x-axis with the same amplitude, wavelength, and frequency are $z_r(x,t) = z_0\sin(kx - \omega t + \phi_1)$ and $z_l(x,t) = z_0\sin(kx + \omega t + \phi_2)$. What is the form of the standing wave that results from their superposition?
15. (II) A harmonic wave traveling to the right along the x-axis has its maximum amplitude at the time $t = 0$ s at the point $x = 0$ m. Superimposed on this is a wave traveling to the left with equal amplitude, wavelength, and frequency, such that the net standing wave has nodes at $x = 3$ m and at $x = 6$ m. What is the largest possible value of the wavelength?

15–3 Beats

16. (I) You have a tuning fork of unknown frequency and a tuning fork of frequency 552.0 Hz. Combined, the two produce a pulse frequency ($f_{\text{pulse}} = 2f_{\text{beat}}$) of 1.8 Hz. What are the possible values of the frequency emitted by the first tuning fork?
17. (I) You have a tuning fork of frequency 512 Hz and look for another tuning fork of smaller frequency so that there is a perceived beat frequency of 6 Hz between them. What frequency should the other tuning fork have?
18. (I) Two violinists play their (identical) A-strings, nominally 440 Hz. A beat is heard at a pulsing of 2 Hz. What is the magnitude of the fractional difference in wave speed, $(v_1 - v_2)/v_1$, for the two strings? [*Hint*: The length L of a violin string is the same from violin to violin.]
19. (I) Two strings of the same material on a pair of guitars are in tune with a frequency of 414 Hz. The string of one of them is tightened slightly, and you hear a beat frequency of 8 Hz. What is the frequency of the tightened string?
20. (I) Two speakers are wired so that they emit sound coherently. Because of a manufacturing error, the same electrical impulse that leads one to emit sound of wavelength 27.10 cm leads the other one to emit sound of wavelength 26.71 cm. What is the pulse frequency ($f_{\text{pulse}} = 2f_{\text{beat}}$)?
21. (II) Two identical piano wires have a frequency of 512 Hz when under the same tension. As a consequence of slippage, the tension of one of the wires changes slightly, so that its frequency decreases slightly. If 4 beats/s are heard when the wires both vibrate, what is the fractional change in the tension of the lower-frequency string?

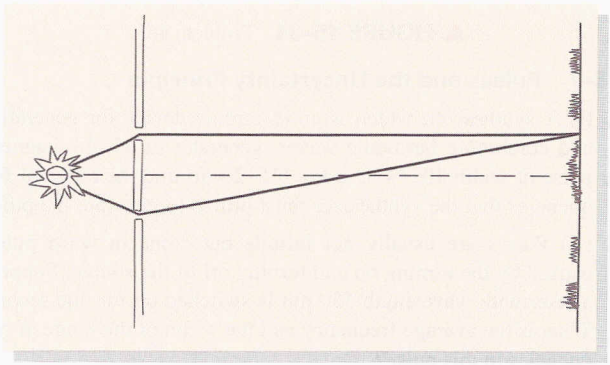
15–4 Spatial Interference Phenomena



22. (I) Two speakers that emit waves with the same wavelength λ are placed at $x = L$ and $x = -L$, respectively. Assuming that the speakers emit waves with equal amplitudes A and that the phase of the wave on emission is zero at $t = 0$ in both cases, what is the form of the traveling waves that travel toward a microphone located between them at $x = 0$?
23. (I) Find the waveform picked up by the microphone in Problem 22; that is, the superposition of the two waves arriving at the microphone.
24. (I) Two speakers separated by 80 cm are fed with the same pure sinusoidal wave of 750 Hz. A microphone is placed 4.0 m away along the center line between the speakers (Fig. 15–29). It picks up an intensity maximum. It is then moved slowly out to the side. (a) How far out to the side, in meters, does the microphone have to be moved to pick up a first minimum? (b) How much farther does the microphone now have to be moved to pick up a second maximum? (c) How do the answers to parts (a) and (b) change if the speakers are now separated by just 10 cm? The approximation $\sin\theta \cong \theta$ is not valid here, although the angles of the lines from the speakers to the microphone are nearly equal.

▲ **FIGURE 15–29** Problem 24.

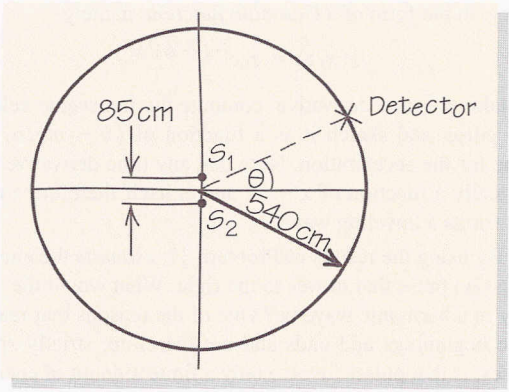
25. (I) Two coherent sources are 3.0 cm apart and make harmonic ripples of the same frequency (see Fig. 15–8). Consider the ripples along a straight line L_1 parallel to the line L_2 that connects the sources and 40.0 cm away from line L_2. If the distance between the central maximum at L_1 and the next maximum on L_1 is 8.0 cm, what is the wavelength of the ripples?



26. (I) Sound of frequency 600 Hz is emitted in phase from two speakers 1.4 m apart (Fig. 15–30). A microphone can move along a line parallel to the line that joins the two speakers and is 10.0 m from the base of the speakers; it measures sound intensity, which can then be plotted versus distance. The interference produced is constructive in the center. Where is the first minimum in the sound intensity curve along the track of the microphone?

▲ **FIGURE 15–30** Problem 26.

27. (II) Two coherent wave sources 5 cm apart make ripples in a water tank (see Fig. 15–8). The wavelength of the waves is 3 cm. (a) Determine the angle between the perpendicular bisector of the line segment connecting the two wave sources and the direction of the first noncentral maximum. (b) What is the direction of the first maximum if the two sources operate with opposite phases? (c) How will the answers to (a) and (b) change if the wavelength is changed to 6 cm?



28. (II) Harmonic light waves are emitted by a source equidistant between two narrow vertical slits 0.18 mm apart in a screen (Fig. 15–31). The light waves detected at a screen parallel to the screen containing the slits but 35 cm away have the usual maximum at the point opposite the midpoint of the two slits, and the first minimum occurs at a point 0.6 mm from the maximum. What is the wavelength of the light?

▲ **FIGURE 15–31** Problem 28.

29. (II) Coherent waves emerge from two slits separated by a distance $2a$. A screen is placed at a distance L away from the slits, and the first interference minimum is found at a distance d from the center point. Use the small-angle approximation to show that the relationship between the wavelength (λ) and the other lengths is given by $\lambda = 4ad/L$.

30. (II) Two tuning forks vibrating in phase with frequency 440 Hz are placed 85 cm apart. A detector is moved in a circle of radius 540 cm around the center of the tuning forks (Fig. 15–32). Plot the approximate variation of the square of the net amplitude as a function of angle. Neglect the small variation in the magnitude of the amplitude that results from the sources not being at the same distance from the detector. Take the velocity of sound to be 330 m/s.

▲ **FIGURE 15–32** Problem 30.

31. (II) An oscillator, located at $(x, y) = (-2\text{ cm}, 0\text{ cm})$, that dips in and out of water in a tank produces a water wave of the form $\psi_1 = (3\text{ cm})\sin(\pi r_1 - \pi vt)$, where r_1 is the distance from the oscillator; a second oscillator, located at $(x, y) = (+2\text{ cm}, 0\text{ cm})$, produces a water wave of the form $\psi_2 = (3\text{ cm})\sin(\pi r_2 - \pi vt)$, where r_2 is the distance from the second oscillator. (a) Where on the line between the sources (the x-axis) are the interference maxima located? (b) What is the form of the wave along the line $x = 0$ cm? (Take all times in seconds.)

32. (II) Two tuning forks that vibrate coherently (in phase) at 512 Hz are placed 0.35 m apart on a horizontal surface. A short circular wall of radius 8 m, centered on the midpoint between the sources, is placed around them. Describe the interference pattern of maxima and minima at the wall.

33. (II) Suppose that two in-phase sources of surface waves in water generate water waves that spread out in circles with equal amplitudes. (a) Show that the intensity of the disturbance or the energy generated in the water is, at a maximum, four times the intensity for each wave taken separately. (b) Similarly, show that there is no intensity at a minimum. (c) Show that the intensity at any given point, if there were no wave interference, is twice the intensity from each wave. (d) Do the different answers to parts (a), (b), and (c) mean that the conservation of energy principle must be abandoned for waves? Explain your answer.

15–5 Pulses

34. (I) A student pulls a rope taut and shakes it once, sending a wave pulse down the rope. The pulse is described by a *Gaussian function*,

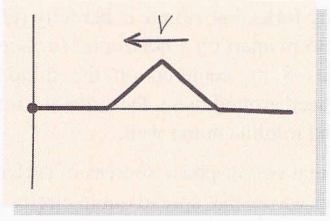
$$z(x, t) = z_0 \exp\left[-\frac{(x - (1\text{ m/s})t)^2}{(0.1\text{ m})^2}\right].$$

Where is the center of the pulse at time t?

35. (I) At $t = 0$, a sawtoothed pulse has the shape $z = 0$ for $x < -a$ and for $x > 0$; $z = k(x + a)$ for $-a < x < 0$. Sketch this pulse. Suppose that the pulse moves at speed v in the $+x$-direction. What is the algebraic expression for the moving pulse?

36. (II) Consider a train of pulses of the type described in Problem 35. Here, at $t = 0$, the displacement is $z = 0$ for $x < -a + nb$ and for $x > nb$; $z = k(x + a - nb)$ for $-a + nb < x < nb$; n is any integer—positive, negative, or zero—and $b > a$. (a) Sketch this wave train of pulses. (b) Suppose that the entire train of pulses moves at speed v in the $+x$-direction. What is the algebraic expression for the train? (c) What are the period and wavelength of this nonharmonic wave?

37. (II) Consider a transverse wave that moves to the right on a string, in the form of a *Gaussian function*, namely



$$z(x, t) = z_0 e^{[-(x-vt)^2/\alpha^2]}.$$

By taking a time derivative, compute the transverse velocity of this pulse, and sketch it as a function of $(x - vt)/\alpha$. Do the same for the acceleration. Note that any time derivative is automatically a function of $x - vt$ and is itself therefore a quantity that forms a traveling wave.

38. (II) By using the results of Problem 37, *estimate* the energy in a Gaussian pulse that moves to the right. What would the total energy in a harmonic wave be? One of the reasons that real waves have beginnings and ends and are therefore, strictly speaking, pulses, is that pulses involve only a finite amount of energy.

39. (II) Two transverse pulses travel along a string at speed v in opposite directions. The pulse that moves to the right approximates a square with sides of length ℓ projecting above the equilibrium level of the string. The pulse that moves to the left approximates a square with sides of length $\ell/2$ projecting below the equilibrium level. Assume that the superposition principle holds, and describe the approximate shape of the string as the pulses collide.

40. (I) A pulse shaped like an upright two-dimensional pyramid, or an isosceles triangle, travels to the left along a string under tension (Fig. 15–33). The left-hand end of the string is free to move up and down. Sketch a sequence of drawings that show how the pulse reflects from the free end.

▲ **FIGURE 15–33** Problem 40.

41. (I) A string with linear mass density μ_1 is attached to another string, with linear mass density μ_2. A wave with amplitude A that travels along the μ_1 string will at the attachment point give rise to a reflected wave with amplitude B and a transmitted wave with amplitude C, where

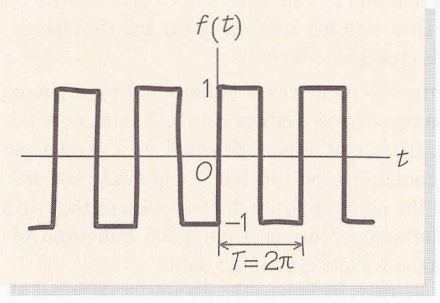
$$B = \frac{\sqrt{\mu_2} - \sqrt{\mu_1}}{\sqrt{\mu_2} + \sqrt{\mu_1}} A, \; C = \frac{2\sqrt{\mu_1}}{\sqrt{\mu_2} + \sqrt{\mu_1}} A.$$

For $\mu_1 = 5.0 \times 10^{-2}$ kg/m and $\mu_2 = 3.8 \times 10^{-2}$ kg/m, what are B and C in terms of the amplitude of the incoming wave?

42. (I) Use the formulas in Problem 41 to show that the average power of the reflected wave plus the average power of the transmitted wave add to the average power of the incident wave.

43. (I) A string with mass density μ_1 is attached to a string with mass density μ_2. The amplitude of a reflected pulse is 85 percent of the amplitude of the incident pulse and is inverted. What is the ratio of μ_1 to μ_2? (See Problem 41.)

44. (II) When a symmetric pulse is incident on the fixed end of a rope, the reflected and incident pulse interfere, and there is a moment when the rope is completely flat. Is this a violation of the conservation of energy? (The energy of waves is discussed in Chapter 14.) Where is the energy at the moment the rope is flat?



45. (III) A string with mass density μ_1 is attached at the point $x = 0$ to a string with mass density μ_2. A tension T is maintained in both strings. A transverse wave of the form $A\cos(kx - \omega t)$, moving to the right, is generated far to the left in the first string. Use the fact that the string is unbroken at $x = 0$ and that no sharp kinks can develop there to obtain the forms of the reflected and transmitted waves. [*Hint*: The stated boundary conditions are sufficient to determine all the parameters of the reflected and transmitted waves. These conditions are (a) that the sum of the incident and reflected waves at $x = 0$ on string 1 equals the transmitted wave at $x = 0$ (unbroken string), and (b) that the derivative with respect to x of the sum of the incident and reflected waves at $x = 0$ on string 1 equals the derivative with respect to x of the transmitted wave at $x = 0$ (no kinks).]

*15–6 Fourier Decomposition of Waves

46. (III) Figure 15–34 shows a square wave $f(t)$ with period $T = 2\pi$ (or angular frequency $\omega = 1$) and amplitude = 1 unit. The wave's Fourier expansion is

$$f(t) = \frac{4}{\pi}\left[\sin(\omega t) + \frac{1}{3}\sin(3\omega t) + \frac{1}{5}\sin(5\omega t) + \cdots\right].$$

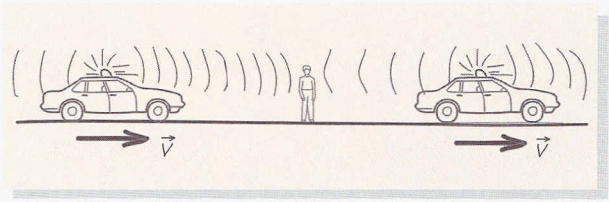
Plot an approximation to the square wave that corresponds to the first, the first two, and the first three terms in this series. (It helps in this to have access to computer software or to a calculator that can plot graphs.)

▲ **FIGURE 15–34** Problem 46.

*15–7 Pulses and the Uncertainty Principle

47. (I) A synthesizer, which is an electronic device for generating and combining harmonic waves, generates an electromagnetic pulse of width 10^{-6} s. Use Eq. (15–26) to find the range of frequencies that the synthesizer must utilize to generate the pulse.

48. (II) Waves are usually not infinite but come in wave pulses caused by the turning on and turning off of the source. Suppose a laser with wavelength 550 nm is switched on for one second. What is the average frequency and the width of the range of frequencies in this pulse?



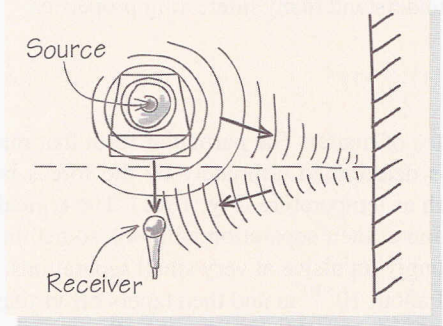
General Problems

49. (I) Two harmonic waves are given by $y_1 = A\cos(kx - \omega t)$ and $y_2 = A\sin[kx - \omega t + (\pi/3)]$, where $k = 5\pi$ m^{-1}, $\omega = 800\pi$ s^{-1}, and $A = 4.0$ cm. (a) What is the frequency of each wave? What is the wavelength of each wave? What is the speed of each wave? (b) What is the amplitude of the wave that is the superposition, $y_1 + y_2$, of these two waves?

50. (I) Two rectangular pulses 4 cm long and of amplitude 3 cm but opposite sign are traveling down a string from opposite directions. At $t = 0$ s, the pulses approach each other with their centers 16 cm apart. The wave speed on the string is 1 cm/s. (a) Describe and sketch the shape of the string at $t = 0$, 2, 5, 8, 10, and 15 s. (b) What has happened at $t = 8$ s? What is the energy at this time?

51. (I) Two violinists play their (identical) A-strings, nominally 440 Hz. A beat is heard at a pulsing of 2 Hz. What is the fractional difference in tensions $(T_1 - T_2)/T_1$ of the two strings? [*Hint*: The length of a violin string is the same from violin to violin; when a violinist tunes his or her instrument, the string tension is changed.]

52. (II) The police are busy on the day that you hear two police cars sounding their one-note sirens as you wait at a light (Fig. 15–35). The police cars are moving at 67.1 mi/h (30.0 m/s) and their drivers hear their own sirens emitting at a frequency of 650 Hz. One police car passes you while the other is still approaching. Do you hear a beat? If so what is it?



▲ **FIGURE 15–35** Problem 52.

53. (II) Consider two sources of sound that both emit waves with a frequency of 1800 Hz. These sources are placed on a turntable of radius 50 cm that rotates with an angular speed of 120 rev/min. Calculate the pulse frequency ($f_{\text{pulse}} = 2f_{\text{beat}}$) that results from the opposite Doppler shifts of the two sources, heard at a large distance from the turntable as a function of time. Ignore the fact that the sources are not quite equidistant from the detector of the sound. The speed of sound in air is 330 m/s.

54. (II) A guitar string has a fundamental frequency of 240 Hz. Another apparently identical guitar string is stretched beside the first one. (a) During successive stretching, each time tightening the second guitar string, the beat frequencies are 10, 5, and 1 Hz, consecutively. During the tightening, the beat frequency never passes through zero. What are the fundamental frequencies of the second guitar string for each case? (b) By what percentage should the tension be increased for the final adjustment to make the guitar strings have identical frequencies?

55. (II) A loudspeaker (source) that emits sound waves uniformly in all directions is 10 m from a microphone (receiver). Both the source and the receiver are 20 m from a smooth, rigid wall that reflects the sound waves from the source (Fig. 15–36). As the frequency of the waves from the source is smoothly increased from zero, there is a first interference maximum detected by the receiver and subsequently a series of further maxima. List the frequencies of the three maxima that occur above 80 Hz. Assume that sound reflects from the walls as would a ball in an elastic collision.

▲ **FIGURE 15–36** Problem 55.

56. (II) Consider two wave sources on a water surface. They generate identical waves of $\lambda = 1$ cm. What possible values of the separation of the sources, d, can you take to ensure that there is no disturbance to the side of the sources (that is, on the extension of the line joining the sources)? When this happens, is there a disturbance on that same line but *between* the sources? If so, describe it; if not, explain why not. Neglect the change in amplitude as a function of distance from the source; that is, treat this as a one-dimensional problem.

57. (II) The speed of the propagation of light in different media depends on the properties of the media. The formula is given by $v = c/n$, where $c = 3.0 \times 10^8$ m/s and n is the *index of refraction* ($n > 1$ for all media). Consider light of frequency 0.50×10^{15} Hz entering from empty space, with $n = 1.00$, into glass, with $n = 1.52$. What is the wavelength of the light in empty space? What is the wavelength of the light in glass?

58. (II) Waves are generated in phase in a water tank. The waves move along the x- and y-axes, respectively, with equal amplitude, so that the total wave is given by $\psi(x, y, t) = \sin(kx - \omega t) + \sin(ky - \omega t)$. Show that the pattern of interference maxima is given by the line $x - y = 2n\pi/k$ (where $n = 0, \pm 1, \pm 2 \ldots$).

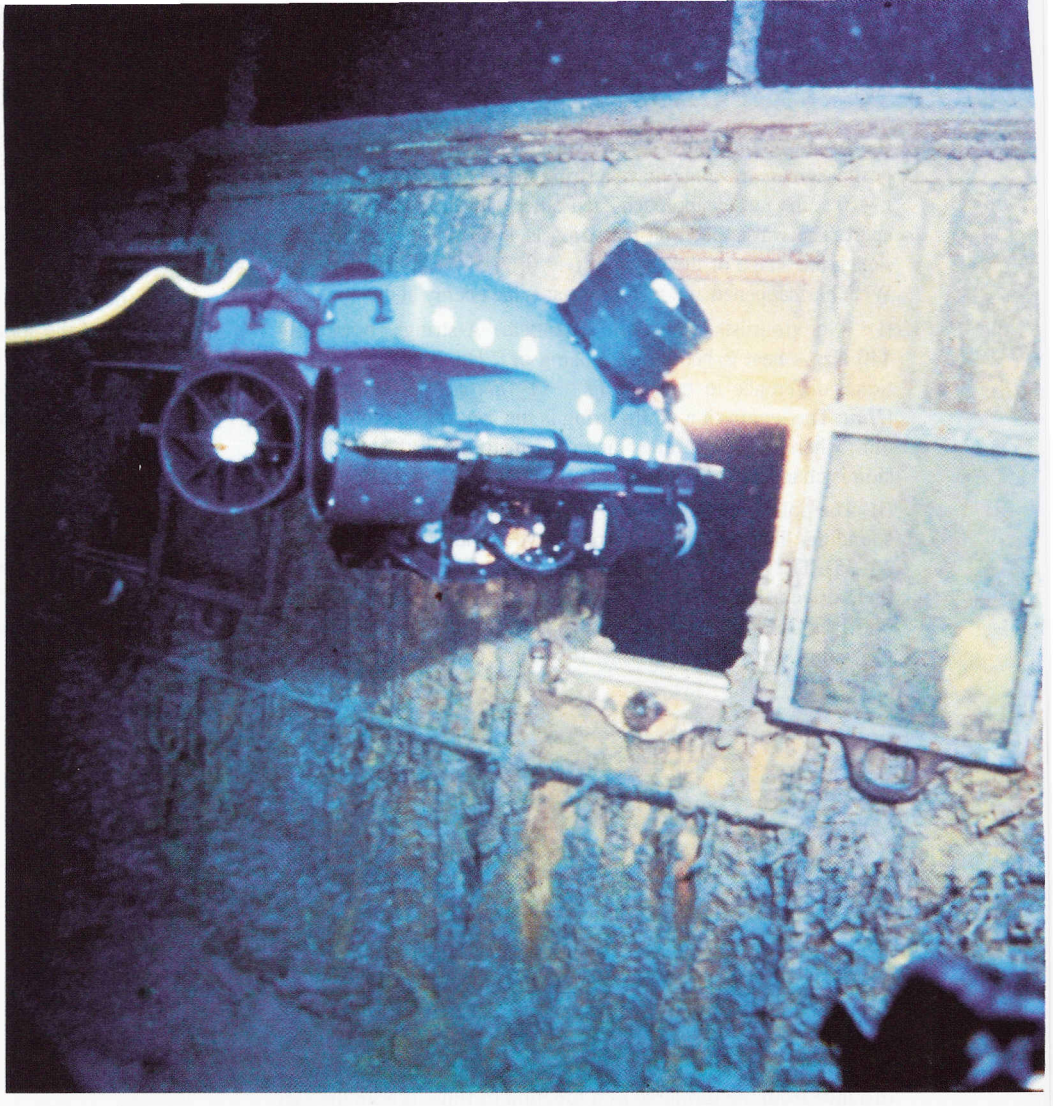
59. (II) Which of the following equations are linear? Explain your reasoning:

(a) $\dfrac{\partial^2\psi}{\partial t^2} = v^2\dfrac{\partial^2\psi}{\partial x^2}$

(b) $\dfrac{\partial\psi}{\partial t} = -K\dfrac{\partial^2\psi}{\partial x^2}$

(c) $\dfrac{\partial^2\psi}{\partial t^2} = a\psi^2 + b\dfrac{\partial\psi}{\partial x}$

(d) $\dfrac{\partial\psi}{\partial t} = 2\psi\dfrac{\partial\psi}{\partial x} + 3\psi$



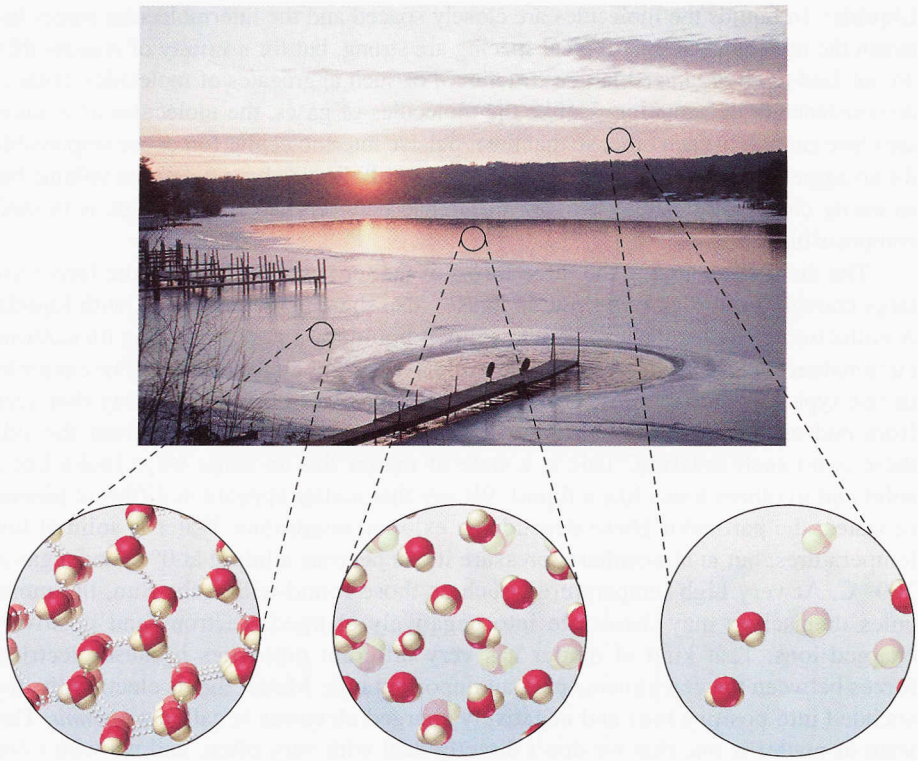
(e) $\dfrac{\partial^2\psi}{\partial t^2} = -k \ln \psi$

60. (II) Two sources emit sound coherently and in phase at a frequency of 1250 Hz with the same intensity. They are 55.0 cm apart on a horizontal surface. A circular wall of radius 220 cm (centered on the midpoint between the sources) is placed around them. Describe systematically the interference pattern of maxima and minima at the wall.

61. (III) Two waves of the form $z_1(x, t) = z_0 \sin(k_1 x - w_1 t)$ and $z_2(x, t) = z_0 \sin(k_2 x - w_2 t)$, respectively, propagate at speed v in a nondispersive medium. The frequency difference $\Delta f = f_1 - f_2$ is small. What function describes the envelope of the resulting superposition of the two waves? Express this envelope as a wave, and give its frequency and wavelength.

62. (III) Sinusoidal waves are generated on an infinitely long rope. One wave, $y_1(x, t)$, moves to the left and has amplitude y_0, wave number k_1, and angular frequency ω_1; the other, $y_2(x, t)$, moves to the right with amplitude y_0, wave number k_2, and angular frequency ω_2. Each wave has the same phase. (a) Express $y_i(x, t)$ for each of the waves. (b) Assuming that the rope is a nondispersive medium, what is ω_2 in terms of k_1, k_2, and ω_1? In parts (c) and (d), assume that $k_2 = k_1 + \delta k$ and $\omega_2 = \omega_1 + \delta\omega$. Take the speed of traveling waves on the rope to be v. (c) What is $\delta\omega$ in terms of δk and v? (d) Superpose these waves, assuming that δk and $\delta\omega$ are small. Use the notation $k_{\text{av}} = (k_1 + k_2)/2$ and $\omega_{\text{av}} = (\omega_1 + \omega_2)/2$. Show that the result of the superposition is two waves, one moving at the low speed $v_l = v\,\delta k/2k_{\text{av}}$ and wavelength $2\pi/k_{\text{av}}$, and one moving at the high speed $v_r = 2vk_{\text{av}}/\delta k$ and the long wavelength $4\pi/\delta k$.

Chapter 16

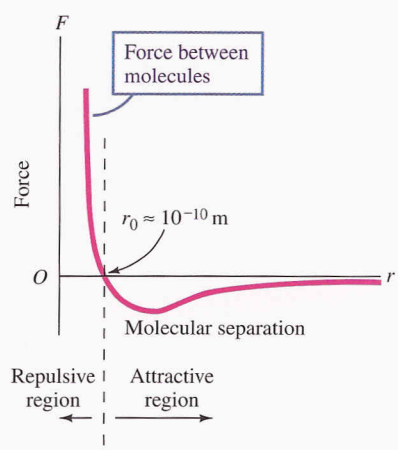


▶ The remote controlled submarine robot, *Jason Junior*, is peeking through a window of the *Titanic* in 1986 during the investigation of the sunken ship. *Jason Junior* was attached to the three-man submersible *Alvin* (which was just outside the *Titanic* at a depth of 4000 m) by a 200 foot cable and eventually entered *Titanic* and explored extensively.

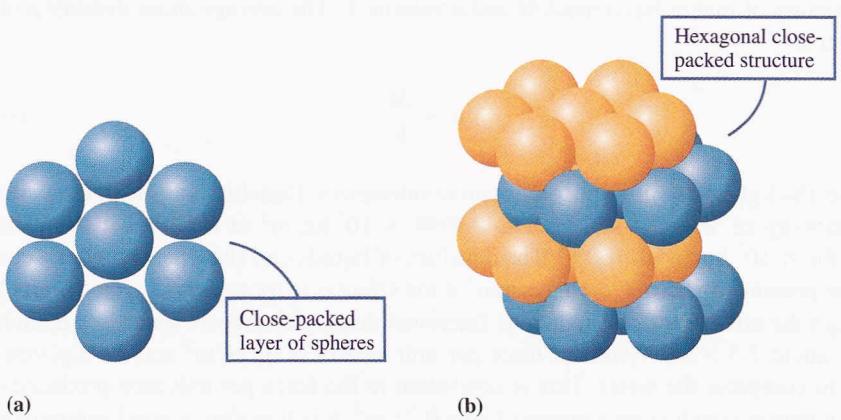
Properties of Fluids

Waves on the sea, smoke rings, and a whirlpool of water flowing down a drain are demonstrations of the wide variety of phenomena visible in fluid flow. Although fluids can support waves, as we have seen, a little observation suggests that the response of fluids to forces goes well beyond wave motion. The physical laws involved are those we have already discussed, but applied in a new, more complex setting. Our job here will be to develop descriptive and dynamical tools for handling both static fluids and fluids in motion. Conservation laws for momentum, energy, and mass will be very helpful in this task. With these tools and a series of approximations that turn out to be surprisingly useful, we can arrive at a description of the behavior of fluids that allows us to understand many interesting properties.

16–1 States of Matter



Let us start with a review of the states of matter. The particular form that matter takes, whether solid, gaseous, or liquid, is determined ultimately by the forces between its molecules, as well as conditions such as temperature (Fig. 16–1). The typical force between a pair of molecules as a function of their separation will look something like Fig. 16–2. Generally these forces are strongly repulsive at very small separations. The force becomes attractive at a separation of about 10^{-10} m and then tapers off virtually to zero at a distance of a few times 10^{-10} m. How does this information allow us to understand the three states of matter?



◀ **FIGURE 16–1** The three states of matter, which for water are ice, liquid water, and water vapor, are very different on the macroscopic scale. These differences are reflections of differences on the microscopic scale. In solids, the molecules are arranged in ordered arrays called crystals. In liquids, the spacing of the molecules is not very different than in solids, but the order of the lattice is lost. The molecules are close enough together in each case that intermolecular forces are important. In gases the molecules are so widely spaced that their interactions come into play only very briefly in collisions.

Gases: If molecules are, on average, sufficiently far apart, then the forces between them are small. In effect, their only interaction occurs when the molecules occasionally collide with each other. The molecules behave as a **gas**. We will study gases further in Chapters 17 through 20 and only note here that gases are easily compressed and that the shape of a body of gas is easily deformed.

Solids: If molecules are sufficiently close together that the forces due to neighboring molecules are significant, matter behaves in a way that depends on the detailed properties of the intermolecular forces. In some cases the forces act to organize the molecules into a **lattice**, which is a regularly repeating three-dimensional structure in which the molecules or atoms can move only by small displacements (Fig. 16–3). This is a typical **solid**: a substance whose structure resists forces that would deform its shape. We described the lattice structure as well as some properties of solids in Chapter 11.

▲ **FIGURE 16–2** Qualitative behavior of the force between a pair of molecules as a function of their separation, r. Near $r = r_0$, the point at which the force is zero, the force is springlike (restoring). For $r < r_0$, the force is strongly repulsive; for $r > r_0$, it is attractive.

▲ **FIGURE 16–3** A lattice structure characteristic of solids. Here we show a hexagonal close-packed structure in which (a) one layer is fit together and (b) the layer above is nested into the depressions in the first layer. The forces between the molecules are springlike for small displacements from the equilibrium positions.

Liquids: In liquids the molecules are closely spaced and the intermolecular forces between the molecules at their typical spacing are strong, but for a variety of reasons they do not lead to an organized lattice structure. For such aggregates of molecules, there is no resistance to deformation. Unlike the molecules of gases, the molecules of a liquid are close enough to each other so that the repulsive intermolecular forces are responsible for an aggregate that resists compression. As a result, liquids have a definite volume but an easily changeable shape. A major difference between gases and liquids is in their compressibility.

The distinction among the three forms of matter is not absolute. If the forces are large enough, even rock will flow, and gases also share many properties with liquids. A collection of molecules can form a solid, a liquid, or a gas, depending on external circumstances. Still other states are possible in the right circumstances. For example, in one type of *liquid crystal* rod-shaped molecules line up in such a way that seen from end on they are ordered like a crystalline solid, whereas seen from the side there is no such ordering. This is a state of matter that in some ways looks like a solid and in others looks like a liquid. We say that matter appears in different **phases** or states; the particular phase depends on external conditions. Water is solid at low temperatures, but at atmospheric pressure it can become a liquid at 0° C and a gas at 100° C. At very high temperatures, such as those found within the Sun, the molecules themselves may dissociate into negatively charged electrons and positively charged ions. That kind of matter has very different properties because electrical forces between the constituents play an important role. Matter that is electrically dissociated into positive ions and negatively charged electrons is called a *plasma*. This state of matter is one that we don't directly deal with very often, and we won't discuss it further.

We shall define a **fluid** to be a substance that is not resistant to the action of shear forces (see Section 11–4). Essentially a fluid undergoes deformation without elastic forces to bring it back to its original shape. This description involves how a material responds to external forces and applies to both liquids and gases. Therefore, except for phenomena in which compressibility is important, our description of the behavior of fluids *applies to gases as well as to liquids*.

16–2 Density and Pressure

We start our study of fluids with **hydrostatics**—the study of fluids at rest. Density and pressure are the two important variables for such fluids, and in this section we'll look at them in some detail.

Density

A quantity of matter has a mass M and a volume V. The average **mass density** ρ of the matter is

$$\rho = \frac{M}{V}. \tag{16–1}$$

Table 16–1 gives densities of some typical substances. Densities vary with temperature; the density of water at sea level is $0.9998 \times 10^3\ \text{kg/m}^3$ at 0°C, but it decreases to $0.9584 \times 10^3\ \text{kg/m}^3$ at 100°C. The densities of liquids can also change under a change of the pressure on them ("compression" if the effect is to try to decrease the volume), although the effect is often small. The fractional density change of water in a cylinder is only about 1.5×10^{-8} when a force per unit area of $3000\ \text{N/m}^2$ acts on a piston that acts to compress the water. This is equivalent to the force per unit area produced by a 75-kg person standing on a piston of area $0.25\ \text{m}^2$. It is therefore a good approximation to treat water as **incompressible**. Finally, we can define the **specific gravity** of a substance as the ratio of the mass density of that substance to the mass density of water; thus, for example, the specific gravity of glycerin is 1.26.

TABLE 16–1 • Mass Densities

Material	Phase	Density (kg/m^3)	Material	Phase	Density (kg/m^3)
Hydrogen (0°C, 1 atm)	Gas	0.090	Liquid mercury	Liquid	13.6×10^3
Air at sea level	Gas	1.29	Sun's core	Plasma	1.6×10^5
Chlorine (0°C, 1 atm)	Gas	3.21	Cork	Solid	0.25×10^3
Ethyl alcohol	Liquid	0.79×10^3	Applewood	Solid	0.745×10^3
A good olive oil	Liquid	0.92×10^3	Ice	Solid	0.917×10^3
Water	Liquid	1.00×10^3	Quartz	Solid	2.65×10^3
Glycerin	Liquid	1.26×10^3	Steel alloys	Solid	7.6×10^3–8.9×10^3
Earth's core	Liquid	9.5×10^3	Iridium	Solid	22.4×10^3

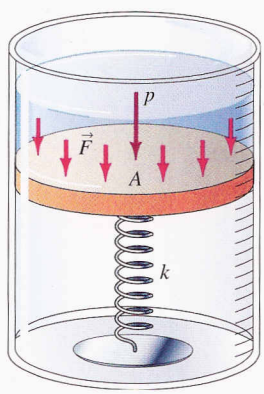
EXAMPLE 16–1 A neutron star is a star that is much smaller than our Sun and has the density of an atomic nucleus. A typical neutron star has a radius of 10 km, but a mass of 2×10^{30} kg (the mass of the Sun). How much would a 1 cm^3 volume of such a star weigh under the influence of Earth's gravity?

Strategy We use the given radius R to find the volume V, which together with the given mass M allows us to find the density. For the weight of 1-cm^3 of a neutron star on Earth's surface, we use the density we have calculated to find the mass of this volume and hence the weight.

Working It Out The density is

$$\rho = \frac{M}{V} = \frac{M}{4\pi R^3/3} = \frac{2 \times 10^{30}\ \text{kg}}{4\pi(10^4\ \text{m})^3/3} = 0.5 \times 10^{18}\ \text{kg/m}^3$$
$$= 0.5 \times 10^{12}\ \text{kg/cm}^3.$$

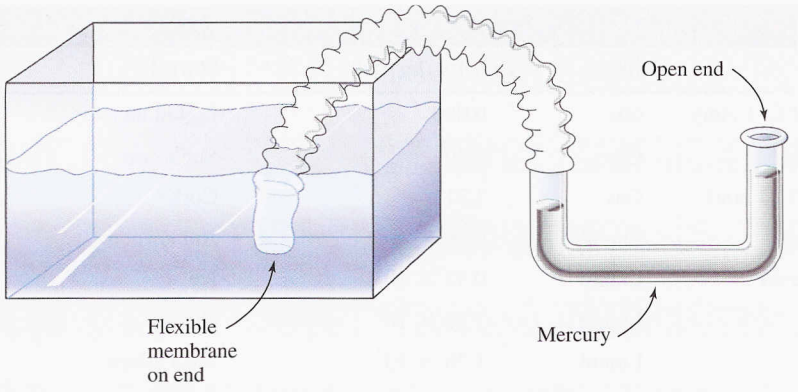
Thus a volume $V_{\text{cube}} = 1\ \text{cm}^3\ (10^{-6}\ \text{m}^3)$ of the material of a neutron star has a mass $m = \rho V_{\text{cube}} = 0.5 \times 10^{12}$ kg, and it weighs $mg = (0.5 \times 10^{12}\ \text{kg})g = (0.5 \times 10^{12}\ \text{kg})(9.8\ \text{m/s}^2) = 0.5 \times 10^{13}$ N. For comparison, 1 cm^3 of water on Earth's surface has a mass of 1 g and weighs 0.01 N. A neutron star is incredibly dense!



What Do You Think? If the radius of a solid sphere doubles, and its mass also doubles, then is the density (a) less than (b) unchanged from (c) greater than the original density? *Answers to **What Do You Think?** questions are given in the back of the book.*

Pressure

Pressure is a measure of the force acting on the surface of an object within a fluid, even a fluid at rest. Swimmers know from experience that liquids do exert such forces. If you dive into deep water, your eardrum may hurt or even rupture due to the pressure of the water on it. Why then doesn't a sheet of glass placed under water shatter? It is because there is as much pressure on one side of it as on the other, and indeed it is a characteristic of the pressure in a static fluid that it acts upon every surface, perpendicular to the surface.



As we see more precisely below, the pressure is defined as the force per unit area. We can in principle determine the force exerted by a fluid by using the spring-balance system shown in Fig. 16–4. The plate on the spring balance is in contact with the fluid, while the spring attached to the other side of the plate is inside an enclosure where there is a vacuum, so that there is no force on the plate from the inside due to any pressure. Only the spring force resists the pressure from the fluid, and the force from the fluid is therefore measured by observing the compression of the spring. Our device would allow us to define the average pressure p on any surface of area A as the *force per unit area* acting perpendicular to that surface:

$$p \equiv \frac{F}{A}. \tag{16–2}$$

▲ **FIGURE 16–4** A device that would allow the measurement of pressure in a liquid. The fit between the piston and cylinder walls allows the piston to move but is tight enough so that a near vacuum can be maintained on the side with the spring. The compression of the spring provides a measurement of the force, from which the pressure is determined.

The device described above is not a very realistic one. The **manometer** shown in Fig. 16–5 is a realistic way to do the measurement. As we shall see later in this chapter, the difference in the mercury levels in the two sides of the U-shape is sensitive to the pressure in the fluid compared to the pressure in the atmosphere. With such an instrument one could see how pressure varies with position, and since it does vary, a more precise local definition of the pressure is in order. We consider a small area ΔA located at point

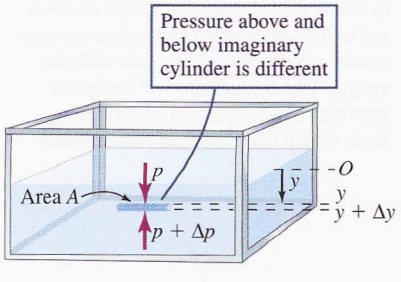
▶ **FIGURE 16–5** A more realistic device to measure pressure. The end of the tube is covered by a flexible membrane that is pushed inward if the pressure in the fluid increases. This pushes the column of mercury higher on the right side of the U-shaped tube than on the left side.

$\vec{r}$, and take the limit $\Delta A \to 0$. If we denote the force perpendicular to this area as ΔF, we find

$$p = \lim_{\Delta A \to 0} \frac{\Delta F}{\Delta A} = \frac{dF}{dA}. \tag{16–3}$$

PRESSURE

This is the pressure at point $\vec{r}$. Pressure is measured in SI units as *pascals* (Pa), named after Blaise Pascal, who studied pressure in the mid-seventeenth century:



$$1 \text{ Pa} = 1 \text{ N/m}^2. \tag{16–4}$$

Other common units for pressure are pounds per square inch (lb/in^2): $1 \text{ lb/in}^2 = 6.9 \times 10^3$ Pa; the atmosphere (atm), which is the atmospheric pressure at sea level: $1 \text{ atm} = 1.01 \times 10^5$ Pa $= 14.7 \text{ lb/in}^2$; the bar: $1 \text{ bar} = 10^5$ Pa; and the torr: $1 \text{ torr} = 133.32$ Pa.

If you took your manometer and moved the membrane about, you would discover two important facts about pressure in static fluids: First, pressure varies only with depth, increasing as one goes deeper. As we shall explain in the next section, this is a consequence of the presence of gravity. Second, you would learn that *when a fluid is at rest, the pressure at any given point must be the same in all directions.* The microscopic origin of pressure is the bombardment of the surface on which the pressure acts by the individual molecules of the substance (Chapter 19). The pressure is the same in all directions because there is no preferred direction for the random motion of molecules. For fluids at rest, the pressure is then simply a positive scalar quantity. Note also that the pressure at a static interface between two fluids, say a layer of oil on water, is the same on both sides of the interface; if it were not, there would be a net force at the interface and a resulting motion of the interface.

16–3 Pressure in a Fluid at Rest

The gravitational force causes the pressure of fluids at rest to be larger at ocean depths than at Earth's surface. In order to establish exactly how pressure varies with depth for an incompressible fluid, consider a liquid of fixed density ρ at rest in a container. Imagine isolating a very thin cylinder of that liquid (Fig. 16–6). (The top, base, and walls of the cylinder are purely imaginary; their sole purpose is to help us visualize the forces acting on an element of the fluid.) The cylinder's top, of area A, is horizontal and lies a distance y below the surface of the liquid. The bottom of the cylinder is at a depth $y + \Delta y$. Note that we measure the depth y downward from the surface, so it increases as we go down. We denote the pressure at the top of our cylinder by p and the pressure at the bottom by $p + \Delta p$. We want to find an expression for Δp.

▲ **FIGURE 16–6** An imaginary thin cylinder of fluid is isolated to show the forces that act to keep it in equilibrium.

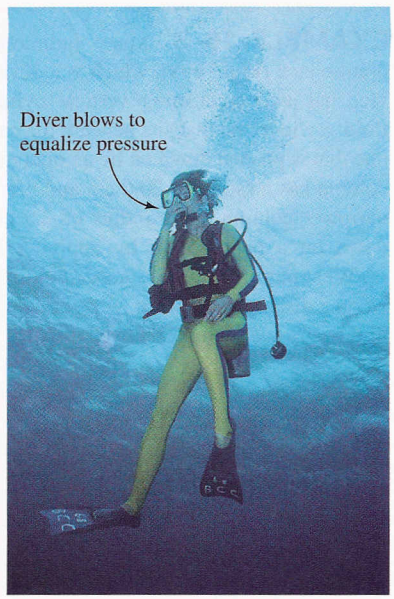
The downward force on the cylinder, which is applied at the top surface by pressure from the surrounding fluid, is pA; the upward force, which is applied at the bottom surface by the pressure there, is $(p + \Delta p)A$. Additionally, there is a downward force on the cylinder due to gravity; namely, the weight of the liquid inside the cylinder. That

force has a magnitude of $(\Delta m)g$, and the mass of the cylinder Δm is the density times the volume of the cylinder. Thus, the downward force of gravity is $\rho(A\Delta y)g$. All together, we find

$$F_{\text{up}} = (p + \Delta p)A,$$
$$F_{\text{down}} = pA + (\Delta m)g = pA + \rho(A\Delta y)g.$$

Because the cylinder does not accelerate, the net force must cancel:

$$F_{\text{net}} = F_{\text{up}} - F_{\text{down}} = (p + \Delta p)A - pA - \rho(A\Delta y)g = 0.$$



We cancel the pA terms, divide by A, and rearrange terms to find that

$$\frac{\Delta p}{\Delta y} = \rho g.$$

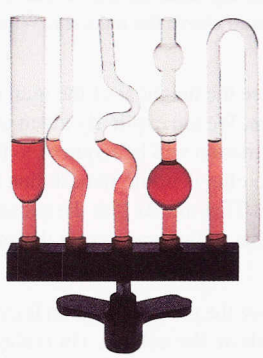
In the limit $\Delta y \rightarrow 0$, this result becomes

$$\frac{dp}{dy} = \rho g. \tag{16–5}$$

According to Eq. (16–5), the pressure change is positive for positive Δy. Pressure therefore increases with increasing depth (Fig. 16–7). In physical terms this phenomenon is a measure of the increased amount, and hence increased weight, of the liquid above any given point as the depth of the point increases. There is a greater weight of water above a diver at an ocean depth of 50 m than above a diver at a depth of 10 m.

▲ **FIGURE 16–7** Divers experience the increased pressure of increased water depth. To equalize the pressures of the surrounding water and the sinus cavities, a diver blows air into his or her sinuses.

Equation (16–5) looks just like the formula for the constant acceleration g of an object acted on by the constant force of gravity, $dv/dt = g$. When we studied projectile motion in Chapters 2 and 3, we saw that this equation has a solution $v = v_0 + gt$. If the fluid is incompressible (as water is, but gases are generally not), then the density does not depend on the depth y, and we can directly compare to write the solution to Eq. (16–5), which gives the pressure as a function of depth:

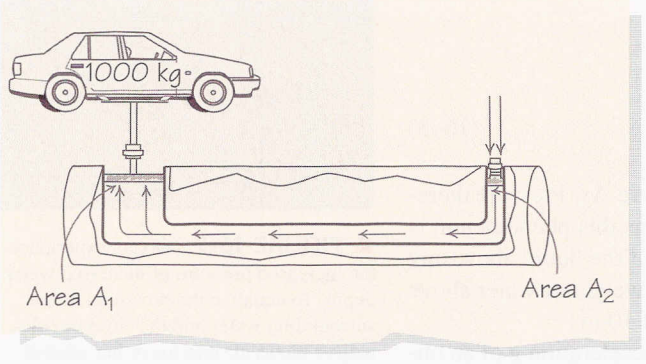


$$p = p_0 + \rho g y. \tag{16–6}$$

Alternatively, we can integrate Eq. (16–5) to find this result. The constant p_0 is the value of the pressure at the surface, where $y = 0$; for a body of fluid such as the ocean, this is just atmospheric pressure. The pressure increase with depth y is equal to the weight per unit area of the overlying fluid. The total mass of the fluid above the cylinder is $\rho V = \rho A y$, so its weight is $\rho A y g$, and thus the weight per unit area is $\rho y g$.

The variation of atmospheric pressure with depth (from the top of the atmosphere) is not at all like that of water, Eq. (16–6). The difference is that gases are compressible, and this changes the form of the equation obeyed by the pressure, and with it its variation with depth. The atmospheric pressure will be treated in Chapter 19.

CONCEPTUAL EXAMPLE 16–2 Look at Fig. 16–8: the level of the liquid in all the connected vessels is the same. Why?



Answer The derivation that led us to Eq. (16–6) is completely independent of the horizontal location of the imaginary cylinder in the water tank of Fig. 16–6. Equation (16–6) itself shows that the pressure in a fluid depends *only* on the depth—not the horizontal position. In our series of vessels the pressures at the fluid surfaces are all equal to atmospheric pressure (the surface is in contact with the atmosphere and is therefore at the same pressure). According to Eq. (16–6), a given pressure corresponds to a given height, and so the level of the top of the fluid will be the same for each vessel.

◀ **FIGURE 16–8** The surface pressure is equal in each individual vessel.

We can see from Eq. (16–6) that if p_0 is changed as a result of some external effect, p is changed by exactly the same amount. In other words, *a change in pressure applied to any point in a fluid at rest results in the same pressure change at every point in the fluid.* This statement is commonly known as **Pascal's principle**.

EXAMPLE 16–3 Many automobile repair shops have a hydraulic jack (Fig. 16–9), which is a device used to lift cars. This device has two connecting vertical cylindrical columns filled with fluid, a wider one that sits beneath the car to be lifted and a narrower one that is pushed down on by an operator. In this problem the wider column has a radius of 20.0 cm and lifts a car of mass 1000 kg. The narrower column has a radius of 2.5 cm, and the operator pushes down on a piston in it by applying air pressure from a pump. (a) What pump pressure is needed to lift the car? (b) If the car is lifted up a distance of 2.00 m, what downward distance must the piston in the narrower cylinder move?

▲ **FIGURE 16–9** A schematic view of the hydraulic lift used in garages.

Setting It Up Figure 16–9 labels two of the variables with which we are going to deal, both given, the areas A_1 and A_2 of the wider and narrower columns, respectively. We denote as d_1 the given vertical distance that the car, mass m, moves. We are going to find the pump pressure p that will allow the car to be raised and the distance d_2 that the piston in the narrow cylinder must move.

Strategy (a) We can lift the car with an upward force of magnitude mg; this has to be supplied by the fluid pressure p, and since this pressure acts over an area A_1, the upward force is pA_1. That will determine what p has to be. (This pressure is in addition to the pressure that is already present and allows the car to remain stationary.) By Pascal's principle this additional pressure p can be applied at the narrower cylinder—at the pump—and it will be transmitted throughout the fluid. (b) There are various ways to approach this part. In one method we note that the car has acquired a potential energy mgd_1 in being raised. According to the work–energy theorem, this energy must come from the work done at the narrower tube. If the force acting at the narrower tube is $F_2 = pA_2$, the work done is d_2F_2. We match this to the energy gain of the car to give us an equation for d_2. In another method, we use the fact that the fluid is incompressible, so the same volume of fluid d_1A_1 that has been added to the wide cylinder must come from the smaller cylinder. Since the volume in the smaller cylinder is d_2A_2, equating d_2A_2 to d_1A_1 gives us an equation for d_2. We'll use the second method, which is very simple.

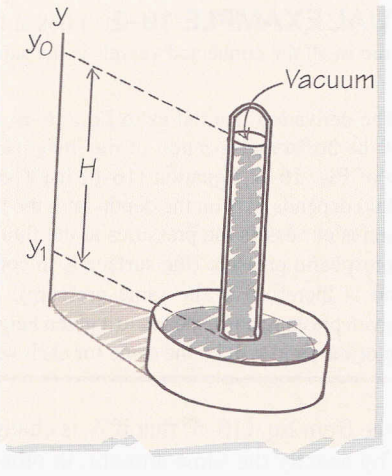
Working It Out We have $pA_1 = mg$, or $p = mg/A_1$. In terms of the given radius $R_1 = 0.20$ m of the wider tube,

$$p = \frac{mg}{\pi R_1^2} = \frac{(1000\text{ kg})(9.8\text{ m/s}^2)}{\pi(0.20\text{ m})^2} = 7.8 \times 10^4\text{ Pa}.$$

This is the necessary pump pressure, a number 80% of the ambient atmospheric pressure. (The ambient pressure alone cannot lift the car as it acts downward on the topmost surfaces of the car and upward on the bottom surfaces, and so forth, and the net force from the ambient pressure is zero. The pump pressure here is really an additional pressure, and it acts in one particular direction because of the orientation of the plate that supports the car.)

(b) We set $d_2A_2 = d_1A_1$ and solve for d_2:

$$d_2 = \frac{A_1}{A_2}d_1 = \frac{\pi R_1^2}{\pi R_2^2}d_1 = \frac{(20.0\text{ cm})^2}{(2.5\text{ cm})^2}(2.0\text{ m})$$
$$= 8^2 \times (2.0\text{ m}) = 1.3 \times 10^2\text{ m}.$$



In the narrower tube there will be some sort of ratcheting mechanism which allows the vertical motion to be carried out in many strokes. Many air pumps have such mechanisms.

What Do You Think? Why do bicycle and car tires have such thin valves?

EXAMPLE 16–4 A column of mercury ($\rho_{Hg} = 13.6 \times 10^3$ kg/m^3) in a vertical tube that is open at the bottom rests in an open pool of mercury. The column is sealed off at the top after all the air has been evacuated from the tube, creating a vacuum above the mercury. What is the height of the column of mercury?

Setting It Up In Fig. 16–10 we see the height H of the mercury column that is asked for in this problem. We are explicitly given only the density of mercury, and more information will be required to find the height of the mercury column. The clue is in the remark that the pool of mercury is open at the bottom. That means that the pressure of the atmosphere acts on it, and so that is the pressure in the mercury at the level of the pool.

Strategy The fact that the tube above the mercury column is evacuated means that there is no pressure above the column. (In reality, a little mercury will have evaporated, but the pressure that it exerts is negligible.) However, the surface of the open pool, and therefore in the interior of the column at the same height, is that of the atmosphere—call this pressure p_0. If the mercury column has a cross section A, then there is an upward force at the bottom, p_0A, that counteracts the weight of the mercury in the column, mg. We can express the mass m of mercury in the column as the density of mercury times the column volume V, and $V = HA$. In this way, H is determined.

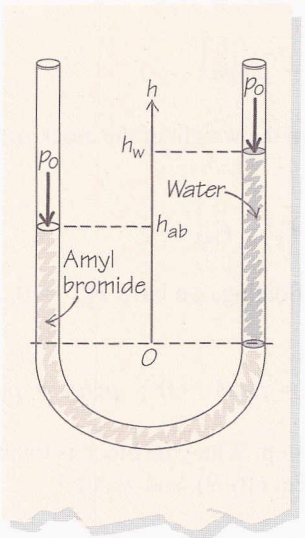
▲ **FIGURE 16–10** A column of mercury balanced by atmospheric pressure.

Working It Out The expression for the balancing of the forces is $p_0A = mg$. But the volume of the column of mercury is $V = HA$, hence the mass is $m = \rho_{Hg}V = \rho_{Hg}HA$, and we have

$$p_0A = \rho_{Hg}HAg.$$

The area cancels from both sides. We solve the remaining equation for H:

$$H = \frac{p_0}{\rho_{Hg}g}.$$



Numerically,

$$H = \frac{1.01 \times 10^5\ \text{Pa}}{(13.6 \times 10^3\ \text{kg/m}^3)(9.8\ \text{m/s}^2)} = 0.76\ \text{m}.$$

This example describes the working principle of a **barometer**, a device used to measure atmospheric pressure. One atmosphere of pressure will support a column of mercury that is 760 mm high.

What Do You Think? What would the height of the mercury column be if the vacuum at the top of the tube were instead a fraction of 1 atm?

EXAMPLE 16–5 A U-shaped tube of uniform cross section is open at both ends. First, amyl bromide is poured into the tube. (Amyl bromide is a fluid that does not mix with water.) Then water is carefully added to one side of the U, so there is water at the top of one column of fluid and amyl bromide is at the top of the other. The two columns of fluid meet at a point that we label $h = 0$, as in Fig. 16–11. What is the ratio of the heights of the fluids above $h = 0$ in each column? The density of water is $\rho_W = 1.00 \times 10^3\ \text{kg/m}^3$ and that of amyl bromide is $\rho_{ab} = 1.26 \times 10^3\ \text{kg/m}^3$.

▲ FIGURE 16–11

Strategy The atmospheric pressure p_0 is the same at the open surface of both columns (we neglect the weight of any amount of air that adds to the pressure over the lower column; air pressure changes very slowly with height). The pressure in the two fluids at $h = 0$, where they meet, is equal—otherwise there would be movement. We can write the expression for the pressure in each fluid at this point and set them equal, and from this we can determine the height ratios.

Working It Out We measure heights from the point where the fluids meet and denote h_{ab} as the height of the amyl bromide column and h_w as the height of the water column. The pressures p_{ab} and p_w at $h = 0$ in the respective columns is the air pressure at the top plus the pressure due to the weight of the fluid above,

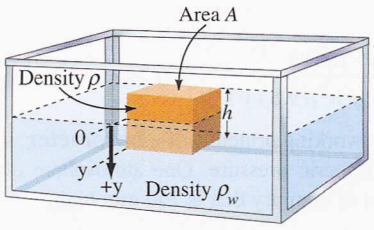
$$\text{for the amyl bromide, } p_{ab} = p_0 + \rho_{ab}h_{ab}g;$$
$$\text{for the water, } p_w = p_0 + \rho_w h_w g.$$

Setting these pressures equal to one another, we have

$$\rho_{ab}h_{ab}g = \rho_W h_W g.$$

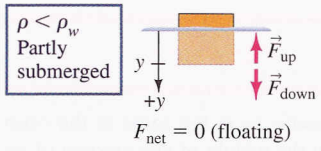
We rearrange this equation to find

$$\frac{h_{ab}}{h_W} = \frac{\rho_W}{\rho_{ab}} = \frac{1.00 \times 10^3\ \text{kg/m}^3}{1.26 \times 10^3\ \text{kg/m}^3} = 0.794.$$



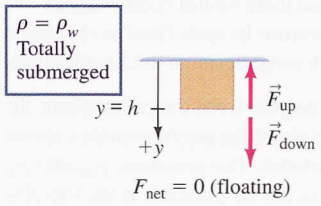
The water column is higher than the amyl bromide column. This makes sense physically because amyl bromide is denser than water; the shorter column of amyl bromide weighs the same as the taller column of water. Note that this result is independent of the amount of either fluid.

What Do You Think? What would happen if we used heptyl ether, another fluid that does not mix with water and has a mass density of $0.81 \times 10^3\ \text{kg/m}^3$?

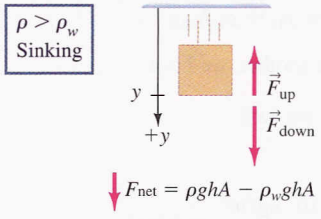


16–4 Buoyancy and Archimedes' Principle

A cork floats in water while a brick sinks. Why? Experience tells us that this has something to do with the density of the material (and not the mass; a small brick sinks just like a large one). Let's consider the situation in Fig. 16–12a, a block of material of volume $V = Ah$ and density ρ (the mass is thus $m = \rho V$) partly immersed in water, which has a density of ρ_W. What forces do you think are acting on the block in this equilibrium position? In particular, focus on the lower surface of the partly submerged block, as in Figure 16–12b. The upward force is due to the pressure of the liquid, as given by Eq. (16–6): $p = p_0 + \rho_W gy$, where y is the vertical submerged distance of the block. The upward force on the block is therefore



$$F_{up} = pA = p_0A + \rho_W gyA.$$



(a)

(b)

(c)

(d)

▲ **FIGURE 16–12** (a) A block of material of density ρ is partly immersed in water, density ρ_w. The volume of the block is $V = Ah$, and the volume of water displaced by the block is $V_d = Ay$. (b) Force diagram of the forces acting on the lower surface of the block, which is partly immersed, as in part (a). The net force is $F_{net} = 0$, and the block floats. (c) When $\rho = \rho_w$, the block is totally submerged, and the block floats because $F_{net} = 0$. (d) When $\rho > \rho_w$, the block sinks because $F_{net} > 0$.

The downward force has two components: that due to the atmospheric pressure p_0 above the block, and the weight of the block. The first downward component is $F_{atm} = p_0 A$, and the second is the force of gravity on the block, $F_g = mg = (\rho Ah)g$. Thus the total downward force is

$$F_{down} = p_0 A + \rho ghA.$$

As the block is in equilibrium—floating but not moving—the net force will be zero. Therefore,

$$F_{net} = 0 = F_{down} - F_{up} = p_0 A + \rho ghA - p_0 A - \rho_W gyA = \rho ghA - \rho_W gyA. \tag{16–7}$$

Dividing by gA, we obtain

$$\text{for a floating object: } \rho h = \rho_W y;$$

$$\frac{\rho}{\rho_w} = \frac{y}{h}. \tag{16–8}$$

If $\rho < \rho_W$, then $y/h < 1$ and only a fraction of the block is submerged. In the limiting case that $\rho = \rho_W$, the block is totally submerged and $y = h$ (Fig. 16–12c). In this case, the block would float just under the surface because the upward and downward forces cancel. If $\rho > \rho_W$, then the block must sink (Fig. 16–12d) because the two forces can no longer cancel completely. In this case, once the block is fully submerged ($y \geq h$), the net (downward) force is

$$F_{net} = \rho ghA - \rho_W ghA > 0. \tag{16–9}$$

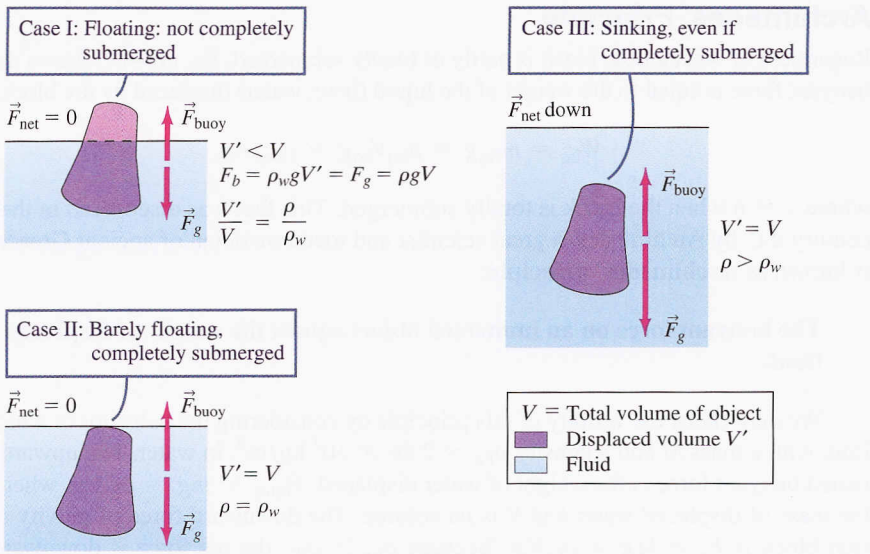
We can interpret the difference between the weight of the block ρghA and F_{net} as an *upward* **buoyant force**:

$$F_{buoy} = F_g - F_{net}. \tag{16–10}$$

When the block is partly submerged and floating, we have $F_{net} = 0$, and Eq. (16–10) gives

$$\text{for partial submergence: } F_{buoy} = \rho ghA - 0 = \rho ghA = \rho_W gyA,$$

where we have used Eq. (16–8) in the last step. When the block is totally submerged (at any depth where $y \geq h$), F_{net} is given by Eq. (16–9), and we find



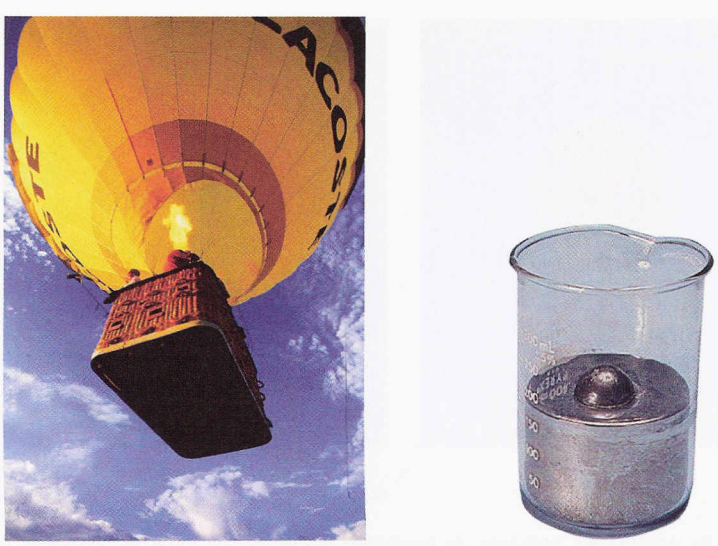
$$\text{for total submergence: } F_{buoy} = \rho ghA - (\rho ghA - \rho_W ghA) = \rho_W ghA.$$

If we think of $V_{submerged}$ as the volume of the object beneath the water ($V_{submerged} = yA$ or hA, according to whether the object is partly or totally submerged), then we can combine our results into the single expression (Fig. 16–13)

$$F_{buoy} = \rho_W g V_{submerged}. \tag{16–11}$$

THE BUOYANT FORCE

The buoyant force opposes the downwardly directed force of gravity, ρghA, on the block. For a floating body, the buoyant force and the force of gravity cancel exactly. When $\rho > \rho_W$, the buoyant force opposes the force of gravity even though it does not cancel the force of gravity completely; a sinking object descends with less acceleration than it would under the influence of gravity alone. When a metal sphere is immersed in



▲ **FIGURE 16–13** By comparing the buoyant force F_{buoy} to the force of gravity F_g, we determine whether a body sinks, just floats, or pops up.

a bucket of water and suspended from a spring balance, the balance will indicate a lower weight than it would for the same sphere in air. The difference in these weights is the buoyant force.

CONCEPTUAL EXAMPLE 16–6 Think about the hot-air balloon in Fig. 16–14a and the steel ball floating in mercury in Fig. 16–14b. Explain both phenomena.

Answer Above we saw that if a material is less dense than the medium in which it is is submerged, the (upward) buoyant force on it exceeds the force of gravity acting downward. The object will float or, if completely submerged, it will rise. This describes the hot-air balloon: Hot air is less dense than cooler air, and the balloon is completely submerged in the cooler air, so the net force on the balloon is upward. More precisely, we can use Eq. (16–7) with $h = y$, ρ_w replaced by the density of cool air and ρ equal to the density of hot air (very nearly the density of the entire balloon). The net upward force is thus $F_{net} = Vg(\rho_{cool} - \rho_{hot})$.

The steel ball is in a situation like that of Fig. 16–13a, floating on the surface of a medium denser than it is. Perhaps that seems odd because we think of steel as being quite dense. That is true, but mercury is a liquid of extraordinarily high density. The steel ball floats easily because its density, 7.8 g/cm^3, is less than that of mercury, 13.6 g/cm^3.

(a)

(b)

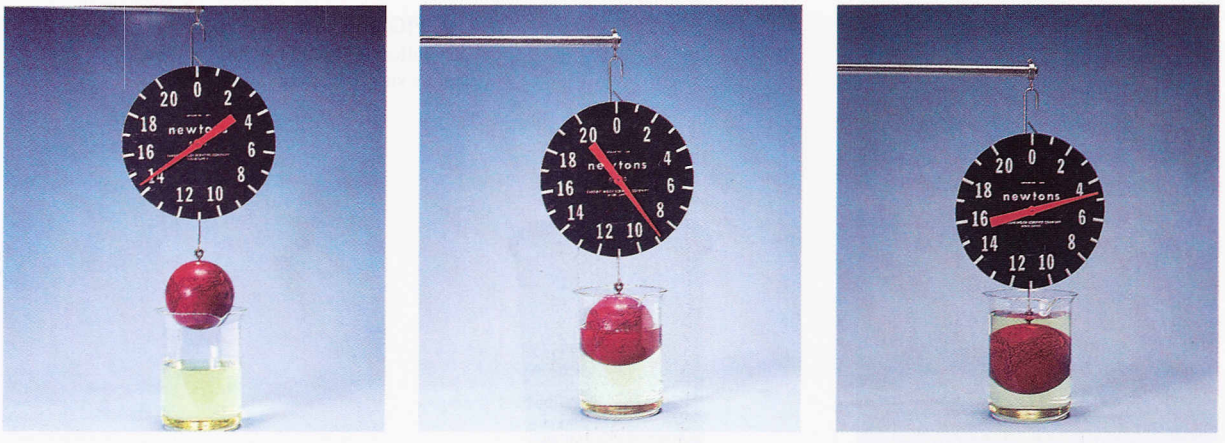
◀ **FIGURE 16–14** (a) A hot air ballon is floating in air. (b) The heavy steel ball floats in mercury.

Archimedes' Principle

Regardless of whether the block is partly or totally submerged, Eq. (16–11) shows that the buoyant force is equal to the weight of the liquid (here, water) displaced by the block:

$$W_{\text{liq}} = m_{\text{liq}}g = \rho_{\text{liq}}V_{\text{liq}}g = \rho_{\text{liq}}yAg,$$

where $y = h$ when the block is totally submerged. This fact was discovered in the third century B.C. by Archimedes, a great scientist and mathematician of ancient Greece, and is known as **Archimedes' principle**:



> **The buoyant force on an immersed object equals the weight of displaced fluid.**

We may check the validity of this principle by considering the behavior of a block of iron, with a mass M and a density $\rho_{\text{Fe}} = 7.86 \times 10^3\ \text{kg/m}^3$, in water. The upwardly directed buoyant force is the weight of water displaced, $F_{\text{buoy}} = mg = \rho_W Vg$, where m is the mass of displaced water and V is its volume. The downward force of gravity on the iron block is $F_g = Mg = \rho_{\text{Fe}}Vg$. Because $\rho_{\text{Fe}} > \rho_W$, the net force is downward and the block sinks. The net downward force—effectively the weight of iron in water—is

$$F_{\text{net}} = F_g - F_{\text{buoy}} = \rho_{\text{Fe}}Vg - \rho_W Vg = \left(1 - \frac{\rho_W}{\rho_{\text{Fe}}}\right)\rho_{\text{Fe}}Vg$$
$$= \left(1 - \frac{\rho_W}{\rho_{\text{Fe}}}\right)F_g. \qquad (16\text{–}12)$$

We can check the magnitude of the net force, and verify Archimedes' principle, by weighing an object in water (Fig. 16–15). Archimedes is said to have discovered this technique when he was asked to ascertain that a crown was made entirely of gold without marring the crown; he did this by weighing the crown in air and in water, thereby measuring its density [Eq. (16–12)]. It is said that he found the density of the crown to be less than that of gold, so that the gold in the crown must have been diluted with another metal.

The crown's owner would have not been very happy if Archimedes had been required to melt the crown down and recast it as a rectangular block to make his test! Although our calculations for buoyancy and Archimedes' principle were carried out for a uniform rectangular block, the results do not depend on the shape or the unifor-

(a) (b) (c)

▲ **FIGURE 16–15** By Archimedes' principle, the magnitude of the buoyant force on the sphere, F_{buoy}, equals the weight of the water the sphere displaces. The scale measures the difference of the magnitudes of the force of gravity on the sphere and the buoyant force on it. (a) No water is displaced; the scale measures the weight of the sphere. (b) Half the volume of the sphere is displaced. (c) The entire volume of the sphere is displaced. The buoyant force in this case is about 10 N.

mity. An object of any shape can be thought of as being composed of small rectangular blocks. Similarly, an object of varying density can be treated as a collection of many elements, each of constant density. The end result is that all that matters is the weight of the liquid that is displaced by the object.

EXAMPLE 16–7 A metal sphere weighs 29.4 N in air and 18.5 N in water. What is its average density?

Setting It Up In contrast to the situation of Fig. 16–14, the sphere sinks. When its weight is measured while it is beneath the surface of the water, there is a nonzero reading (Fig. 16–15c). We label the weight of the metal sphere in air $F_g = mg$ and in water W_w.

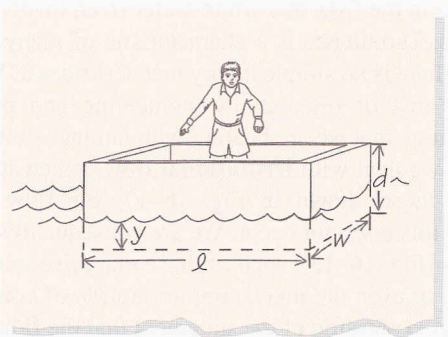
Strategy Equation (16–12) applies directly; it gives the weight of the sphere in water. Since W_w is proportional to F_g, it is simplest to eliminate the weight in air by taking the ratio W_w to mg. The resulting relation can be solved for the unknown average density ρ_{sphere} of the sphere.

Working It Out We have

$$\frac{W_w}{F_g} = \frac{\left(1 - \dfrac{\rho_w}{\rho_{\text{sphere}}}\right)mg}{mg} = \left(1 - \frac{\rho_w}{\rho_{\text{sphere}}}\right).$$

We solve for ρ_{sphere}:

$$\rho_{\text{sphere}} = \rho_w \frac{1}{1 - \dfrac{W_w}{mg}} = \rho_w \frac{1}{1 - \dfrac{18.5}{29.4}}$$



$$= \rho_w \times 2.70 = 2.70 \text{ g/cm}^3.$$

At this point you could also solve for the unknown mass of the sphere: Knowing the sphere density, the expression for W_w would give us the mass.

What Do You Think? If the metal sphere had been weighed in salt water rather than fresh water and given the same weight reading, would the density of the metal sphere have been (a) greater, (b) smaller, (c) the same, (d) can't tell. (Salt water is denser than fresh water.)

EXAMPLE 16–8 A rectangular tub made of a thin shell of cement has length $\ell = 1$ m, width $w = 80$ cm, depth $d = 60$ cm, and mass $M = 200$ kg. The empty tub floats in a lake. How many people of mass $m = 80$ kg each can stand in the tub before it sinks?

Setting It Up The tub is shown in Fig. 16–16. The depth of the bottom of the tub is y, and we denote the unknown number of passengers by N.

▲ **FIGURE 16–16** A tub sinks to a water depth y. When $y > d$, the depth of the tub, the tub sinks.

Strategy With the tub submerged to a distance y, we can find the volume ℓwy of displaced water and then the weight of the displaced water. This will allow us to find the buoyant force. The buoyant force will cancel the weight of the tub with its passengers up to the point that the immersed depth is equal to the tub's height, $y = d$. This is the point at which the boat is barely floating. Beyond this the tub will fill with water, increasing its average density, and it will sink to the bottom. So we set the buoyant force at $y = d$ to the total weight, and this relation will determine that total weight and in turn the maximum number of passengers N_{max}.

Working It Out With the tub submerged a vertical distance y, the mass of the displaced water is $\rho(\ell wy)$, where ρ is the water density, $1 \text{ g/cm}^3 = 10^3 \text{ kg/m}^3$. Then the weight of the displaced water is the mass times g, and this is the buoyant force,

$$F_{\text{buoy}} = \rho(\ell wy)g.$$

This force cancels the total weight of the tub and N passengers, $(M + Nm)g$. The equality of the buoyant force and the total weight,

$$\rho(\ell wy)g = (M + Nm)g,$$

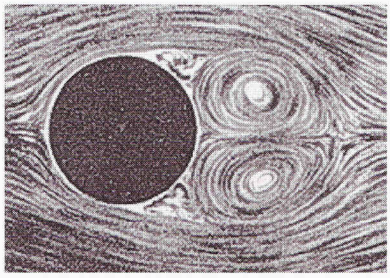
is what determines y. We see from this relation that y increases as N does (the tub moves lower in the water), until the critical value $y = d$ is reached, at which point any additional mass sinks the tub. We thus set $y = d$ to find N_{max}. With $\rho(\ell wd)g = (M + N_{\text{max}}m)g$, we solve for N_{max}:

$$N_{\text{max}} = \frac{\rho\ell wd - M}{m}.$$

Numerically,

$$N_{\text{max}} = \frac{(10^3 \text{ kg/m}^3)(1 \text{ m})(0.80 \text{ m})(0.60 \text{ m}) - 200 \text{ kg}}{80 \text{ kg}} = 3.5.$$

With three people the tub does not sink; with four people she goes down. Cargo ships were built out of concrete during both World Wars because of the high demand for steel. The older ships also served a useful purpose when they were deliberately sunk during the Normandy invasion of World War II to serve as a breakwater that would improve conditions for landing ships.



What Do You Think? If this tub had been weighed in water, what would the scale read?

16–5 Fluids in Motion

The marvelous fluid flow patterns observed in nature go far beyond the particle and rigid body motions we have studied to this point. **Hydrodynamics** describes fluids in motion, including the flow of streams, the eddies of oars in a pond, mudslides, smoke rings, ocean waves and tides, arterial blood flow, Jupiter's (and Earth's) atmosphere, the rotational flow of galaxies, and nuclear fission. Numerical calculations performed by supercomputers are necessary to solve the most complex types of behavior, but a remarkable variety of phenomena can be described with a very simplified set of equations. This simplified set involves a number of assumptions that we describe here.

We assume, as we have already discussed, that the fluid under consideration is incompressible. This does not mean that we exclude phenomena that involve gases, such as airflow; but it does mean that we will discuss these phenomena only under circumstances in which compressibility does not play a role.

We also assume that we are dealing with a fluid at constant temperature. (We will learn more about temperature and heat flow in Chapters 17 through 20.) Phenomena such as the **convection** of fluids—in which a liquid in the bottom of a vessel is heated, rises, cools, and falls in a circulating pattern—will not be considered.

▲ **FIGURE 16–17** Streamlines for a cylinder pulled steadily through a fluid, showing circulation in the fluid in the form of the two vortices on the right.

We assume **steady flow**, in which the velocity $\vec{v}$ and the pressure p of a fluid at a given point do not depend on time. The velocity and pressure may vary from point to point, but we assume that any changes are smooth ones.

The description of how velocity can change from point to point deserves a more detailed discussion and leads us to some further simplifying assumptions. Consider a fluid in motion. We could represent the direction of the velocity at some point by an arrow at that point, with the length of the arrow proportional to the magnitude of the velocity. For steady (time-independent) flow, there is a *local velocity* $\vec{v}(\vec{r})$. If we start at some point, then a tiny element of the fluid is at that point, and it will move in the direction of the velocity vector. An instant later the element is at an adjacent point, which has a slightly different velocity vector. This vector dictates the element's direction and speed of motion in the next instant and determines the next step of the motion. In this way, the motion of a tiny element of fluid can be traced. (That we can follow such an element is an idealization that approximates reality if the element is small enough.) The line of motion traced out by our element is called a **streamline**. Flow described by streamlines is called **laminar flow**; in laminar flow each element of fluid travels along a smooth, well-defined path. Under certain circumstances fluid flow ceases to be laminar and becomes turbulent. **Turbulent flow**, as in the flow of a white-water river, involves rapidly fluctuating velocities and pressures. Turbulence is a characteristic of many flow patterns that we observe in nature, but there is no simple theory that describes it. We'll look further at turbulence, an exciting area of research in engineering and physics, in Section 16–9, but we'll assume for now that we are dealing with laminar flow.

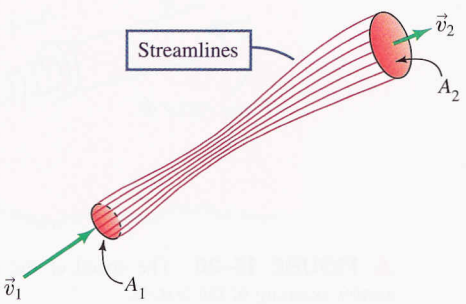
We will also assume here that we deal with **irrotational flow**. When streamlines close in on themselves, such as those shown in Fig. 16–17, the flow is called **rotational**, and in irrotational flow this does not occur. We are consequently unable to discuss here vortices, or whirlpools (Fig. 16–18), such as those that arise in water running out of a bathtub, smoke rings, or even the much simpler motion of coffee stirred by a spoon in a cup. A mathematical expression of the statement that the flow is irrotational is that the **circulation**, defined as the integral of the velocity along any *closed* path in the fluid, is zero.

▲ **FIGURE 16–18** The water moves faster near the center of the vortex than it does far from the center. The water is in rotational flow.

To simplify matters further, we make one more assumption: We neglect the analogue of friction in the fluid. That there is such an analogue is obvious from simple observations. The flow of honey is different than the flow of water. The friction that enters here is an internal friction which is called **viscosity**. In neglecting viscosity, we are neglecting internal energy losses, and the conservation of energy can then be used profitably.

To summarize, in the next two sections we make the following assumptions about fluid flow:

1. The fluid is incompressible.
2. The temperature does not vary.



3. The flow is steady, so that the velocity and pressure do not depend on time.
4. The flow is laminar rather than turbulent.
5. The flow is irrotational, so there is no circulation.
6. There is no viscosity in the fluid.

In Section 16–9 we will look at some of the important differences between this idealized flow and the flow in real fluids. In particular, we'll come back to the subjects of viscosity and turbulence.

16–6 The Equation of Continuity

For a fluid in motion, we can focus on a group of adjacent streamlines, which we say form a *bundle*, and follow them (Fig. 16–19). (We must work with a bundle because a single streamline is just a one-dimensional line—it contains no mass, hence no energy, no momentum, and so forth.) By their definition, streamlines cannot cross. If they did, the crossing point would be a point where the fluid has two different velocities simultaneously, and that is impossible. And because streamlines never cross, the bundle, which forms a thin tube of nonuniform cross section known as a **streamtube**, has the property that no fluid passes from the inside to the outside of it. We can then choose a streamtube thin enough so that the velocity across a section drawn at right angles to the tube is the very nearly the same across the whole cross section. The volume of fluid that crosses the section of area A_1 (Fig. 16–19) in a given time t is the volume of a cylinder whose base is A_1 and whose length is $\ell_1 = v_1 t$, where v_1 is the speed across that section; the volume of fluid is thus $v_1 t A_1$. If the density of the fluid at this section is ρ_1, then the mass of fluid crossing the section in the given time t is

$$m_1 = \rho_1 v_1 t A_1. \tag{16–13}$$

▲ **FIGURE 16–19** Flow contained in a bundle of streamlines (streamtube). The velocity perpendicular to the surface of area A_1 is $\vec{v}_1$, and that perpendicular to the surface of area A_2 is $\vec{v}_2$.

Similarly, the mass of fluid crossing a section of area A_2 at right angles to the bundle of streamlines with speed v_2 and density ρ_2 in the same time t is

$$m_2 = \rho_2 v_2 t A_2.$$

But because fluid neither enters nor leaves the tube by the side walls, the *conservation of mass* implies that $m_1 = m_2$, or, if we cancel the time t,

$$\rho_1 v_1 A_1 = \rho_2 v_2 A_2. \tag{16–14}$$

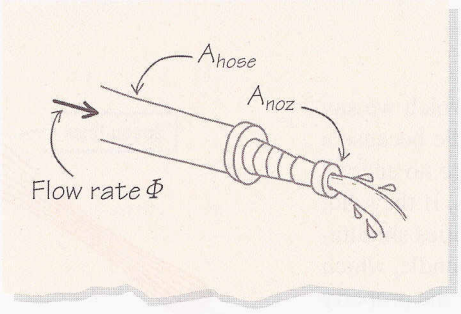
EQUATION OF CONTINUITY

This equation, the **equation of continuity**, is true even for fluids whose densities can vary with position. Note that $m/t = \rho v A$ is the mass flow per unit time.

When we restrict ourselves to incompressible flow, we have $\rho_1 = \rho_2$, and Eq. (16–14) simplifies to the very useful equation

$$v_1 A_1 = v_2 A_2. \tag{16–15}$$

CONSERVATION OF RATE OF FLOW, OR FLUX



Since $\rho v A$ is the mass flow per unit time, for constant density the combination vA is the *volume flow per unit time*—usually we call this just the rate of fluid flow. Equation (16–15) is a conservation law for the rate of flow. It states that the product of speed and area of any bundle of streamlines is the same anywhere along the bundle. The speed of fluid flow thus varies inversely with the streamtube cross section A. The rate of flow—the product (velocity perpendicular to an area) × (area)—is also known as the **flux**, Φ,

$$\Phi \equiv vA. \tag{16–16}$$

Equation (16–15) describes the **conservation of flux**. Perhaps you have observed the conservation of flux while entering or leaving a building on a windy day: The wind speed is greatest in the smallest doorway.

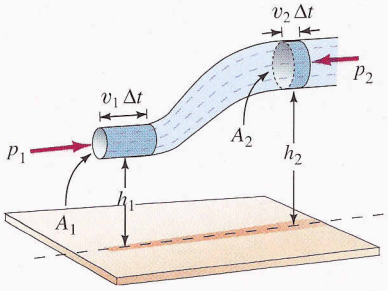
EXAMPLE 16–9 Water flows at a rate of 0.25 L/s through a garden hose of inside diameter 2.0 cm. What is the speed of the water in the hose? The nozzle of the hose is a circular opening of diameter 1.0 cm. What is the speed of the water when it emerges?

Setting It Up Figure 16–20 indicates the area A_{hose} of the hose and the area A_{noz} of the nozzle. We denote the known flow rate as Φ. We want the water speeds v_{hose} in the hose and v_{noz} in the nozzle—the latter is also the speed just outside the nozzle.

▲ **FIGURE 16–20** The speed of the water must be larger in the narrow opening of the nozzle.

Strategy The given flux Φ is the product vA. The fact that flux is conserved allows us to say that product vA is the same at the nozzle as in the hose. We can then solve for v for either the hose or nozzle in terms of Φ and the appropriate area.

Working It Out We have immediately $v_{\text{hose}} = \Phi/A_{\text{hose}}$ and $v_{\text{noz}} = \Phi/A_{\text{noz}}$, where Φ is the same in the two sections. We can note that since the nozzle is half the diameter of the hose, the area of the nozzle is one quarter the area of the hose, so that the speed in the nozzle is four times higher than in the hose. This will save a little numerical work. The quantitative results are



$$v_{\text{noz}} = \frac{(0.25\ \text{L/s}) \times (10^3\ \text{cm}^3/\text{L})}{\pi(0.50\ \text{cm})^2} = 3.2 \times 10^2\ \text{cm/s} = 3.2\ \text{m/s},$$

and $v_{\text{hose}} = \frac{1}{4} v_{\text{noz}} = 0.87\ \text{m/s}$.

What Do You Think? If the nozzle were of a type that adjusts the diameter of the hose when twisted, should the nozzle diameter be reduced or increased to increase the distance reached by the water stream?

16–7 Bernoulli's Equation

In principle, the motion of a fluid can be understood by dividing the fluid into small elements and applying Newton's second law to each of them. Alternatively, providing that only conservative forces are present, we can use the conservation of energy. If there is no viscosity in a fluid, and hence no energy dissipation, and if the fluid is incompressible, it is straightforward to formulate the conservation of energy for fluids. This is a simple and important tool for the study of fluid motion. In the application here, we will use the conservation of energy in the form of the work–energy theorem and will end with an equation that relates speed, pressure, and height for an ideal fluid.

▲ **FIGURE 16–21** A streamtube of fluid at different heights. In time Δt, the fluid moves to the right under the influence of a difference in pressures between p_1 and p_2. In effect, the shaded slice in region 1 is transferred to the shaded slice in region 2.

We again consider a streamtube—a bundle of streamlines of fluid—this time under the influence of gravity. Concentrate on the fluid forming a plug between two points along the tube: point 1, which has height h_1 and cross-sectional area A_1 and point 2, which is at height h_2 and has area A_2 (Fig. 16–21). The velocity perpendicular to the cross sections will have magnitudes v_1 and v_2, respectively, and we take our tube to be thin enough so that the velocity does not vary across the slices. The fluid to the left of the plug exerts pressure p_1 on the plug to the right, while the fluid to the right of the plug exerts pressure p_2 on the plug to the left. There will be, say, flow to the right if the force to the right, p_1A_1, is larger than the force to the left, p_2A_2.

Let's examine what happens during a time interval dt. The plug of fluid that starts out in the region between A_1 and A_2 at $t = 0$ will advance—in Fig. 16–21 we have supposed the movement is to the right. The distance by which it advances at point 1 is $v_1\,dt$, and the distance by which it advances at point 2 is $v_2\,dt$. We calculate the net work done in advancing the fluid in the tube by looking at the forces acting at either end. The work done by the force of the fluid to the left of point 1 is the force there times the displacement. The force is p_1A_1, so this work is

$$W_1 = (p_1A_1)(v_1dt). \tag{16–17}$$

The work done by the force of the fluid to the right of point 2 can be calculated similarly, but there is a minus sign because the force (and thus the pressure) acts to the left while the displacement is to the right, so that $\vec{F} \cdot \vec{s} = -Fs$. Thus

$$W_2 = -(p_2A_2)(v_2\,dt).$$

The net work done on the streamtube plug between regions 1 and 2 is then

$$W_{\text{net}} = W_1 + W_2 = (p_1 - p_2)vA\,dt, \tag{16–18}$$

where in the last line we have made use of Eq. (16–15), which expresses the constancy of the flux vA at any point along the tube: $vA = v_1A_1 = v_2A_2$.

We have now determined the amount of work done in moving the fluid in the plug during the time dt. To apply the work–energy relation, we next find the change in energy. If we examine Fig. 16–21, we can see that in the time interval dt, the effect of the motion is to transfer a small slice of fluid from region 1 to region 2. This transfer has two effects on the energy: The potential energy changes as the slice is lifted from h_1 to h_2, and the kinetic energy changes as the speed changes from v_1 to v_2. The change in potential energy is

$$\Delta U = mg\Delta h = (\rho vA\,dt)g(h_2 - h_1). \tag{16–19}$$

Again we have used the constancy of vA. The change in kinetic energy is

$$\Delta K = \frac{1}{2}(\rho vA\,dt)(v_2^2 - v_1^2). \tag{16–20}$$

Because $W_{\text{net}} = \Delta K + \Delta U$, we find, from Eqs. (16–18) through (16–20),

$$(p_1 - p_2)vA\,dt = \frac{1}{2}(\rho vA\,dt)(v_2^2 - v_1^2) + (\rho vA\,dt)g(h_2 - h_1).$$

After the factor $vA\,dt$ is divided out, we are left with

$$p_1 - p_2 = \frac{1}{2}\rho(v_2^2 - v_1^2) + \rho g(h_2 - h_1).$$

This equation can be rearranged into a conservation law, with one side dependent on the quantities defined in region 1 and the other side dependent on the quantities defined in region 2:

$$p_1 + \tfrac{1}{2}\rho v_1^2 + \rho g h_1 = p_2 + \tfrac{1}{2}\rho v_2^2 + \rho g h_2. \tag{16–21}$$

In other words,

$$\text{along a streamline: } p + \tfrac{1}{2}\rho v^2 + \rho g h = \text{a constant.} \tag{16–22}$$

BERNOULLI'S EQUATION

Our derivation deals with the motion of one particular streamline. But it can be shown in general that *for irrotational flow, the constant in Eq. (16–22) is the same for all streamlines* within a fluid. Equation (16–22) is **Bernoulli's equation**, derived in 1738 by Daniel Bernoulli, one of a remarkable family of scientists and mathematicians. In Section 16–8 we discuss applications of this formula.

Problem-Solving Techniques

Bernoulli's equation expresses conservation of energy for a fluid; as such, its use is similar to the use of all conservation laws. Keep in mind the following points:

1. When we say the right-hand side of Eq. (16–22) is a constant, we mean that it takes on the *same* value for all points within the fluid. If we know the value of $p + \frac{1}{2}\rho v^2 + \rho g h$ at one point, then that is the value it takes at all points.
2. In its typical application, we can find the value of the constant in Bernoulli's equation because we know the value of all the variables at some point. Then we can use the value of the constant to find the unknown value of a variable at another point.
3. When one of the three terms in the expression $p + \frac{1}{2}\rho v^2 + \rho g h$ is the same at all points, then we can ignore it and concentrate on using Bernoulli's equation to learn about the other variables. For example, in Section 16–8 we first apply Bernoulli's equation to the case of a fluid at rest. In that case, v is the same everywhere ($v = 0$), and we can use Bernoulli's equation as a conservation law for the quantity $p + \rho g h$.

(a)

(b)

▲ **FIGURE 16–22** By blowing over the top of the paper, the pressure above the paper is reduced according to Bernoulli's principle. Below the paper the pressure is unchanged, and there is a net force that makes the paper rise.

16–8 Applications of Bernoulli's Equation

Bernoulli's equation is useful for describing a variety of phenomena. First, we observe that if a fluid is at rest, so that $v = 0$ in Eq. (16–22), then

$$p + \rho gh = \text{a constant.} \tag{16–23}$$

This is just the hydrostatic relation between pressure and height that we obtained in Eq. (16–6).

The Bernoulli Effect

For flow at constant height, the conservation of energy [Eq. (16–22)] implies that

$$p + \tfrac{1}{2}\rho v^2 = \text{a constant.} \tag{16–24}$$

Thus the pressure must be lower in a region in which a fluid is moving faster. You can observe this phenomenon—known as the **Bernoulli effect**—in a simple experiment. If you blow air across the top of a single sheet of paper (Fig. 16–22), the pressure above the paper is reduced. However, the pressure is unchanged below the paper; thus, the paper rises. The Bernoulli effect also enters into the operation of a chimney. When the wind blows over the top of a chimney, the pressure is decreased at the top by the Bernoulli effect, and the air in the tube rises. This is an important element in a chimney's "draw."

THINK ABOUT THIS . . .

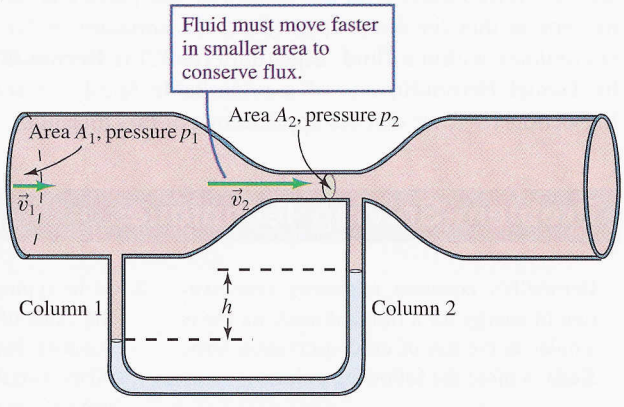
HOW IS FLUID SPEED IN A CLOSED PIPE MEASURED?

How does an engineer running a refinery know the speed of the fluids that pass through the pipes? Equation (16–24) is applied in the *Venturi flowmeter*, a device designed for just this purpose (Fig. 16–23a). Figure 16–23b is a simplified version of the flowmeter. The large pipe, with cross-sectional area A_1, is constricted smoothly to a smaller area A_2. A U-shaped tube containing a different fluid connects the two segments of pipe. The speeds in the larger and smaller sections of the pipe are v_1 and v_2, respectively; similarly, the pressures in the two sections are p_1 and p_2, respectively. Then Eq. (16–24) tells us that

$$p_1 + \frac{1}{2}\rho v_1^2 = p_2 + \frac{1}{2}\rho v_2^2;$$

or

$$p_1 - p_2 = \frac{1}{2}\rho(v_2^2 - v_1^2).$$



The continuity equation, Eq. (16–15), tells us that $v_2 = v_1 A_1/A_2$, so

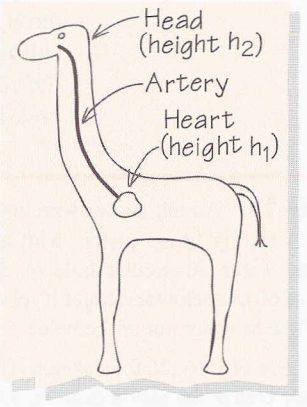
$$p_1 - p_2 = \frac{1}{2}\rho v_1^2\left[\left(\frac{A_1}{A_2}\right)^2 - 1\right]. \tag{16–25}$$

The difference in pressures is determined from the difference in heights, h, of the two columns of fluid in the U-shaped tube (see Section 16–3). Equation (16–25) is then used to find speed v_1 in terms of this pressure difference.

(a)

(b)

▲ **FIGURE 16–23** (a) The Venturi flowmeter. (b) The speed v_1 of a fluid in a pipe is measured by the difference in heights, h, of column 1 and column 2 of a different fluid. The number of measuring tubes that tap the pipe through which the fluid flows can be varied according to the measurement desired.



EXAMPLE 16–10 A giraffe needs a strong heart because of its long neck. Suppose that the difference in height between the aortic valve (the place where arterial blood comes out of the heart) and the head of a giraffe is 2.50 m, and that the artery leading from near the aortic valve to the head has constant cross section all the way to the head. What is the minimum pressure at the aortic valve? Blood is an incompressible fluid with density $\rho = 1.0\ \text{g/cm}^3$.

Setting It Up See Fig. 16–24 for a sketch. We will use Bernoulli's equation with constant speed in order to relate pressure at the heart to pressure at the head and the height change, and for that we will need to know the minimum value of pressure at the giraffe's head. For the survival of the giraffe this value must be more than $p = 0$ and we would have to ask a veterinarian what the true minimum at the head is. For our purposes we'll just assume that $p = 0$ at the head is the smallest physical value allowed.

Strategy Because blood is incompressible and the arterial area is constant, the equation of continuity (flux conservation) implies that the speed of the blood will be the same at the head as at the heart. Bernoulli's equation in the form of Eq. (16–23) (the form appropriate to constant speed) is a relation between the heart height and pressure and the head height and pressure. Only the heart pressure is unknown in this expression, and we can solve for it.

Working It Out Let's use subscripts 1 and 2 for the heart and head, respectively. Then, with $p_2 = 0$, Eq. (16–23) reads $p_1 + \rho g h_1 = \rho g h_2$, which can be solved for p_1:

$$p_1 = \rho g(h_2 - h_1).$$

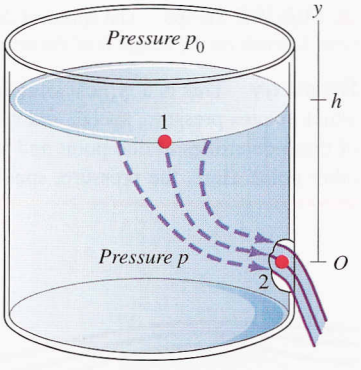
▲ **FIGURE 16–24** A giraffe's long neck requires a strong heart for arterial blood flow.

Numerically, $p_1 = (1.0\ \text{g/cm}^3)(10^2\ \text{cm/m})^3(10^{-3}\ \text{kg/g})(9.80\ \text{m/s}^2)(2.50\ \text{m}) = 2.5 \times 10^4\ \text{Pa}$. Various factors, in particular the loss of energy due to friction between the blood and the arterial walls and the desire to have a larger value than 0 for the head pressure, make this a low estimate. Comparing this to the *peak* output pressure of the human heart, 1.6×10^4 Pa, we can see that the giraffe's long neck requires a strong heart.

What Do You Think? What would be the effect on the giraffe if the artery diameter narrowed down as it approached the brain?

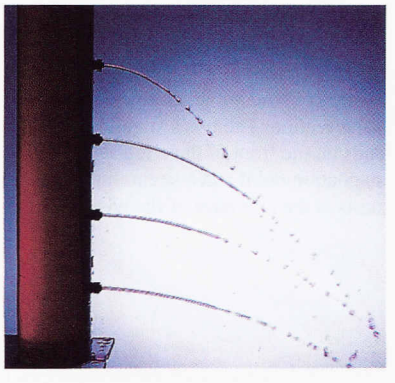
Fluid Motion with Constant Speed

In the Bernoulli effect, height is constant but the speed of the flowing fluid is not. But we can easily imagine reversing this and confronting constant speed but changing height. To fix the speed, we need only confine our moving fluid to a pipe of unchanging cross section. If the fluid is incompressible, then the equation of continuity, Eq. (16–15), shows that the speed cannot change. However, the pipe could perfectly well move from one height to another, and in this situation the pressure will change. For this case Bernoulli's equation is $p + \rho g h =$ a constant, identical to the static case expressed by Eq. (16–23) (see Example 16-10).



Flow from a Tank

Another interesting phenomenon of practical importance in fluid flow is the speed of flow of a liquid from an opening in a tank (Fig. 16–25a). If we make a small hole in the side of an open tank of water at a depth h below the surface, we can apply Bernoulli's equation, Eq. (16–22), to the fluid at different locations in the tank. We denote the height above the hole by the variable y, so that the height at the water surface is $y = h$ and at the opening $y = 0$. Equation (16–22) states that the value of $p + \frac{1}{2}\rho v^2 + \rho g y$ is the same at point 1 (on the upper surface, where the pressure $p = p_0$) and point 2 (just outside the hole, where $p = p_0$ because the sides of the stream of fluid flowing from the tank are in equilibrium with the atmosphere). The speed v_2 at point 2 is to be determined. We equate the values of $p + \frac{1}{2}\rho v^2 + \rho g y$ at the two points and obtain

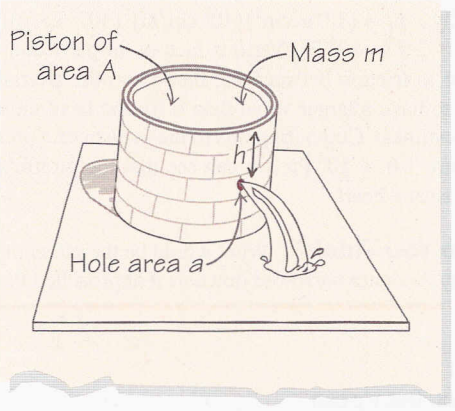


$$p_0 + \tfrac{1}{2}\rho v_1^2 + \rho g h = p_0 + \tfrac{1}{2}\rho v_2^2 + \rho g \times 0.$$

We can neglect the small velocity v_1 of the liquid at the top of the tank. We solve for the speed at point 2 (the hole) to find that

$$v_2 = \sqrt{2gh}, \qquad (16\text{–}26)$$

(a)



(b)

▶ **FIGURE 16–25** The escape of fluid through a hole in a tank. (a) The curved lines are streamlines for real fluid flow. (b) The pressure at the bottom of the tank is greater than the pressure at the top, so a stream of water leaving the tank has greater speed if it leaves from a hole that is lower on the tank.

as is consistent with Fig. 16–25b. This is just the speed of a single particle falling through a height h under the influence of gravity, as in Eq. (2–27). We find the same result for the falling liquid as for a falling object because they both are consequences of the conservation of energy. To find the rate of fluid flow from the hole,[†] we use the expression for the flux, Eq. (16–15), namely $\Phi = vA$.

EXAMPLE 16–11 A tank of cross-sectional area 0.07 m^2 is filled with water. A tightly fitting piston, with a total mass 10 kg, rests on top of the water. A circular hole of diameter 1.5 cm is opened at a depth of 60 cm below the water level of the tank. What is the initial rate of flow of water out of the hole?

Setting It Up See Fig. 16–26 for a sketch. The sketch labels the tank area A, the hole area a, the piston mass m, and the hole depth h; all three quantities are given in the question. We'll also need to assume that the atmospheric pressure p_0 does not change from the top of the tank to the place where the hole is cut.

▲ **FIGURE 16–26** The speed of the water flowing out of the small hole depends on the height h of the water above it.

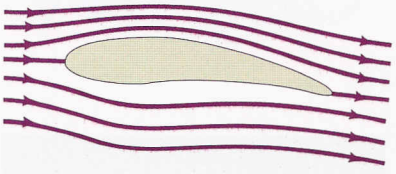
Strategy This is a typical situation where Bernoulli's equation, which relates pressure, speed, and height, is useful: We know some of these quantities at one point and want to learn about them at another point. Here, the pressure, speed, and height are known at the top, as are the pressure and height at the hole. We can then use Bernoulli's equation to learn about the speed at the hole. Then given the water speed v, we can find the flow rate va.

Working It Out At surface level, the total pressure $P = p_0 + p_1$, where p_0 is the atmospheric pressure and p_1 is the pressure due to the piston resting on the water, $p_1 = mg/A$. The water at the surface, which we set at height h, is essentially stationary. At the hole, which here is at height 0, the pressure just outside the hole is p_0, as in the discussion above. An application of Bernoulli's equation at the top of the water and at the opening leads to the equality

$$p_0 + p_1 + \rho gh = p_0 + \tfrac{1}{2}\rho v^2.$$

We cancel p_0 from both sides of the equation and solve for v^2:

$$v^2 = \frac{2(p_1 + \rho gh)}{\rho} = \frac{2\left(\frac{mg}{A} + \rho gh\right)}{\rho} = 2g\left(\frac{m}{\rho A} + h\right).$$



In turn, the flow rate is $\Phi = va = v\pi(d/2)^2$, where d is the hole diameter. If $\rho = 10^3$ kg/m^3, we find

$$v^2 = 2(9.8\ \text{m/s}^2)\left[\frac{10\ \text{kg}}{(10^3\ \text{kg/m}^3)(0.07\ \text{m}^2)} + 0.6\ \text{m}\right] = 15\ \text{m}^2/\text{s}^2,$$

or $v \cong 4$ m/s, and $\Phi = (4\ \text{m/s})\pi(7.5 \times 10^{-3}\ \text{m})^2 = 7 \times 10^{-4}\ \text{m}^3/\text{s} = 0.7$ L/s.

What Do You Think? Let's assume that we want the water coming out of the hole to land as far away as possible. How would you determine where to put the hole? Discuss, qualitatively, how far the stream would land according to whether the hole is near the top or bottom of the tank.

*Lift

▲ **FIGURE 16–27** Schematic version of streamlines over an airplane wing section. There is a streamline that ends on the front of the wing at the stagnation point and a streamline that starts at the rear edge of the wing.

The upward force that keeps a heavy airplane in the sky is an example of **lift**. The Bernoulli effect—the fact that when the speed of a fluid increases, pressure in the fluid decreases—helps us to understand the origin of lift. However, there are some subtleties, and circulation, viscosity, and turbulence all play an important role in lift. Thus it is necessary to relax some of the simplifying assumptions listed at the end of Section 16–5 to provide a correct description of this phenomenon. Consider the cross section of a wing shown in Fig. 16–27. We visualize the situation from the reference frame of the wing, so that we think of the air moving toward the wing, which is at rest, rather than the wing moving through stationary air. (This is, in fact, just what happens in a wind tunnel in which problems such as this one are studied.) Air approaches the wing with some speed v along a set of streamlines. Some of the streamlines go below the wing, some go above. The wing is designed so that the air speed above the wing is greater than that below the wing, which can happen only if there is circulation in the clockwise direction[‡]. Circulation occurs only around the wing.

[†]A more careful treatment replaces the rate of flow with the expression kvA, where the coefficient k is less than 1. Its correct value for a simple small hole is 0.62. In the examples and problems, we use $k = 1$ for simplicity.

[‡]No air actually moves forward under the wing; rather, the speed beneath the wing is less than the speed above the wing.

The flow elsewhere is irrotational, which means that the constant appearing in the Bernoulli equation, Eq. (16–22), is the same for all the streamlines that flow near the wing, below or above. From Eq. (16–24) we see that the pressure on top of the wing, p_t, must therefore be less than the pressure below, p_b, and there is a net upward force, or lift, on the wing. The net upward pressure, $p_{\text{net}} = p_b - p_t$, is determined from Eq. (16–24):

$$p_b + \tfrac{1}{2}\rho v_b^2 = p_t + \tfrac{1}{2}\rho v_t^2,$$

where here ρ is the air density. We thus find that

$$p_{\text{net}} = p_b - p_t = \frac{1}{2}\rho(v_t^2 - v_b^2) = \rho\left(\frac{v_t + v_b}{2}\right)(v_t - v_b) \cong \rho v(v_t - v_b), \quad (16\text{–}27)$$

where v is the average of the top and bottom speeds. Because the difference between the top speed and the bottom speed is small, both are nearly equal to the average speed, which we call the *airstream speed* v.

The expression in Equation (16–27) can be used to calculate the lift. If the wings have a width w and a tip-to-tip span S, then their total area is wS (we are ignoring the fuselage), and the lift is given by

$$L = wSp_{\text{net}} = wS(p_b - p_t) \cong wS\rho v(v_t - v_b).$$

Experiments show that for speeds much slower than the speed of sound, $v_t - v_b$ is proportional to the airstream speed v, with a proportionality constant K (in general, $K \ll 1$), which depends on the wing design and the wing angle relative to the airplane direction. Thus we can finally write the lift as

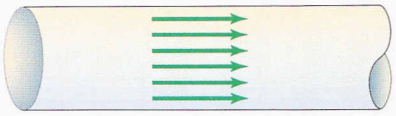
$$L \cong wS\rho K v^2. \quad (16\text{–}28)$$

A typical value of the constant K is 0.12, so for a small plane with a total wing area of 30 m^2 and an air speed of 200 km/h = 56 m/s and with air density of about 1.3 kg/m^3, the lift is given by

$$L = (0.12)(30\ \text{m}^2)(1.3\ \text{kg/m}^3)(56\ \text{m/s})^2 = 1.6 \times 10^4\ \text{N}.$$

Thus the mass that can be lifted is $(1.6 \times 10^4\ \text{N})/(9.8\ \text{m/s}^2) \cong 1600$ kg. The fact that air is compressible plays little role if the relative speed of the wing and the air is much smaller than the speed of sound in air, $v_s \cong 330$ m/s. (The design and operation of the wings of supersonic aircraft presents a different set of problems.)

To give the flow around the wing a nonzero circulation, it is necessary to have some turbulence. The turbulence is induced by the viscosity of the air and further enhanced by the placement of small protuberances (ailerons) on the wings.



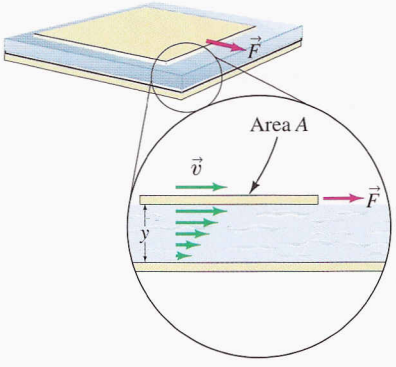
THINK ABOUT THIS . . .

WHY DO RACING CARS HAVE WINGS?

In contrast to airplanes, racing cars are designed so that the air beneath the car moves faster than the air above it, and a downward pressure is exerted on the car. This downward pressure is produced or augmented by both front and rear wings, sometimes called *spoilers*. These act like upside-down airplane wings, producing a reverse lift that pushes the car vertically down onto the road. The increased contact force with the road is very useful to a racing car, because static friction between the wheels and the track is proportional to the contact force. Increased friction allows more torque to be supplied to the wheels without them spinning, and in this way larger accelerations and speeds are possible. Moreover, the increased friction allows better steering control.

*16–9 Real Fluids

Our discussion has mostly been limited to idealized kinds of flow of idealized fluids. Some of our assumptions apply only approximately, at best, to real fluids. Nonviscous flow, for example, has been called the flow of "dry water." Here we give some qualitative notions of how real fluids behave under ordinary circumstances.



(a)

(b)

▲ **FIGURE 16–28** Velocity profiles for laminar flow in a pipe: (a) idealized fluid flow that does not take into account viscosity; (b) realistic fluid flow (Poiseuille flow).

▲ **FIGURE 16–29** Two glass plates have a film of fluid between them; one slides against the other. The top plate moves with speed v. Fluid near the top plate moves with the same speed as that plate, while fluid near the bottom plate is at rest.

Viscosity

Figure 16–28a is a picture of the velocity profile of pipe flow for fluids idealized as we have described. For real fluids the liquid near the surface of the pipe is at rest, and the velocity profile is actually parabolic (Figure 16–28b). Such flow is referred to as **Poiseuille flow**, after Jean Poiseuille, who studied blood circulation. The reason for this effect is the internal friction of the fluid, or *viscosity*. Viscosity comes from intermolecular collisions. The molecules of a fluid have a random motion, to be described in Chapter 19. If two adjacent layers of fluid flow with slightly different speeds, the random sidewise intrusion of some slower molecules into the faster stream will tend to slow down the faster stream, whereas intrusion of faster molecules into the slower stream will tend to speed up the slower stream.

Viscous flow can be analyzed by taking two glass plates with a film of fluid between them and sliding one plate over the other. The easier it is to slide the plates, the less viscous is the fluid between them. To quantify this effect, take the smaller plate to have an area A; it is separated from the other plate by a distance y (Fig. 16–29). If the upper plate is to move with a uniform velocity $\vec{v}$, a force must be applied—just as if a brick is made to slide along a rough surface at constant speed. This force, F, is proportional to A and inversely proportional to y. In addition, the force increases linearly with speed (like the damping force on a mass at the end of a spring or like air drag). A formula that reflects these factors will have a proportionality constant η that will differ in different materials,

$$F = \frac{\eta v A}{y}. \tag{16–29}$$

The coefficient η is the **coefficient of viscosity**. It is measured in newton seconds per square meter or equivalently kilograms per meter second. Typical values are 10^{-3} kg/(m · s) for water and 830×10^{-3} kg/(m · s) for glycerin, both at 20°C. We mention the temperature because, as anyone who has poured syrup over pancakes knows, viscosity is strongly temperature-dependent.

Turbulence

A fluid flow marked by complex and chaotic movement is referred to as turbulent. At the onset of turbulence, the whole notion of neatly separated streamlines ceases to make sense (Fig. 16–30). A dimensionless parameter known as the **Reynolds number**, Re,

▶ **FIGURE 16–30** Turbulence, an important feature of fluid flow, is seen in the steam and smoke from the eruption of Mount Augustine in Alaska.

determines when turbulent flow occurs, and this parameter contains the fluid speed. It is defined as

$$Re = vL\left(\frac{\rho}{\eta}\right), \tag{16–30}$$

where ρ is the density of the fluid, v is its speed, L is a length associated with the flow, such as the pipe's diameter for flow in a pipe, and η is the viscosity coefficent. When the Reynolds number increases past about 2000 to 3000, the flow becomes turbulent. For water flowing through a pipe 1 cm in diameter, $Re \cong (10^4\ \text{s/m})v$ so the flow becomes turbulent when v reaches a mere 0.3 m/s. Turbulence is very common, but fortunately a small amount of turbulence does not change the applicability of Bernoulli's equation for short distances of flow (just as a small amount of friction does not disturb energy conservation over short times), so Eq. (16–22), although not exact, is still a very good and useful approximation.

THINK ABOUT THIS . . .

OF WHAT USE ARE THE DIMPLES ON A GOLF BALL?

When an object such as a golf ball moves through the air, there is drag on it. We can identify two different sources of drag. There is drag associated with turbulence, in which energy is lost in churning the air. There is also a type of drag known as pressure drag associated with laminar (smooth) flow, in which to satisfy continuity equations the air flow leaves a region *behind* the moving object where there is a lower pressure than the pressure before it. Pressure drag can be more important than turbulent drag at high speeds. The dimples on a ball increase the turbulence around the ball, and while this means more turbulent drag, it has a second important effect: it decreases the size of the region with reduced pressure behind the ball and thereby decreases the pressure drag. Experiment shows that this is a winning strategy: a dimpled ball will travel farther. Moreover, the increased turbulence due to the dimples can also increase a lift associated with the spin of the golf ball. The dimples may look cute, but they also have a solid positive effect on the flight of the ball.

Summary

Liquids are distinguished from gases in that the molecules that form liquids are closer together and impose strong forces on each other. Liquids are distinguished from solids in that the molecules in liquids do not form a rigid lattice. Both liquids and gases deform in response to external forces and therefore flow as fluids. The density of a material of mass M and volume V is unchanging in incompressible fluids:

$$\rho = \frac{M}{V}. \tag{16–1}$$

The fluids we study in this chapter are for the most part incompressible.

Pressure, measured in SI in pascals, expresses the way that fluids transmit forces. The pressure in a fluid is the (pushing) force per unit area on any area A:

$$p \equiv \frac{F}{A}; \tag{16–2}$$

and is perpendicular to A. When a fluid is at rest, the pressure at any given point is the same in all directions. For an incompressible fluid in Earth's gravity, the pressure increases with the depth y according to

$$p = p_0 + \rho g y, \tag{16–6}$$

where p_0 is the pressure at $y = 0$. A change in pressure applied to a fluid at rest is transmitted without change to every part of the fluid, a statement known as Pascal's principle. This principle is the basis of hydraulic lifts and brakes.

For an object immersed in a fluid, there is an upward buoyant force equal to the weight of the displaced fluid,

$$F_{\text{buoy}} = \rho g V_{\text{submerged}}. \tag{16–11}$$

This is Archimedes' principle.

Nonviscous (friction-free) fluids in smooth (nonturbulent) motion follow paths traced out by streamlines. The conservation of mass for a fluid moving in this way is stated as the continuity equation,

$$\rho_1 v_1 A_1 = \rho_2 v_2 A_2. \tag{16–14}$$

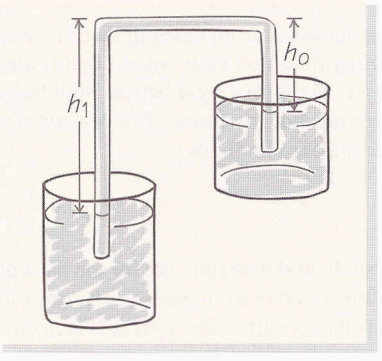
Here ρ and v are the density and speed at some point in a tube of streamlines; A is the corresponding cross section of the tube. If the fluid is incompressible, the (constant) density cancels, and the resulting expression is the conservation of flow rate, or flux:

$$v_1 A_1 = v_2 A_2. \tag{16–15}$$

The conservation of energy for a moving fluid under the influence of gravity is Bernoulli's equation:

$$\text{along a streamline: } p + \tfrac{1}{2}\rho v^2 + \rho g h = \text{a constant.} \tag{16–22}$$

When the fluid is at rest, this reduces to Eq. (16–6); when the fluid flow is horizontal, this reduces to



$$p + \tfrac{1}{2}\rho v^2 = \text{a constant.} \tag{16–24}$$

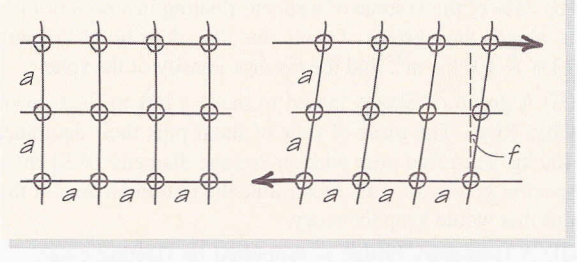
This equation is the basis of the Venturi flowmeter, which measures the speed of fluids in pipes, as well as the basis for understanding the flow of fluids from holes and the lift on wings.

It is possible to go quite far in understanding fluids with a number of simplifications. The relaxation of the simplifying assumptions brings in rotational flow, viscosity, and turbulence. The behavior of real fluids remains a field of active study.

Understanding the Concepts

1. How does a hot-air balloon get off the ground?
2. We weigh a brick twice with a bathroom scale. The first time, the scale and the brick are inside a tub of water, and the second time, they are outside the tub. Water can enter the scale. Does the scale indicate a difference in weight in the two cases?
3. One accurate method of measuring the fat content of your body is to measure your weight twice: once while you are immersed in a tank of water, and once when you are out of the water. Explain how such a method might work.
4. The most exciting white water for canoeing often occurs when the river narrows. Why is this?
5. If an empty balloon is weighed on a scale, a certain value is obtained. If a child now blows up the balloon and waits for several minutes so that the temperature of the air in the balloon is the same as the room temperature, what value will the scale give for the balloon's weight?
6. Suppose that a certain fluid has no viscosity. Will the acceleration of objects falling under gravity within this fluid be independent of the mass of the objects?
7. You have two objects in a bathtub—one floating high up, the other just barely floating. Does the buoyant force cancel gravity in each of these cases?
8. Water-storage tanks for communities normally are placed high off the ground rather than underground. This is obviously a safety hazard, so why is it done?
9. Mercury is poisonous. Why, then, is it typically used in barometers to measure atmospheric pressure?
10. The "antilift" effect for a racing car, the opposite of the lift effect on airplanes, is said to be so strong that a car could race on an upside-down track. Is this a plausible statement? Make some rough estimates of the surface area of a racing car, its mass, and its velocity, and assume that the difference between the air speeds under the car and over the car is about 20 m/s.
11. In Example 16–10 we suggested that the minimum pressure at the giraffe's head must be $p = 0$. But why couldn't the minimum value of pressure be negative? Comment on the signs of the three terms in Bernoulli's equation, Eq. 16–21.
12. One way to get the water out of a stopped-up sink is to use a long piece of rubber tubing. You put one end in the water and suck on the other end until you have filled the tubing. You then close off your end, bring that end to a point below the bottom of the sink, and reopen that end (Fig. 16–31). The water will flow out through the tubing until the sink is empty. You have made use of the *siphon mechanism* (see Problem 73). Explain how it works.

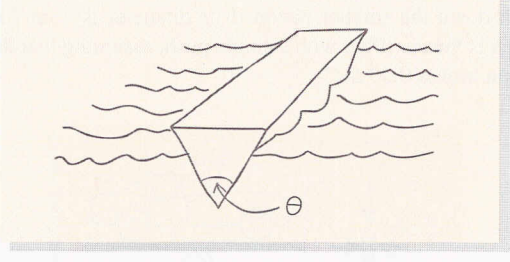
▲ **FIGURE 16–31** Questions 12, 13, and Problem 73.



13. The siphon shown in Fig. 16–31 and described in Question 12 is limited in the height h_0 that it can overcome. What determines this limit?
14. Suppose mercury were less dense than it is. Would the height of a barometer column be (a) taller or (b) shorter?
15. Do sailboats make use of any of the aspects of Bernoulli's laws, such as those we described for airplanes? In particular, do sails need to be curved in order to work?
16. A common classroom demonstration employs a table tennis ball in a funnel. An air hose is connected to the tube of the funnel and air is blown through. If the funnel is held upside down, the ball does not fall out. Why?

17. Which weighs more, a ton of Styrofoam or a ton of lead? Which of the two has the larger volume? How might you estimate the density of each?
18. People find it very easy to float in the Dead Sea. Why?
19. The point of a cone-shaped bottle (pointed end up) is removed to provide an opening. The pressure of the liquid at the very bottom of the bottle is the sum of the atmospheric pressure and the weight of the liquid above. If we consider a part of the bottom that is not directly below the opening, we might argue that there is less pressure because, above that point, there is less liquid and no atmosphere. This argument violates Pascal's principle. What has the argument left out?
20. In Example 16–11 we described water flowing from a hole cut in a tank. What happens to the flow with the passage of time? In particular, is the rate of flow constant? Is the distance from the tank to the landing point of the stream constant?
21. Suppose that you put a mixture of oil and water into a centrifuge that rotates at high speeds (the oil is less dense than the water and does not mix with it). The two liquids separate. Why, and which component will be farthest from the center of the centrifuge?
22. An old proposal for transcontinental travel along a fixed latitude is the following: Take a balloon high into the stratosphere. Wait until Earth has rotated the desired distance beneath you, then descend. Comment on the feasibility of this mode of transport.
23. A snorkel is a breathing tube meant to be used while you swim under water; it runs from your mouth to the water surface. Why is the length of a snorkel limited?
24. A pressure of 8 kPa across the eardrum is enough to cause serious pain, and 17 kPa will rupture the eardrum. What fraction of an atmosphere is this? Given your answer, why is it that merely stepping outside is not dangerous?
25. In the course of a lazy summer morning, ice cubes floating in a pitcher of water melt. What happens to the water level in the pitcher? (Ignore evaporation.)
26. Suppose that you put a kilogram weight and a jar half-filled with water on a kitchen scale. The scale reads 2.5 kg. Now you place the kilogram weight *inside* the jar, and no water spills out. You might argue that because the kilogram weight weighs less in water than in air, the scale would read less than 2.5 kg, but the reading remains 2.5 kg. What is wrong with your argument?

Problems

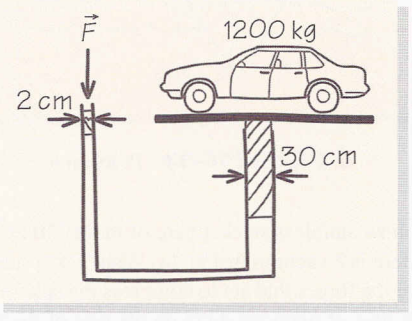


16–2 Density and Pressure

1. (I) Jupiter has a radius $R = 7.14 \times 10^4$ km, and the acceleration due to gravity at the surface is $g_J = 22.9\ \text{m/s}^2$. Use these data to calculate Jupiter's average density.
2. (I) The numbers given in Problem 1 have the following values for some of the other planets: Venus: $R = 6.05 \times 10^6$ m, $g = 8.86\ \text{m/s}^2$; Mars: $R = 3.39 \times 10^6$ m, $g = 3.73\ \text{m/s}^2$; Uranus: $R = 2.54 \times 10^7$ m, $g = 9.12\ \text{m/s}^2$; Neptune: $R = 2.48 \times 10^7$ m, $g = 12.0\ \text{m/s}^2$. Calculate the densities of these bodies.
3. (I) The density of a nucleus is about $2 \times 10^{17}\ \text{kg/m}^3$. The amount of water in a large lake is $10^{13}\ \text{m}^3$. If this amount of water were compressed to nuclear density, how many liters of water would there be?
4. (I) A platinum sphere has a diameter of 0.96 cm. What is the diameter of an aluminum sphere of the same mass, given that the densities of platinum and aluminum are $21.4 \times 10^3\ \text{kg/m}^3$ and $2.70 \times 10^3\ \text{kg/m}^3$, respectively?
5. (I) Atoms of an imaginary two-dimensional solid are arranged in a square lattice. The distance of neighboring atoms is a. Assume that the solid is acted upon by a shear force and deformed by a *small* angle f without any change in the nearest neighbor distance (Fig. 16–32). Calculate the change in the distance between atoms situated at opposite corners of a square.

▲ FIGURE 16–32 Problem 5.

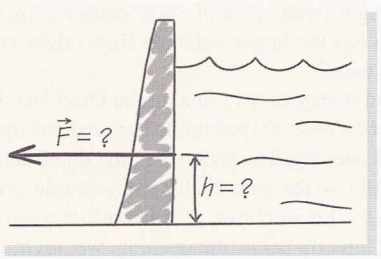
6. (I) The density of mercury is 13.6 times that of water. Compare the height of a column of water to that of a column of mercury, assuming that the pressure exerted by the weights of the respective liquids at the bottom of each column are the same.
7. (I) A circus clown stands on a pair of stilts that each have a square cross section of 4.0 cm per side. If the mass of the clown plus the stilts is 68 kg, what pressure is exerted on the floor?
8. (II) A wedge of mass 15 N and opening angle $\theta = 55°$ is floating on the surface of water in the symmetrical position shown in Fig. 16–33. Calculate the force of the water that acts on each of the two surfaces.



▲ FIGURE 16–33 Problem 8.

9. (II) A hollow stainless steel sphere of radius 20 cm is evacuated so that there is a vacuum inside. (a) What is the sum of the magnitudes of the forces that act to compress the sphere? (b) There is a circular hole of diameter 4 cm on the side of the sphere for access to the inside. Calculate the force needed to pull a flat plate off the hole when the sphere is evacuated. Do you think that you could remove such a plate by pulling on it?
10. (II) During a hurricane, the atmospheric pressure changes dramatically. Explain why it is recommended that house windows be kept slightly open during a hurricane. What is the net force on a wall that is 300 ft^2 in area when the pressure on one side is 14.7 lb/in^2 and the pressure on the other is 14.0 lb/in^2?

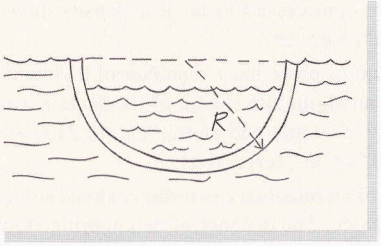
11. (II) A hollow metal pyramid with a square base that is 15 cm on each side has a mass of 1.8 kg. What is the pressure exerted by the pyramid on the table on which it stands? Suppose that the temperature in the room rises so that the metal expands. Will the pressure increase or decrease as a result of the expansion?



16–3 Pressure in a Fluid at Rest

12. (I) Using the densities in Table 16–1, what is the height of a fluid column in a barometer that has water as its fluid, in an air pressure of 1 atm? One that has alcohol? (Neglect the vapor pressure of the fluid above the column.)
13. (I) What is the pressure at depths of 1 m, 10 m, 100 m, and 10 km under the surface of the ocean? Take $\rho = 1.03 \times 10^3$ kg/m^3 for the density of sea water and $p_0 = 1.01 \times 10^5$ Pa for the atmospheric pressure at the ocean surface. (Ignore the fact that, to this accuracy, density varies with depth.)
14. (I) Recreational scuba divers rarely go deeper than 20 m. What is the water pressure at this depth? By what factor does your result differ from sea-level water pressure?
15. (I) What is the pressure 1 cm below the surface of a column of mercury exposed to air? 3 cm below the surface?
16. (I) An oceanic research vehicle operates at a depth of 1.20 km under water. Assuming that the pressure inside the vehicle is 1.0 atm, what is the force on a small window of dimensions 10 cm × 10 cm?
17. (II) Assume that a spaceship lands on Venus with the cabin pressure maintained at 1 atm. What would be the height of a column of mercury in a barometer in the spaceship on Venus? Repeat for a spaceship landing on Neptune. (Use the data given in Problem 2.)
18. (II) Tests in pressure test chambers show that mental processes are affected when the gauge pressure exceeds 35 lb/in^2. *Gauge pressure* is the pressure in excess of atmospheric pressure. This is a well-known effect that limits the depth at which scuba divers should breathe pure air. In sea water, whose density is 1.03 g/cm^3, to what depth should a diver be limited?
19. (II) A hydraulic jack is used to lift a 1200-kg car on a piston of diameter 30 cm (Fig. 16–34). How large a force is needed to push down the smaller piston if its diameter is 2 cm? By how much is the car lifted with a single push, assuming that the small piston moves 0.50 m?

▲ **FIGURE 16–34** Problem 19.



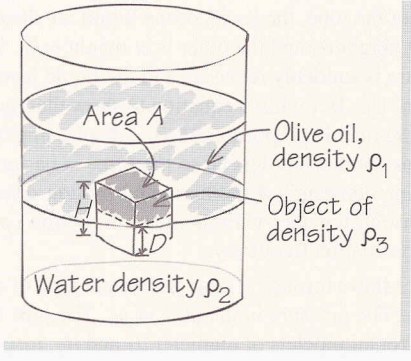
20. (III) The vertical wall of a small dam is 32 m long and it holds back a body of water that is 5 m deep (Fig. 16–35). Calculate the force acting on the wall due to the pressure of the water. Determine the effective point of action of this force. [*Hint*: Recall the method used to calculate the center of mass of a nonuniform object in Chapter 8.]

▲ **FIGURE 16–35** Problem 20.

16–4 Buoyancy and Archimedes' Principle

21. (I) A bathysphere (a spherical, watertight research facility) 2.6 m in diameter has a mass of 9400 kg. It is released from a submarine at a depth of 20 m below the surface. Will the bathysphere sink or rise?
22. (I) Use the densities in Table 16–1 to show that ice floats in water. What fraction of the volume of a floating ice cube will be above the surface?
23. (I) A cubical box, contents unknown, floats in water; 16 percent of the volume of the box is above water. What is the average density of the box and its contents?
24. (I) Over 10,000 icebergs are calved from Greenland each year. These icebergs are a serious danger to Atlantic shipping because most of the iceberg remains under water, invisible. If 10% of the iceberg sticks out of the water, what is an iceberg's density?
25. (II) A supertanker can carry 2.2 × 10^5 m^3 of oil with a density of 0.88 g/cm^3. When fully loaded its mass is 2.3 × 10^8 kg, and the dimensions of its hull are approximately 400 m long, 60 m wide, and 38 m high. Given that the density of seawater is 1.03 g/cm^3, how deeply is the hull submerged in the water?
26. (II) A hemispherically shaped bowl is floating on the surface of water; the mass of the bowl is 0.6 kg (Fig. 16–36). Water is poured into the bowl; when 4.3 × 10^3 cm^3 of water has been added, the bowl just sinks. What is the outer radius of the bowl?

▲ **FIGURE 16–36** Problem 26.



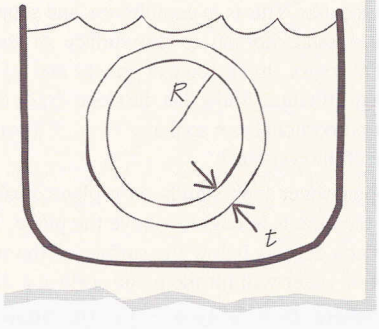
27. (II) Find the volume of the smallest block of ice which when floating on salt water will carry a person of mass 80 kg. Assume that the density of salt water is 1.03 × 10^3 kg/m^3. You will have to look up the density of ice.
28. (II) 75% of the volume of a sphere floating in a pool of mercury is above the surface. Given that the density of mercury is 13.6 × 10^3 kg/m^3, find the average density of the sphere.
29. (II) A group of Scouts intend to make a raft to float down the Ohio River. The mass of four of them plus their equipment is 400 kg. They find trees with an average diameter of 20 cm and a specific gravity of 0.80. Determine the minimum area of the log raft that would keep them dry.
30. (II) A temporary bridge is supported on floating empty drums that are 1.0 m in diameter and 1.8 m long. The design criterion is

that the drums may only be submerged to 2/3 of their diameter under a maximum load of 5000-kg trucks, 7.5 m long, that follow each other bumper to bumper in a single line. How far apart should the drums be placed? Neglect the weight of the bridge and of the drums.

31. (II) A valuable preserved biological specimen is weighed by suspending it from a spring scale. It weighs 0.45 N when it is suspended in air and 0.081 N when it is suspended in a bottle of alcohol. What is its density?

32. (II) Consider a spherical balloon filled with helium, with a density of 0.18 kg/m^3. The density of air is 1.3 kg/m^3. What must the radius of the balloon be in order to lift a load of 130 kg (including the mass of the balloon)?

33. (II) Olive oil floats on water. Take ρ_1 to be the density of the oil and ρ_2 to be the density of the water. Consider an oil–water interface across which a bouillon cube of density ρ_3 floats; use the geometry shown in Fig. 16–37. We know that for the oil to float on the water, ρ_1 must be less than ρ_2. What is the condition on ρ_3 so that the cube floats at the oil–water interface? How much of the cube will be in the water?



▲ FIGURE 16–37 Problem 33.

34. (II) A beaker of mass 350 g contains 2.8 kg of water and rests on a bathroom scale. A 5.2-kg block of aluminum, of specific gravity 2.7, is suspended from a spring scale and completely submerged in the water. Find the readings on both scales.

35. (II) Balloons of mass 3.5 g can be filled with helium to make spheres of radius 21 cm. How many of these balloons must a child of mass 32 kg hold in order to float off Earth's surface? Assume that helium has a density of 0.18 kg/m^3.

36. (II) An air-filled lead balloon of radius $R = 0.1$ m is totally submerged in a tank of water (Fig. 16–38). What is the thickness t of the lead skin of the balloon if the balloon neither rises nor sinks? The density of lead is 11.3×10^3 kg/m^3.

▲ FIGURE 16–38 Problem 36.

37. (II) (In this problem we ask you to draw the figure that is described here.) When a body floats it is because the downward force of gravity just cancels the upward force of buoyancy. This alone is not enough; one also wants to know if the floating is stable, that is, whether the floating object might tip over. In thinking about whether, say, a tilting boat will right itself, it is important to note that gravity acts as a single downward force passing through the center of mass of the body (denote this point by M) while the buoyancy acts as a single upward force *passing through the center of mass of the displaced fluid* (a point denoted by B). In equilibrium B and M lie on the vertical, with B usually below M. To determine stability, we look at the body tilted. Denote the new center of mass of the displaced fluid by C. Draw a vertical line up through C. If this line intersects MB below M then the torques due to the forces of gravity and the force of buoyancy act in the same direction, and the body will topple. (a) Draw a diagram to show that a wooden log will not float vertically in water. (b) Draw a diagram to show why having several people stand up in a canoe is likely to tip it over.

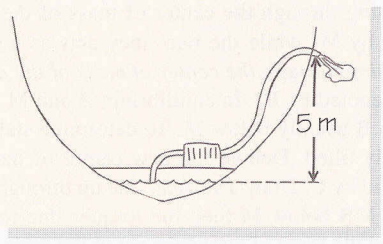
38. (III) A sphere of radius R of material with an average density of 0.82 g/cm^3 is immersed in a body of water. What is the height of that portion of the sphere that projects above the surface?

16–6 The Equation of Continuity

39. (I) Water flows at a speed of 1.3 m/s through a hose of diameter 1.5 cm and emerges from a nozzle of radius 0.50 cm. With what speed does the water emerge? How much water emerges from the nozzle per second?

40. (I) Water flows down a channel 1.0 m deep and 0.5 m wide at a rate of 2 metric tonnes/s. At some point the channel widens to 0.8 m. How fast does the water flow in the wider channel?

41. (I) A steady stream of automobiles moves along the eastbound side of a highway in a region where there is neither exit nor entrance. Where two eastbound lanes are available, the automobiles are spaced so that there are 66 cars per mile in each lane, and the average speed is 45 mi/h. In a region to the west, where three eastbound lanes are available, the automobiles are spaced to give 35 cars per mile in each lane. What is the average speed in the region where three eastbound lanes are available?



42. (II) A lawn sprinkler is connected to a garden hose of inside diameter 2.5 cm that has a water-flow rate of 0.5 L/s. The sprinkler has four nozzle openings, each with a diameter of 7 mm. (a) Calculate the speed of the water that emerges from the nozzles. (b) How could the nozzles be arranged to cause the sprinkler to rotate? What principle could you use to calculate the torque on the sprinkler? What are the limitations, if any, on the speed of rotation of the sprinkler?

43. (II) Students would like to spray water 18 m across their neighbor's yard onto a patio. They have a hose of inside diameter 1.5 cm that can spray a distance of only 1.5 m. What size nozzle do they need?

44. (II) When water drains out of a hole in the bottom of a tank, the stream radius contracts as the speed of the water in the stream increases. Assume that the stream starts with zero water velocity at the top of the tank, at a height H above the hole, and ignore the various instabilities that will eventually cause the stream to break up. Find the distance below the hole at which the radius of the stream is 80 percent of the hole radius.

16–8 Applications of Bernoulli's Equation

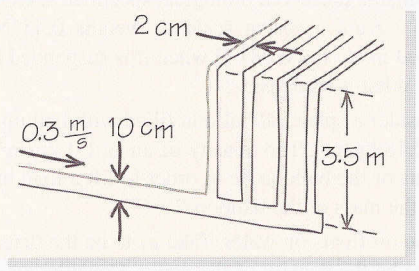
45. (I) A bilge pump is used to pump water out of a leaking ship (Fig. 16–39). The pump's hose has a diameter of 3.0 cm, and the pump moves water through the hose up and out of a porthole 5.0 m above the waterline at a speed of 4.0 m/s. Calculate the power of the pump.

▲ FIGURE 16–39 Problem 45.

46. (I) What pressure must a pump generate to get a jet of water to leave a nozzle at a speed of 8 m/s? Can this jet reach a height of 8 m above the nozzle? If so, what angle should the nozzle make with the horizontal so that the jet reaches 8 m at its maximum height?

47. (I) Wind gusts at 60 mi/h past a ship's cabin in which the air is at rest and the pressure is 1 atm. What are the pressure outside the cabin and the net pressure on the walls past which the wind blows?

48. (I) A stream of water sprays like a fountain vertically from a small hole in a pipe, reaching a height of 2.4 m. Assuming that the water in the pipe is static, what is the gauge water pressure in the pipe? (See Problem 8.)



49. (I) A folded piece of notebook paper can exhibit lift in the air flow from a fan of a window air conditioner. A plastic straw is taped perpendicular to the plane of the paper through the paper's middle, and a thread runs through the straw allowing the paper to move up and down the thread. The folded paper has an area of 300 cm^2. The air speed is about 4 m/s and the proportionality constant K in the approximate lift formula $KA\rho v^2$ is taken to be $K = 0.14$. Here, A is the surface area of the wings, ρ is the air density, and v is the air speed. How much lift is possible? Given the mass of the paper and straw to be 8 g, will the paper rise?

50. (II) A fountain shoots a vertical jet of water at a rate of 0.33 L/s to a height of 1.6 m. (a) What is the initial speed of the jet, and what is the radius of the hole out of which the jet passes? (b) What pressure must the pump of the fountain supply? (Assume that it sits just below the emerging jet.) (c) At height 1.2 m, what is the speed of the jet, and what is the radius of the column of water? Ignore effects of turbulence; in particular assume that the jet does not break up.

51. (II) Heavy rains have flooded your favorite professor's basement to a depth of 15 cm. This basement is 7.5 m × 12 m in area. You have a hose of diameter 1.2 cm and can run the hose from the water in the basement to a level 3 m below the level of the basement floor, into a low portion of the yard. When the hose is filled with water, it acts as a siphon (see Question 9) and empties the basement. (a) What is the speed of the stream of water leaving the hose? (b) Approximately how long does it take to empty the basement?

52. (II) A liquid of density 1.05×10^3 kg/m^3 flows in a horizontal pipe. The cross-sectional area in one part of the pipe is 42 cm^2. When the liquid enters another part of the pipe with cross-sectional area 56 cm^2, the pressure as measured by a gauge is 0.4×10^4 Pa higher than it was in the first part. Calculate the velocities of the liquid in the two parts of the pipe.

53. (II) A large horizontal pipe of diameter 10 cm contains water flowing with a speed of 0.3 m/s. The pipe branches into four pipelets, each of diameter 2 cm. The four pipelets each run horizontally after an initial height change of 3.5 m (Fig. 16–40). (a) What are the speeds of the fluid in the horizontal portion of each pipelet? (b) If the pressure in the large pipe is $p = 2.5$ atm, what is the pressure in the pipelets?

▲ FIGURE 16–40 Problem 53.

54. (II) A uniform glass tube with internal cross-sectional area A is formed into a U-shape and partly filled with a volume V of an incompressible fluid of density ρ. The two ends of the tube are open to the atmosphere. At equilibrium, the level in each vertical segment of the tube is $h = 0$. By applying additional pressure to one end of the tube, the levels of the liquid are displaced, so one side is at height h_0 and the other is at height $-h_0$. The additional pressure is suddenly released, and the liquid level starts to oscillate. (a) Use Bernoulli's equation to show that the force on the fluid in the tube is proportional to the displacement of the fluids from their equilibrium levels, so the force is harmonic. (b) Find the "spring constant" of the harmonic motion described in part (a) and use it, together with the mass in motion (ρV), to calculate the oscillation frequency.

55. (II) Water flows through a large horizontal pipe of diameter D at speed v_0. The pressure in the pipe is p_0. The pipe branches into two horizontal pipelets of diameter d_1 and d_2, respectively, both at the same height as the large pipe. Write the equations that would allow you to find the pressures p_1 and p_2 and the speeds v_1 and v_2 in the two pipes. Show that one of these four quantities must be known to be able to solve for the others.

56. (II) A vertical cylinder of height 1.0 m and radius 10 cm is filled with water and placed at the edge of a table. A 1 cm diameter hole is drilled in the side wall near the base. Water starts flowing out, forming a stream that passes over the edge of the table. Neglecting any turbulence, calculate the velocity of the water as it leaves the cylinder. What will be the diameter of the stream of water at a point 1.0 m below the opening?

57. (III) The surface of a bucket of water centered on a rotating turntable will form a parabola with its minimum on the rotation axis. Prove that this is the case by the consideration of a small mass element at the surface, located at the point (y, r), where y is the height from the eventual minimum on the axis and r is the radial distance from the axis. This is in equilibrium, and subject to (a) the atmospheric pressure normal to the surface of the liquid at the location of the mass, (b) the force of gravity, and (c) the forces associated with the rotation. Show that the slope dy/dr at the location of the mass is proportional to r, so that $y = y_0 + (\text{constant})r^2$. What is the value of the constant?

58. (III) An open water tank stands on a plane surface. The water surface in the tank is a height h above the plane. A small hole is opened up at a depth y below the surface of the water. (a) Show that the jet of water will hit the plane surface a distance D from the tank, where $D = \sqrt{4y(h - y)}$. (b) Show that the hole should be placed at a depth $y = h/2$ for the jet to cover a maximum horizontal distance.

*16–9 Real Fluids

59. (II) The retarding force on a sphere of radius R that moves with speed v through a fluid of viscosity η is proportional to η and depends on R and v, in the form $R^a v^b$. Use dimensional analysis to determine the powers a and b.

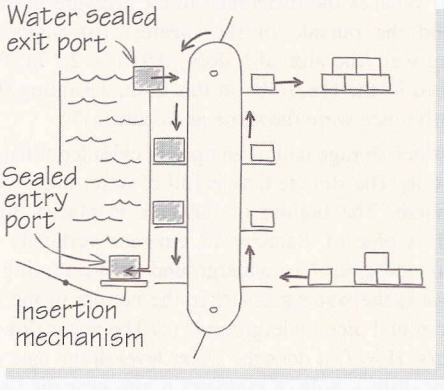
60. (III) The result of the solution of Problem 59, the retarding force on a sphere of radius R that moves with speed v through a fluid of viscosity η, is $F = 6\pi\eta Rv$, known as *Stokes's law.* Such a sphere, with mass density ρ_m, falls through glycerin, whose density is ρ. The forces on the sphere are the retarding Stokes's law force, the buoyant force, and the force of gravity. (a) Derive a formula for the value of the velocity v_t for which the net force is zero. (b) How does v_t depend on the radius of the sphere? (c) If the viscosity of glycerin is $8.3\ \text{kg/(m}\cdot\text{s)}$ and its density is $\rho = 1.26 \times 10^3\ \text{kg/m}^3$, what is the terminal velocity v_t of a sphere of iron, which has $\rho = 8.5 \times 10^3\ \text{kg/m}^3$ and a diameter of 5 cm? Of an iron sphere with a radius of 1 mm?

General Problems

61. (II) A rectangular container is divided into two parts by a movable vertical partition. This partition is sealed so that no water can seep from one side to the other. Initially, the wall is held in the middle of the 30-cm length of the container. One side is filled with 2 kg of water to a depth of 10 cm; the other side is attached to a spring in equilibrium (unstretched, uncompressed). The spring constant is 180 N/m. The partition is now released and the spring compresses. What is the position of the partition at maximum compression? Assume that the process takes place without turbulence so that no energy is dissipated.

62. (II) A hollow sphere of radius 0.08 m and total mass 0.35 kg is placed in water. One very small lead pellet of mass 0.08 kg is attached to the inside surface of the sphere. When the sphere is floating in equilibrium, the lead pellet is oriented on the bottom. If the sphere is rotated slightly, so that the pellet is moved off to the side, and then released, the sphere will rock, and the pellet will move like a pendulum. Calculate the period of small oscillations for this motion. Assume that the center of the sphere does not move.

63. (II) A depth of about 100 ft ($\approx$30 m) is as deep as a scuba diver should go without special precautions because of an effect that causes disorientation. What is the water pressure at a depth of 30 m? Does a scuba diver take in the same mass of air in each breath at 30 m that he or she would at a depth of 5 m? Explain.

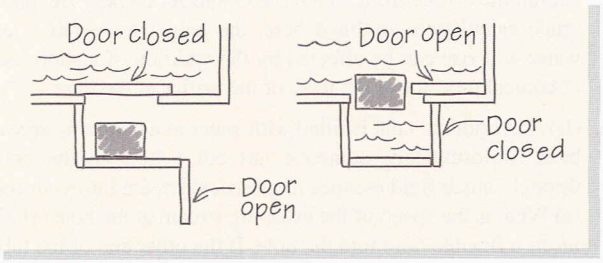


64. (II) A cylindrical bucket of fluid of density ρ sits at the center of a turntable that rotates with some fixed angular velocity, ω. Show that the pressure variation in the fluid at a horizontal distance r from the axis is given by $p = p_{\text{axis}} + \frac{1}{2}\rho\omega^2 r^2$. [*Hint*: If you place yourself within the rotating fluid and at rest relative to it, the problem is one of hydrostatics. The only force in the horizontal direction is a fictitious force away from the axis of the rotation, due to the fact that your frame of reference is not inertial. This force is the centrifugal force.]

65. (II) Late in the seventeenth century, King Louis XIV of France had a series of fountains constructed at Marly, some 20 km from his chateau at Versailles. These fountains were fed from the Seine River, whose altitude is some 150 m below that of Marly, through a remarkable series of pumps. The tallest of these fountains was the Grand Jet, which is calculated to have risen a height of 37 m from its base. (a) At what speed does this jet leave the orifice at the fountain's base? (b) The rate of flow in the Grand Jet is measured to be $0.051\ \text{m}^3/\text{s}$. Compare this to an estimate of the rate of flow from a garden hose. (c) Given the rate of flow in part (b), calculate the area of the orifice from which the Grand Jet comes. (d) What is the pressure of the water just behind the orifice from which the Grand Jet comes? Beyond the crude calculations outlined here, the height to which a jet of water will rise can be affected by the addition of a short length of conical pipe above the level of the orifice at the base.

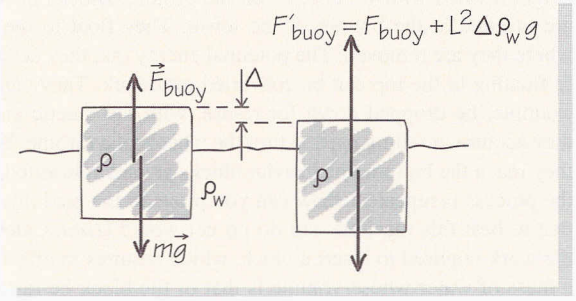
66. (II) A cylindrical tank is filled with water to a height h_1 above its base. Unfortunately, someone has cut a hole in the bottom through which fluid escapes in a vertical stream into your room. (a) What is the speed of the escaping stream at the hole? (b) You insert a flexible hose into the hole. If the other end of the tube is held at the same height as the base of the tank and is directed horizontally, what is the speed of the water as it leaves the hose? (c) You hold the tube, whose end is still at the height of the base of the tank, so that the stream is directed straight up. How high does the escaping stream shoot?

67. (II) An inventor proposes to you the following perpetual motion machine (a machine that can do work "forever" without your having to add energy to it) (Fig. 16–41). A cylindrical tower of height h filled with water rests on the ground. Blocks of wood are inserted at the bottom of the tower. They float to the top, where they are removed. The potential energy that they acquired in floating to the top can be converted into work. They can, for example, be dropped down for re-use, with the kinetic energy they acquire in falling used to turn the wheels of a turbine. When they reach the bottom, the heavier blocks are again inserted, and the process is repeated. How can you prove to the mad inventor that at best this machine can do no net work? [*Hint*: Calculate the work required to insert a block, which requires in effect that a mass of water whose volume is that of the block be raised to the top. Compare this to the energy the block acquires in being accelerated to the top under the influences of gravity and the buoyant force. Neglect any drag caused by the water.]



Do not buy this machine! Perpetual motion machines are impossible to construct (see Chapters 18 and 20). A close analysis of the details of such machines always reveals this fact.

▲ **FIGURE 16–41** Problem 67.

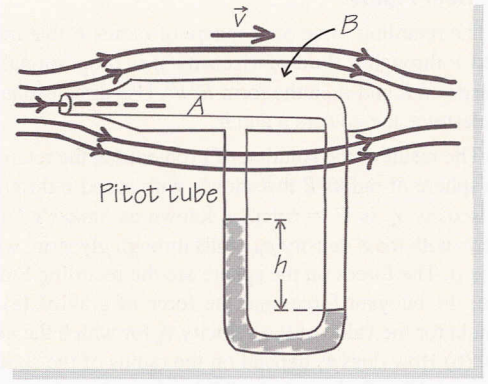


68. (II) Consider the machine discussed in Problem 67. Why does the machine still fail if you replace the entry port by an exchange chamber (Fig. 16–42, see next page) with two sliding doors, so that the insertion of the blocks does not require that work be done?

69. (II) A cubical block of wood 0.20 m on each side floats in water, with 8.0 cm of the block above the surface of the water (Fig. 16–43). (a) What is the density of the wood? (b) Suppose that the block of wood is pushed down below the equilibrium level by a distance Δ. What is the magnitude of the restoring force that pushes the wood back toward the equilibrium level? (c) In general, if dissipation of energy is ignored, the block will overshoot the equilibrium level and rise to a height Δ above that level, and is then subjected to a downward force. How large is that force?

▲ **FIGURE 16–42** Problem 68.

(d) Recall from Chapter 13 that a force that is proportional to the displacement Δ from equilibrium (of the form $F = -k\Delta$) and acts on an object of mass m leads to oscillations with the frequency $f = (k/4\pi^2 m)^{1/2}$. Calculate that frequency for the block that bobs in the water.



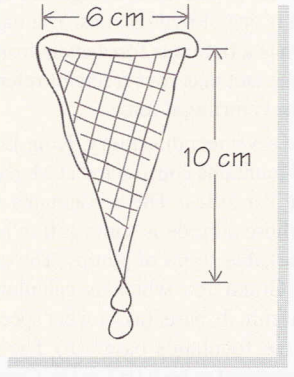
▲ **FIGURE 16–43** Problem 69.

70. (II) The ticket-window opening of a movie theater, where money goes into the cashier's hands and tickets emerge, is a rectangle 12 cm × 15 cm. A breeze of speed 3 m/s comes out of this opening. Sometimes, as a result, paper money goes flying. (a) What is the difference in air pressure between the inside and the outside of the theater? (b) Suppose that the opening were the size of a door, 0.9 m × 2.1 m. What would the speed of the breeze be in this case, assuming the air pressure difference were the same as in part (a)?

71. (II) A water-storage tank is an upright cylinder of height 8 m and radius 6 m. The storage tank is full of water but is vented to the atmosphere. The bottom of the tank is placed 30 m off the ground. A pipe of diameter 12 cm runs vertically down from the tank and goes 1 m underground before turning horizontal. (a) What is the water pressure in the bottom of the tank? (b) in the horizontal pipe underground? (c) The water flow in the pipe is 80 L/s. How fast does the water level in the tank drop? (d) A saboteur drills a hole of diameter 6 mm near the bottom of the tank. How fast does the water shoot out? (e) What volume flow of water is lost out the hole?

72. (II) A *Pitot tube* is a device for measuring flow velocities (Fig. 16–44). It is as useful for measuring the flow velocity of blood in an artery as for measuring the air speed of a jet airplane. The fluid passes the opening at point B, creating a pressure p_B inside. The fluid enters the opening of the tube and comes to a halt, creating a pressure p_A. Apply Bernoulli's equation as needed to show that the flow velocity is given by $v = \sqrt{2(p_A - p_B)/\rho} = \sqrt{2gh\rho_\ell/\rho}$, where ρ is the density of the fluid being measured, ρ_ℓ is the density of the fluid shown in the device, and h is the difference in height of the liquids.

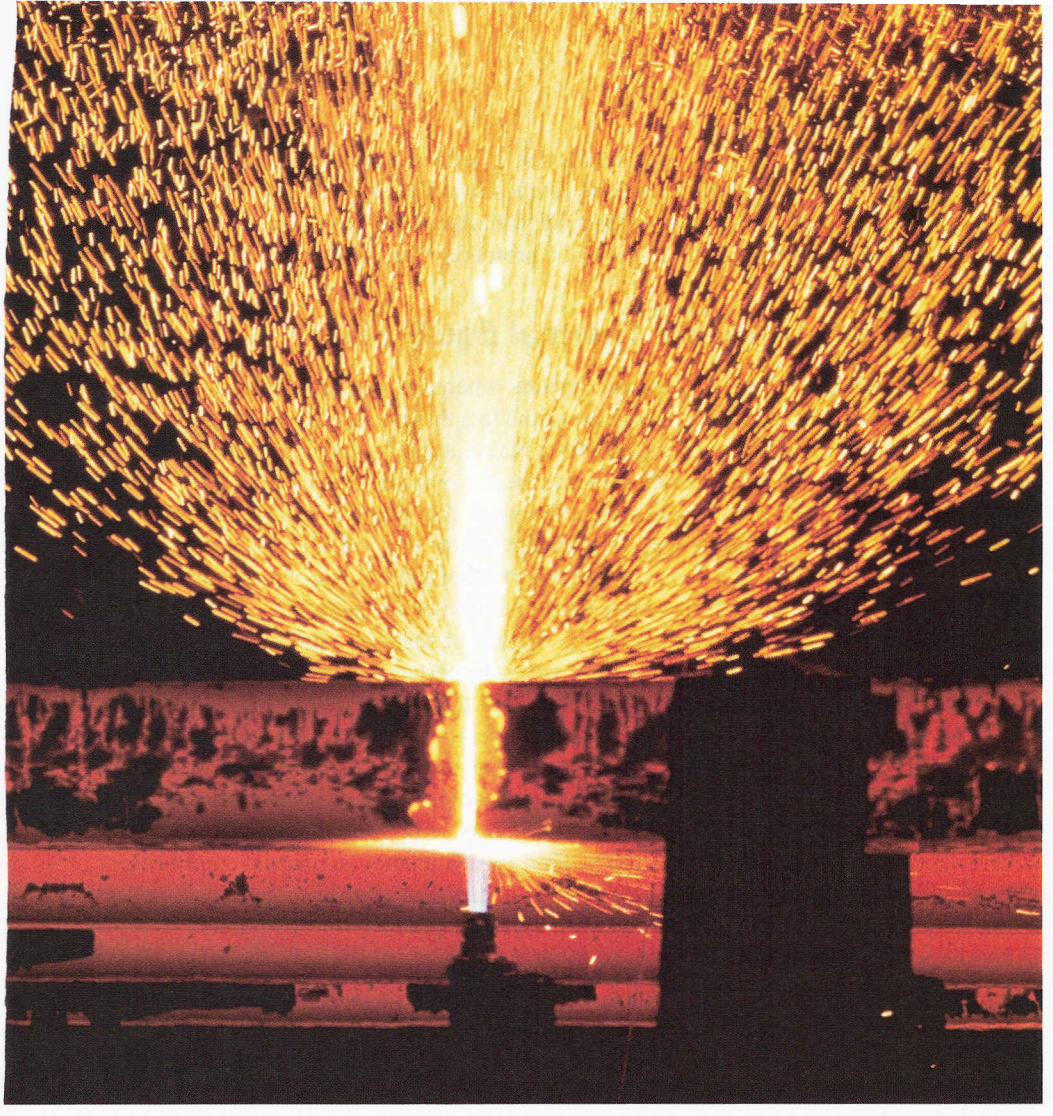
▲ **FIGURE 16–44** Problem 72.



73. (II) With a siphon, it is possible to transfer fluids from one container to another. Figure 16–31 shows a siphon that must be filled with fluid to start the transfer. If the speed with which the fluid leaves the higher container is zero, and if the fluid has a fixed density ρ, find an expression for the speed of the fluid as it enters the lower container, in terms of the heights h_0 and h_1.

74. (III) A tank of surface area A is filled with water to a height x above the position of a hole of surface area σ, and the water flows out. Assume throughout that the fluid speed is zero at the top surface. (a) How much water flows out of the hole in the first time interval Δt after the hole is opened? (b) How large is the drop in the water level, Δx, in that time interval? (c) Use the results of parts (a) and (b) in the limit of small Δt to express a relation of the form $dx/dt = f(x)$. This is a differential equation for the height as a function of time. Take care to get the right signs, noting that x decreases with time, so that Δx is a negative quantity. (d) Show that this equation is solved by the formula

$$x(t) = \left[\sqrt{x_0} - \frac{1}{2}\left(\frac{\sigma}{A}\right)t\sqrt{2g}\right]^2.$$



(e) How long will it take for the water to drop to the level of the hole?

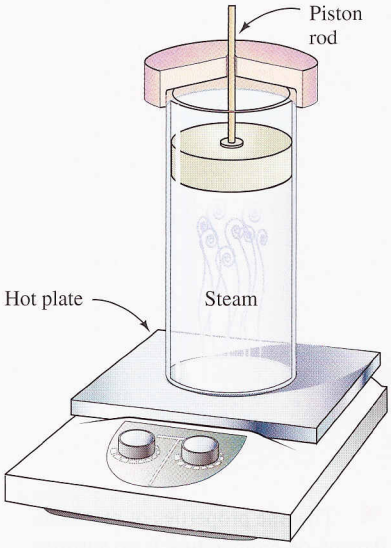
75. (III) The ice-cream cone shown in Fig. 16–45 is filled with melted ice cream of density 1.2 g/cm^3. The cone has a diameter of 6 cm at the larger end and is 10 cm long. Find the pressure at the bottom of the cone. If a small hole of diameter 1 mm is opened at the bottom, the ice cream starts to run out. Ignoring the viscosity of the melted ice cream, find the amount of time it takes the ice cream to run out. Assume that the fluid speed is zero at the top.

▲ **FIGURE 16–45** Problem 75.

Chapter 17

That the properties of materials depend on temperature is no surprise. Whether we are referring to the steel being worked in this photograph or to the properties of the air over the polar ice cap, we would fail to pick out essential features if we did not recognize the role of temperature.

Temperature and Ideal Gases



Many properties of the physical world depend on temperature. For example, the compound water behaves quite differently at temperatures below its freezing point than it does at temperatures above its boiling point. Temperature has something to do with energy, as we can see from the fact that hot steam can lift a piston, and the hotter the steam, the better it is able to perform the work. How much energy does hot steam contain, and how does that energy get into the steam? How can we quantify "hotness" or "coldness?" To answer these questions, we will consider both the macroscopic properties and microscopic behavior of gases, liquids, and solids, focusing primarily on gases. These properties lead us to a good definition of temperature. We will see how temperature relates to energy, how that energy is like the mechanical energy we have earlier studied, and how efficiently that energy can be used.

The historical development of thermal physics was based on the properties of bulk matter—such as density, pressure, volume, and temperature—before atomic theory was well established. The study of thermal phenomena received its strongest impetus from engineers who studied the steam engines that powered the Industrial Revolution of the 19th century. Their treatment of thermal phenomena on the macroscopic scale is known as **thermodynamics**. Nineteenth-century physicists also learned how these macroscopic phenomena could be understood in terms of the behavior of the atomic constituents of matter. This work, known as **statistical mechanics**, brings in an entirely new idea—that it

is the statistical behavior of these constituents that is reflected in thermal behavior in the macroscopic world. All these topics will be discussed in Chapters 17 through 20 under the general heading of thermal physics. Thermal phenomena are pervasive in the physical world, and our understanding of them has had a profound effect on the way we live.

17–1 Temperature and Thermal Equilibrium

We call a physical system a **thermal system** whenever we are interested in its temperature-dependent properties. By virtue of the fact that it is hot, steam can lift a piston and do work on its surroundings, so that a piston and a cylinder full of hot steam (Fig. 17–1) form a good example of a system that is worth keeping in mind as we proceed, even if we will be more interested in the work that thermal systems do in later chapters. We all have an intuitive feeling for temperature—for example, we can usually tell when one system is hotter than another or, in other words, that its temperature is higher. Our aim here is to develop a more precise notion of temperature.

▲ **FIGURE 17–1** A bottle of hot steam with a piston at one end provides us with a system that can do work by virtue of the thermal properties of the steam. In particular, the hotter the steam, the farther it can move the piston.

▲ **FIGURE 17–2** The vendor's stand is not in thermal equilibrium with its environment. The steam is evidence of an interaction with the surroundings that would eventually cool the stand down to where it would be serving frozen hot dogs.

Central to the idea of temperature is the notion of thermal equilibrium. Suppose that we pour cold water into a bucket of hot water. Experience shows that after a short time the water becomes lukewarm throughout. Until that point, we cannot say that the water has a particular temperature. When the temperature and temperature-dependent quantities are no longer changing, we can say that **thermal equilibrium** has been reached (Fig. 17–2). At this point the temperature becomes a variable that characterizes the whole bucket of water; that is, the whole thermal system. Similarly, the gas in a container eventually comes to thermal equilibrium if its container is in thermal equilibrium with its surroundings, and two containers of gas at different temperatures will come to thermal equilibrium if they are allowed to mix. One mechanism for this process is collisions between the constituent molecules of the gas, but as we shall see there are other mechanisms and mixing is not necessary. We shall see in some detail that the temperature is a measure of how fast the molecules of the gas are moving, and in collisions between fast-moving and slow-moving molecules, the fast-moving ones will generally slow down and the slow-moving ones speed up, thus bringing the ensemble to a common temperature.

If two thermal systems are in thermal equilibrium with one another, then *they have the same temperature*. We can add that if two systems are each in thermal equilibrium with a third, then they are in thermal equilibrium with one another. The observation that if system A is in thermal equilibrium with system B, and if system B is in thermal equilibrium with system C, then A is in thermal equilibrium with C is sometimes called the **zeroth law of thermodynamics.**

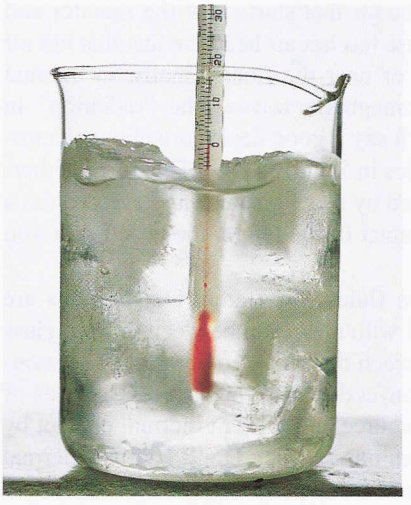
If we put an ice cube into a bathtub full of hot water, the temperature of the tubful of water changes very little; if we add a teaspoon of hot water to a swimming pool, the temperature change is virtually undetectable. These observations allow us to define a **thermal reservoir** (or **heat bath**) as a thermal system so large that it maintains a constant temperature when it interacts with other thermal systems. A thermal reservoir is of importance because it allows us to bring a given (smaller) system to a predetermined temperature, the temperature of the reservoir, simply by bringing the system into **thermal contact** with the reservoir.

Thermal contact is established between thermal systems in three important ways. We can illustrate them with two metal plates in an enclosure, one red hot and the other cold. Thermal contact by *conduction* occurs when the two plates actually touch. "Something" passes between them, which with foreknowledge we can describe as the agitation of the molecules of the hot plate passing through collisions to the agitation of the molecules of the cold plate. When you sit on a cold metal bleacher seat at a football game, there is thermal contact by conduction between you and the seat. Thermal contact by *convection* occurs when there is a fluid (a liquid or a gas) between the plates. The fluid acts as a third thermal system whose temperature increases in the region near the hot plate through its own thermal contact with the plate. The fluid then circulates in currents to the colder plate, increasing its temperature. The reason for this circulation has to do with thermal properties of the conducting fluid; for example, as we saw in Chapter 16, hot gas is less dense than cold gas, so that it tends to rise. If you live in a

house with radiators, then you are warmed by the air that starts near the radiator and then circulates in the room. Similarly, if your house has hot air heat, the fact that hot air rises explains why heating ducts are placed on or near the floor. Finally, in thermal contact by *radiation*, a hot plate emits electromagnetic waves—the "radiation" in question—while a cold plate absorbs them. (We'll say a good deal more about electromagnetic radiation in the context of thermal physics in Section 17–5.) This form of thermal contact operates even with the plates separated by some distance and even across a vacuum. You experience this form of thermal contact if you tan on the beach or if you stand in the vicinity of a fire.

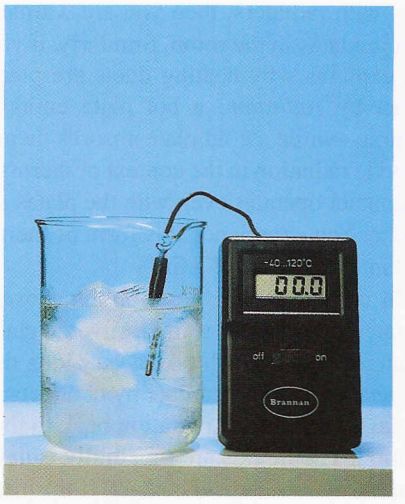
In contrast to the descriptions above, if two fluids at different temperatures are separated by a double-walled, silvered glass flask with a vacuum between the two glass surfaces, the fluids will take a very long time to reach the same temperature. The vacuum prevents thermal contact by conduction or convection, and the silvered surfaces of the glass walls reflect radiation back to the heat source and prevent thermal contact by radiation. The liquids are **thermally isolated** from one another. Don't confuse thermal contact with mechanical contact. If the pistons in an automobile engine were not in mechanical contact with the drive train, the car could not go very far, but the manufacturer goes to some length to keep the hot cylinders and their contents out of close thermal contact with most of the remainder of the vehicle.

THINK ABOUT THIS . . .



IS IT EASY TO MAKE A POT OF TEA IN A SPACE STATION?

That depends on the method you use. Aside from the fact that you would have to make sure the pot was closed to keep the water from drifting out, the technique you use for boiling water would have to change from what you do at home. On Earth the heating of a pot of water proceeds as follows: The water at the bottom becomes heated first, by conduction, and then a process of convection begins. The liquid moves in a circular pattern. The hot water rises, because on heating it expands, and since the density of the hot water is lower, there is a buoyant force. The hot water then pushes the cold water from above it to the bottom and the process continues until the water is uniformly heated. On a space station, the fact that the density of hot water is less than that of cold water makes no difference, because without an "up" or "down" as on Earth, there is no buoyancy. So some external stirring mechanism is needed to help you boil the water. Or you could wait for the entire pot to heat by conduction, a slower process. We might guess that microwaving a container of water would be a good way to proceed, since with a good microwave oven the heating of the water occurs uniformly throughout the volume.



Thermometers

A **thermometer** is a device that measures the temperature of a thermal system quantitatively, generally by coming to thermal equilibrium with that system. A thermometer must satisfy several criteria. It should have a minimal effect on the system being measured. (A small room thermometer brought inside from the cold will have this property.) The thermometer must make good thermal contact with the system being measured. Like a meter stick for measuring length, the thermometer should have a reproducible and easily read scale.

There are several properties of matter that are suitable for thermometry. Ordinary fever thermometers rely on the fact that fluids, such as mercury, expand and contract when their temperatures change. We can therefore make a thermometer by marking numbers on a column of mercury that measure the mercury's volume. Other properties, such as the pressures and volumes of gases, the volumes of liquids or solids, reflective properties of liquid crystals, electrical and magnetic properties of solids, and the color of light emitted by hot objects, all vary with temperature and can be used as thermometers (Fig. 17–3). Not all of the properties of matter that depend on temperature, however, are suitable for making thermometers: The brittleness of many materials depends on temperature, but we would not make a thermometer that works by seeing how easy it is to smash a material with a hammer! Table 17–1 lists some useful thermometers.

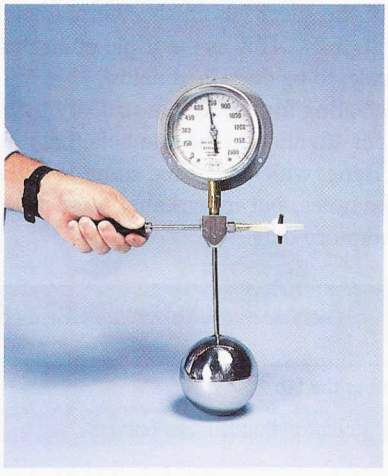
(a)

(b)

▶ **FIGURE 17–3** (a) This thermometer contains a (red) fluid that expands at higher temperatures and contracts at lower temperatures. (b) This digital thermometer uses the temperature dependence of electronic properties of materials. It is calibrated in the Celsius scale, in which the temperature of ice melting in pure water is 0 degrees.

TABLE 17–1 • Some Thermometers

Thermometer	Physical Property Measured	Comments
Ideal gas	Pressure and volume of dilute gas	See Section 17–2
Mercury bulb	Expansion or contraction of fluid	Good where fluid does not change phase
Bimetallic strip	Difference in expansion of two metals	
Resistance	Electrical resistance	See Chapter 26
Thermocouple	Electrical voltage across different metals	Most widely used thermometer in industry
Paramagnetic	Magnetic properties of matter	Useful at ultracold temperatures; see Section 31–5
Optical pyrometer	Color of emitted light	Useful at high temperatures; see Section 17–5



CONCEPTUAL EXAMPLE 17–1 A friend proposes that you check the temperature of boiling water that you have prepared in order to make some hot tea by dumping 10 large ice cubes of a calibrated size in it and seeing how long it takes for the ice cubes to melt. What is wrong with this thermometer?

Answer This is indeed a thermometer, and assuming that the initial temperature of the ice is known, a measurement of the melting time would indeed give you a way to measure the initial temperature of the water. However, this thermometer would change the temperature of the very system it is supposed to measure. By the time you complete your measurement, your water would be too cold to make your tea!

17–2 Ideal Gases and Absolute Temperature

Consider a gas in a container of fixed volume with a gauge that can read the pressure of the gas (Fig. 17–4). If we dip the container into thermal reservoirs at various temperatures, we find that as the gas becomes hotter, its pressure increases. The pressure correspondingly decreases when the gas becomes colder.

We can alternatively arrange to allow the volume to vary while keeping the pressure fixed, as in Fig. 17–1, with masses of various sizes sitting on the top of the piston. We find that the hotter gas has a larger volume for a fixed pressure, while the colder gas has a smaller volume for that same pressure. In fact, if we take all this into account, we find the following relation between the pressure p, the volume V, and the amount of gas n:

▲ **FIGURE 17–4** A container of gas of fixed volume with means to measure the pressure of the gas. This system forms a constant volume thermometer whose pressure is a measure of the temperature of the system with which the gas is in thermal contact.

The product of pressure and volume divided by the amount of gas in the bottle increases or decreases according to whether the thermal reservoir in contact with the bottle is hotter or colder, respectively. We accordingly define temperature T as proportional to the product of pressure and volume, divided by the number of moles, that is, $T \propto pV/n$.

The *constant volume gas thermometer* that we are describing here comes extremely close to being a universal thermometer because experiment shows that the proportionality constant is the same for all gases as long as their *densities are sufficiently low.* Dilute (or low-density) gases, which we call **ideal gases**, will enable us to give an unambiguous definition of temperature, a definition that can be employed by anyone who follows the simple set of instructions that we'll give below. In other words, we will have a thermometer that meets the requirements we have laid out. Just how dilute the gas needs to be is simply a question of the accuracy demanded of the thermometer. The lower the density of the gas, the more 'ideal' the behavior of the gas. Gas thermometers accurate enough for laboratory use may contain gas hundreds of times less dense than air at sea level.

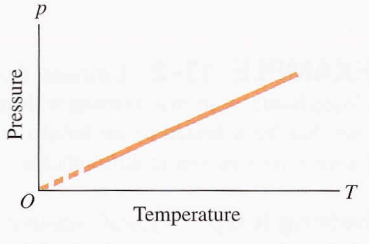


Figure 17–5 plots the pressure of a fixed amount of a dilute gas at fixed volume against our temperature scale. The dashed part of the curve, near where T and p drop to zero, is an extrapolation and is drawn as a straight line.

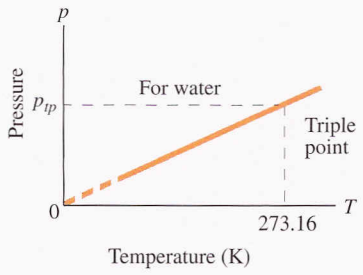
We have not yet set our temperature scale. To do so, work with a constant-volume ideal gas thermometer and define the temperature $T = 0$ as the point where the pressure, p, would become *zero* (if that were possible), so



$$\text{for constant volume: } p = (\text{a constant}) \times T. \tag{17–1}$$

The point $T = 0$ is sometimes called **absolute zero**. Although experiments have come quite close to absolute zero, this temperature cannot in fact be reached and it corresponds to an extrapolation. We need to specify the constant in this relation, and we do so by defining T at some other point. This second point, called a *defined point*, was chosen in 1968 by international agreement to be the **triple point** of water. The triple point of water is the state at which water vapor, liquid water, and frozen water coexist. This can only happen at a single pressure p_{tp} (= 4.58 mm of mercury) and temperature; that temperature is defined as 273.16K. The letter K stands for kelvin, and the temperature scale so defined is the **Kelvin scale**, after Sir William Thomson, Lord Kelvin, who did important work on thermal phenomena and on electricity and magnetism during the mid- to late nineteenth century.) To summarize, temperature in the Kelvin scale, T, is defined by a constant-volume ideal-gas thermometer as

$$T = \left(\frac{p}{p_{tp}}\right) 273.16\text{K}, \tag{17–2}$$

▲ **FIGURE 17–5** As p varies in an ideal gas of constant volume, T is defined by drawing a straight line.

▲ **FIGURE 17–6** The Kelvin temperature scale is defined by a constant-volume ideal-gas thermometer. The two fixed points are $T = 0$K, located where p extrapolates to zero, and $T = 273.16$K, located at the pressure of the triple point of water, where $p = p_{tp}$.

where p is the pressure of the ideal gas in the thermometer. Figure 17–6 illustrates Eq. (17–2). The assignment of 273.16K as the triple point makes the Kelvin scale compatible with the Celsius scale, to be described below.

Table 17–2 gives us a feeling for the Kelvin scale by listing some temperatures that occur in nature. We call your attention to the numbers that refer to the origin of our universe in the so-called Big Bang, which occurred some 13 billion years ago. No one was around at that time to take notes, but remarkably these values can be estimated with some confidence from laboratory data.

TABLE 17–2 • Temperatures Occurring in Nature

Physical System	Temperature (K)
Lowest temperature reached in the lab	$\cong 10^{-9}$
Temperature of background radiation that fills the universe	3
Liquid helium at 1 atm	4.2
Coldest recorded outdoor temperature on Earth	185
Average surface temperature on Mars	218
Freezing point of water	273.15
Typical sea-level temperature on Earth	300
Body temperature	310
Hottest recorded outdoor temperature	331
Boiling point of water	373
Melting point of gold	1335
Surface of the Sun	6000
Interior of the Sun	10^7
Helium fusion reaction	10^8
Interior of hottest stars	10^9
Universe at 3 min after the Big Bang	5×10^8
Universe at 1 s after the Big Bang	10^{10}
Universe at 10^{-6} s after the Big Bang	10^{14}
Universe at 10^{-12} s after the Big Bang	10^{16}

EXAMPLE 17–2 Estimate the pressure in a hypothetical closed bottle of air that, starting with sea-level temperature and pressure, has been heated to the temperature of the surface of the Sun. Express your answer in atmospheres.

Setting It Up "Typical" sea-level temperature and pressure are 300K and 1 atm, respectively. As Table 17–2 shows, the temperature at the Sun's surface is 6000K.

Strategy We assume that the gas in the bottle is ideal over the temperature range involved. According to Eq. (17–1), the ratio of the two temperatures in question—300K and 6000K—is the same as the ratio of the two pressures.

Working It Out If we refer to the temperature and pressure on Earth and the Sun with the subscripts E and S, respectively, we have

$$\frac{p_E}{T_E} = \frac{p_S}{T_S};$$

$$p_S = p_E\left(\frac{T_S}{T_E}\right) = 1 \text{ atm}\left(\frac{6000\text{K}}{300\text{K}}\right) = 20 \text{ atm}.$$

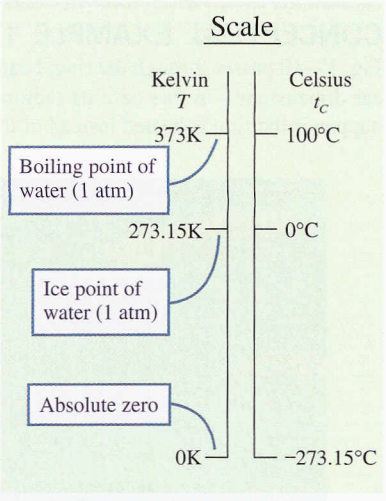
Ideal-gas thermometers are not very practical at high temperatures, as it is not easy to construct a suitable container for temperatures much above 2000K, even at atmospheric pressure.

What Do You Think? According to Fig. 17–5, there also seems to be a difficulty in producing ideal-gas thermometers at low temperatures and pressures. Why is this so? *Answers to **What Do You Think?** questions are given in the back of the book.*

Other Temperature Scales

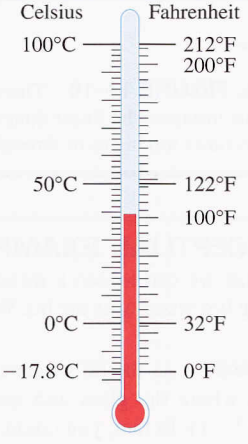
By changing both the slope and the intercept in Fig. 17–6, we can construct other temperature scales. Equivalently, if two points on the linear curve are assigned to special temperatures, a new scale emerges. The temperature in the **Celsius scale**—once known as the centigrade scale—is denoted by t_C and measured in units of °C. It assigns the

value $t_C = 0°C$ to the freezing point of water at 1 atm of pressure (the *ice point*) and $t_C = 100°C$ to boiling water at 1 atm. From Fig. 17–7, we see that



$$t_C = T - 273.15, \tag{17–3}$$

where T is the temperature in the Kelvin scale.† Note that the slopes of the Kelvin and the Celsius scales are exactly the same.



Other scales differ from the Kelvin scale in slope as well as in zero level. The **Fahrenheit scale**, in which the temperature t_F is measured in °F, is an example. Different scales are useful for different purposes, and the Fahrenheit scale was invented with humans in mind. The ice point of water is 32°F, the temperature of the human body is about 100°F, and the steam point of water is 212°F. The relation between the Fahrenheit scale and the Kelvin scale is

$$t_F = \frac{9}{5}T - 459.67, \tag{17–4}$$

with T again measured in kelvins. We can easily find the relation between any two scales (Figs. 17–7 and 17–8).

▲ **FIGURE 17–7** Comparison of the Kelvin and Celsius temperature scales.

▲ **FIGURE 17–8** Comparison of the Celsius and Fahrenheit temperature scales.

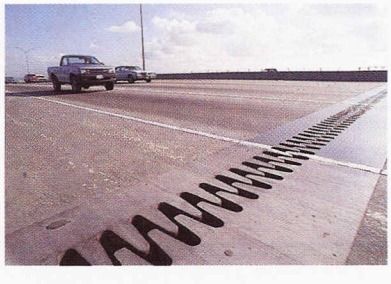
17–3 Thermal Expansion

Observation shows that a solid expands when its temperature increases. A simple demonstration of this fact is shown in Fig. 17–9. Empirically, this expansion is described by the **coefficient of thermal expansion**, α, defined by

$$\alpha \equiv \frac{1}{L}\frac{dL}{dT}. \tag{17–5}$$

The quantity $\alpha\Delta T$ is the fractional change $\Delta L/L$ in the length L of a solid due to a change ΔT in its temperature. In principle, the coefficient α is a function of temperature T, but tends to vary quite slowly with T. The analogous **coefficient of volume expansion**, β, is simply related to α. It gives the fractional change in the volume V due to a temperature change ΔT: $\beta\Delta T = \Delta V/V$, or

$$\beta \equiv \frac{1}{V}\frac{dV}{dT}. \tag{17–6}$$



We can show that $\beta = 3\alpha$ by considering a cube of volume $V = L^3$. We have

$$\beta = \frac{1}{V}\frac{dV}{dT} = \frac{1}{L^3}\left(3L^2\frac{dL}{dT}\right) = \frac{3}{L}\frac{dL}{dT} = 3\alpha. \tag{17–7}$$

This result applies as long as the material is *isotropic*; that is, its properties are the same in any direction within the material. Unless a uniform solid is a single crystal, with consequent preferred directions, we would normally expect it to be isotropic. Thermal expansion also occurs in liquids, which are more correctly described as isotropic than are solids. The volume expansion coefficient β is usually given when liquids are involved. Both β and α are measured in units of K^{-1}. Table 17–3 lists some thermal expansion coefficients.

TABLE 17–3 • Coefficients of Thermal and Volume Expansion (at 20°C)

Material	$\alpha(K^{-1})$	Material	$\beta(K^{-1})$
Aluminum	23.0×10^{-6}	Ethyl alcohol	11.2×10^{-4}
Copper	16.7×10^{-6}	Gasoline	9.5×10^{-4}
Iron	19×10^{-6}	Mercury	1.82×10^{-4}
Pyrex glass	3.2×10^{-6}	Water	2.07×10^{-4}
Fused quartz	0.42×10^{-6}		
Steel	10.5×10^{-6}		

▲ **FIGURE 17–9** The expansion joint in this bridge allows the material of the bridge to undergo expansion in hot weather and contraction in cold weather.

†The difference of 0.01 between 273.16 in Eq. (17–2) and 273.15 here is the difference between the temperature of water at its triple point and water at its ice point.

CONCEPTUAL EXAMPLE 17–3 The unheated ball in Fig. 17–10 passes through the ring; heated it will not, because its linear dimensions—in this case its radius—have increased. What will happen if the ring is heated instead of the ball?

Answer In thermal expansion, *all* the linear dimensions increase, including the dimensions of the holes. For the ring, both inner and outer radii are linear dimensions. The holes—increase in size just as if they were made of the material in question, and the ball will go through.

(a) (b) (c)

▲ **FIGURE 17–10** Thermal expansion: The linear dimensions of a material expand proportionally with the temperature increase. In this instance, the linear dimension of the metal ball is its radius. (a) It just fits through a ring at room temperature, (b) is heated, and (c) becomes too big to fit through the ring.

CONCEPTUAL EXAMPLE 17–4 We learn by experience that we can loosen a metal lid that is stuck on a glass jar by pouring hot water over the lid. Why does this work?

Answer As the lid's temperature rises, it expands. Movement occurs where the glass and metal are stuck and the lid releases (Fig. 17–11). In fact, you could dip the entire system (lid and glass container) in hot water, and the different expansions of the metal and the glass will lead to the same result. Note that the same difference in the thermal expansion is used in making a good seal: lids are placed on jars when the contents are hot.

▶ **FIGURE 17–11** By pouring hot water over this lid, you can take advantage of thermal expansion to free it from the jar.

EXAMPLE 17–5 A steel bridge is 600 m long. How much allowance must be made for linear expansion between the temperatures of +40°C and −40°C?

Setting It Up We know the values of L, ΔT, and the coefficient of expansion α for steel; we are interested in the length change ΔL.

Strategy This is a straight application of Eq. (17–5), which gives ΔL in terms of L and ΔT.

Working It Out We take α from Table 17–3: $10.5 \times 10^{-6}\,\text{K}^{-1}$ for steel (α varies little with temperature in the range +40°C to −40°C). Eq. (17–5) rearranged in the form $\Delta L = \alpha L \Delta T$ then gives

$$\Delta L = (10.5 \times 10^{-6}\,\text{K}^{-1})(600\,\text{m})(80\text{K}) = 5 \times 10^{-1}\,\text{m} = 50\,\text{cm}.$$

Expansion joints that allow for this much thermal expansion are distributed at regular intervals along bridges (Fig. 17–9). If there are N joints, then each joint need accommodate a length for $\Delta L/N$.

What Do You Think? Would it be more pleasant to drive over the steel bridge in this example at +40°C or −40°C?

EXAMPLE 17–6 You want to fill an aluminum container with gasoline in the dead of winter, at a temperature of −20°C. The filled container is to be stored into the middle of summer, when the temperature may reach $T = +40°C$. How much unfilled space must you leave in the container to allow for expansion when summer comes around?

Setting It Up We know from Table 17–3 that $\beta_{gas} = 9.5 \times 10^{-4}\,K^{-1}$ is the coefficient of volume expansion for gasoline. The coefficient of volume expansion for aluminum can be found from α using Eq. (17–7); from the table $\beta_{alu} = 3\alpha_{alu} = 6.9 \times 10^{-5}\,K^{-1}$. We want to find the difference in the fractional volume changes of the gasoline and the container.

Strategy Both the gasoline and the aluminum of the container will expand when T increases. We calculate and compare the fraction volume change $\Delta V/V = \beta\Delta T$ for both. With $\beta_{gas} > \beta_{alu}$ the gasoline expands more than the container, and the difference is the fraction that would be lost if the container were full; it is thus the fraction that should be left unfilled. If β_{gas} had turned out to be smaller than β_{alu}, the fractional volume increase of the gasoline would be smaller than that of the container, in which case there would be no need for expansion space.

Working It Out The temperature change ΔT is positive, $\Delta T = +60°C = +60K$. Then for the gasoline

$$\Delta V/V = \beta_{gas}\Delta T = (9.5 \times 10^{-4}\,K^{-1})(60K) = 0.057.$$

For the container the volume change is

$$\Delta V/V = \beta_{alu}\Delta T = (6.9 \times 10^{-5}\,K^{-1})(60K) = 0.004.$$

The container volume change is negligible compared to the nearly 6% volume change of the gasoline. You should fill the container only to the 94% level in winter if you want to avoid a dangerous situation.

What Do You Think? Can you safely fill the container to the brim in summer?

17–4 The Equation of State of Gases

A thermal system such as a gas in a bottle is described by its pressure p, temperature T, volume V, and the amount (or mass) of the gas. We have already discussed the first three variables. A useful unit for the amount of material in a thermal system is the **mole** (abbreviated mol), which represents either an amount of gas with a certain mass (according to the chemical species of the material) or a count of the number of molecules. (You should be familiar with this unit from your chemistry studies.) One mole of a given gas is defined to be the amount of gas with a mass in grams equal to the *atomic* (or *molecular*) *weight* of the gas. For example, 1 mol of helium gas has a mass of 4 g; the atomic weight of helium is 4 units of atomic mass. One mole of gas *always* contains *Avogadro's number* of molecules—$N_A = 6.022 \times 10^{23}$ molecules. The total number of molecules in a container, N, can be written in terms of the number of moles, n, as

$$N = nN_A. \tag{17–8}$$

Variables such as p, T, V, and n describe thermal systems, and we refer to them as **thermodynamic variables**.

CONCEPTUAL EXAMPLE 17–7 In an experiment, a tiny known volume V of oil is placed on calm water and subsequently spreads over an area A, forming a film of oil one molecule thick (a monolayer). The oil has a known density ρ and molecular weight M. How can you use this information to (a) estimate the size of a molecule of the oil, and (b) estimate Avogadro's number N_A. What additional assumptions are necessary for your estimates? (This experiment was apparently first performed by Benjamin Franklin.)

Answer (a) If we make the additional assumption that the oil molecules in the monolayer are as close as they are in the original drop, then we estimate the thickness t of the monolayer as follows: The original drop forms a "pancake" of volume At equal to the original volume V. Thus $t = V/A$. If we now assume further that the molecules themselves are compact—that we can, for example, treat them as little cubes of size l—then we can identify $l = t = V/A$. (b) For an estimate of N_A, we note that the number N of our molecules is given by $N = V/l^3$. But we have another way to get N: If $m = \rho V$ is the (known) mass of the drop, then $N : N_A = m : M$. (Remember, N_A is the number of molecules in a mass M of the material.) In other words, $N_A = N(M/m)$.

Ideal gases—think of dilute gases here—obey *Boyle's law*, discovered in 1662 by Robert Boyle. Boyle's law states that for a dilute gas held at constant temperature, the product of pressure p and volume V divided by the number of moles n is a constant:

$$\text{for constant } T\text{: } \frac{pV}{n} = \text{a constant.} \tag{17–9}$$

BOYLE'S LAW

We previously defined temperature as a linear function of pressure if volume is constant. We can combine this result [Eq. (17–1)] with Boyle's law into the **ideal gas law**:

$$pV = nRT, \tag{17–10}$$

IDEAL GAS LAW

where R is a proportionality constant. The ideal gas law is an example of an **equation of state**, a relation between the thermodynamic variables of a thermal system. Such a relation holds for any thermodynamic system. The ideal gas law is the equation of state for an ideal gas. Measurements of ideal gases give

$$R \cong 8.314 \frac{\text{N} \cdot \text{m}}{\text{mol} \cdot \text{K}} = 8.314 \text{ J/mol} \cdot \text{K}. \tag{17–11}$$

R is known as the **universal gas constant**. If we count the number of molecules N of a gas rather than the number of moles n, we can use Eq. (17–8) in order to rewrite Eq. (17–10) as

$$pV = NkT, \tag{17–12}$$

IDEAL GAS LAW

where the constant k, **Boltzmann's constant**, is given by

$$k = \frac{R}{N_A} \cong 1.381 \times 10^{-23} \text{ J/K}. \tag{17–13}$$

Boltzmann's constant, named for Ludwig Boltzmann, one of the important figures in nineteenth-century thermal physics, provides the bridge between temperature and energy. To see how, note that the quantities pV/n and pV/N, from Eqs. (17–10) and (17–12) respectively, have the dimensions of [force/length^2][length^3] = [force][length], which is the same as work or, equivalently, energy. *The dimensions of RT and kT are those of energy.* This is already reflected in the units of R and k [Eqs. (17–11) and (17–13)]. The significance of this observation is that temperature, as defined by the ideal gas law, must be closely related to the energy of a thermal system. This *thermal* (or *internal*) energy is the subject of Chapter 18.

CONCEPTUAL EXAMPLE 17–8 Before you drive through West Texas on Interstate 10 toward El Paso in the summer, you are advised not to pressurize your automobile tires to the maximum allowed pressure. Why?

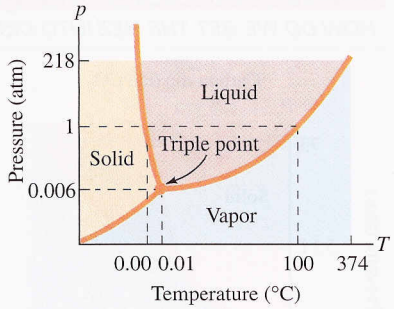
Answer First, you should know that the air temperature is likely to be high and that people drive very fast on the wide-open roads of Texas. The tires will get quite hot. However, tires are constructed with steel belts so that they do not expand in volume past a certain amount. If the volume stays constant, and the temperature increases considerably, then the pressure in the tires will increase substantially, and they may become unsafe against a blowout. This is good advice for driving anywhere in summer.

EXAMPLE 17–9 Calculate the volume occupied by 1.0 mol of an ideal gas at 20°C and at atmospheric pressure. Use this volume to calculate the mass density of air, whose molecular weight M is 29 g/mol.

Strategy The ideal gas law gives us the volume for n moles of gas, $V = nRT/p$. We then use the M of air (= 29 g/mol) to find the density of air, $\rho = nM/V$. Here we'll want to set $n = 1.0$.

Working It Out The temperature T is 20°C = (20 + 273)K = 293K, and T must be in K for the ideal gas law. The volume is

$$V = \frac{nRT}{p} = \frac{(1.0 \text{ mol})(8.3 \text{ J/mol} \cdot \text{K})(293\text{K})}{1.0 \times 10^5 \text{ Pa}} = 2.4 \times 10^{-2} \text{ m}^3.$$



As for the mass density of air,

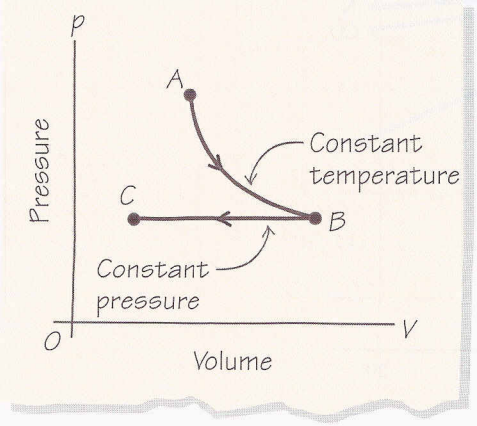
$$\rho = \frac{29 \text{ g}}{2.4 \times 10^{-2} \text{ m}^3} = \frac{(29 \text{ g})(10^{-3} \text{ kg/g})}{2.4 \times 10^{-2} \text{ m}^3} = 1.2 \text{ kg/m}^3.$$

What Do You Think? Where does the molecular weight 29 g/mol used in this example come from?

Changing the Thermodynamic Variables of a Gas

Thermal systems change as the thermodynamic variables change. We say that a *thermal transformation* or, alternatively, a *thermal process*, occurs. For example, when the cylinder of gas in Section 17–2 was put in contact with a hotter thermal reservoir, the gas' temperature changed; so does the gas' volume in the set-up in Fig. 17-1. In this transformation the temperature, the volume, and the pressure all changed subject to the constraints of the equation of state. There are many different ways to change a thermal system. For example, in an **isothermal** transformation the temperature remains fixed while the pressure and volume both change. In an **isobaric** transformation the pressure is held fixed while both temperature and volume change. Such transformations are most easily shown on diagrams in which one variable is plotted against another. For example, in a p–V diagram, pressure is plotted against volume. When such a diagram shows various *phases* of a material—whether it is solid, liquid, or gas—it is referred to as a *phase diagram.* Figure 17–12 is a p–T phase diagram for water. We'll be looking at phase diagrams throughout, concentrating on phase changes—transitions across phase boundaries—in Chapter 18. Careful: the line that separates phases on a phase diagram is not a transformation!

▲ **FIGURE 17–12** Phase diagrams are useful for the different phases of a material, such as those for water, shown here: liquid, solid (ice), and vapor (steam). The intersection of these phases is the triple point of water.



CONCEPTUAL EXAMPLE 17–10 Referring to Fig. 17–12, what changes can be made to water to allow you to go from solid ice to liquid water without any change in temperature? How might this be useful for understanding ice skating?

Answer Consider the almost vertical line near 0.00°C on the phase diagram in Figure 17–12. In the region of 1 atm, increasing the pressure—moving up along the constant temperature line, say at 0°C—takes you from the solid phase (ice) to the liquid one. It is the fact that the slope of the line describing the solid-liquid phase separation is negative on the p–T diagram that allows this to happen. As an ice skater moves over the ice, the weight of his or her body increases the pressure under the blade on the ice. If the temperature is not too low, this increased pressure will be enough to melt the ice, forming a film of water between the ice skate and ice, in effect lubricating the motion of the blade over the ice. A narrow blade makes the pressure higher and the effect more pronounced. A glance at the diagram shows that this effect is more difficult to realize at lower temperature.

EXAMPLE 17–11 Exactly 1 mol of an ideal gas is taken through the sequence of changes shown on the p–V diagram in Fig. 17–13. The change $A \rightarrow B$ is an isothermal transformation. In $B \rightarrow C$ the transformation is isobaric, that is, the gas is compressed in volume in such a way that the pressure remains fixed. (a) If $p_A = 5.00$ atm and $V_A = 8.00$ L, what is the temperature T_A? (b) If $V_B = 40.0$ L, what is p_B? (c) If $T_C = T_A/8$, what is V_C?

Setting It Up Figure 17–13 provides a very useful picture of what is happening. Diagrams such as this one are very important in problems involving thermal transformations.

Strategy We can apply the equation of state for the ideal gas, $pV = nRT$, with $n = 1$ mol. This gives us T_A immediately.

▲ **FIGURE 17–13**

Then, since $T_B = T_A$, we can use the ideal gas law to find p_B. Finally, since $p_C = p_B$ and T_C is given, we can again use the ideal gas law to find V_C.

Working It Out (a) We know p_A and V_A; the temperature T_A is then given by

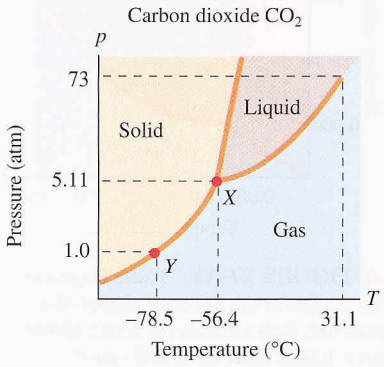
$$T_A = \frac{p_A V_A}{nR} = \frac{(5.00\text{ atm})(8.00\text{ L})}{(1\text{ mol})(8.314\text{ N}\cdot\text{m/mol}\cdot\text{K})}.$$

We make some unit conversions in order to cancel units:

$$T_A = \frac{(5.00\text{ atm})(1.01\times10^5\text{ Pa/atm})(8.00\text{ L})(10^{-3}\text{ m}^3/\text{L})}{(1\text{ mol})(8.314\text{ N}\cdot\text{m/mol}\cdot\text{K})} = 486\text{K}.$$

(b) $T_B = T_A$ from the conditions stated in the problem. We know V_B and T_B, and hence we can compute p_B:

$$p_B = \frac{nRT_B}{V_B} = \frac{nRT_A}{V_B} = \left(\frac{nR}{V_B}\right)\left(\frac{p_A V_A}{nR}\right) = p_A\left(\frac{V_A}{V_B}\right)$$
$$= (5.00\text{ atm})\left(\frac{8.00\text{ L}}{40.0\text{ L}}\right) = 1.00\text{ atm}.$$



(c) Since we know $p_C = p_B$ and we know T_C, we can calculate V_C. It is given by

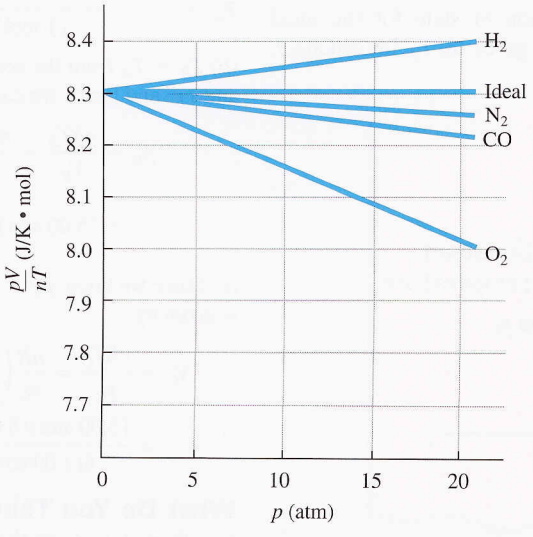
$$V_C = \frac{nRT_C}{p_C} = \frac{nR}{p_C}\left(\frac{T_A}{8}\right) = \frac{nR}{8p_C}\left(\frac{p_A V_A}{nR}\right) = \frac{p_A V_A}{8p_C} = \frac{p_A V_A}{8p_B}$$
$$= \frac{(5.00\text{ atm})(8.00\text{ L})}{8(1.00\text{ atm})} = 5.00\text{ L}.$$

What Do You Think? Suppose you had followed a straight line from A to C on the diagram of Fig. 17–13. What would have been constant: *p, V, or T*?

THINK ABOUT THIS . . .

HOW DO WE GET THE FIZZ INTO DISPENSED DRINKS?

◀ **FIGURE 17–14** Phase diagram for carbon dioxide. At a pressure of 1 atm, only the solid and gas phases exist.



A fizzy drink from a carbonated beverage dispenser is made by mixing a "syrup" of sugar and flavorings with water and carbon dioxide as it is dispensed. It is the carbon dioxide that gives the drink its fizz. But how is the carbon dioxide handled? At a pressure of 1 atm, carbon dioxide exists only in the solid phase (at low temperatures) and in the gas phase (at normal temperatures). This is visible in the p–T phase diagram for carbon dioxide (Fig. 17–14). Both forms are inconvenient to use; the gas is bulky, and the solid is difficult to incorporate in mixing systems. Carbon dioxide is therefore transported and delivered at pressures greater than 40 atmospheres, pressures at which the room-temperature phase is liquid. This liquid can then be conveniently stored, transported efficiently through pipes, controlled by automatic valves, and so forth. When it is needed for incorporation into soft drinks near room temperature, it is released to one atmosphere of pressure, at which point it changes to the gas phase, becoming the bubbles in your drink.

How Close Do Real Gases Come to Being Ideal?

When is a real gas "sufficiently dilute" to obey the ideal gas equation of state? Of course, this is a question without a definite answer, because there is no sharp line dividing ideal gases from nonideal ones, just a matter of tolerance to approximation. But we can approach this question by asking how well Boyle's law is satisfied as we vary the density of a gas. Consider a series of identical closed tubes. A pressure gauge can measure the pressure of any gas in the tubes. Put different amounts (a different number of moles, n) of the same gas in each tube and immerse them in the same thermal reservoir. If Boyle's law is satisfied exactly, the (measured) ratio pV/n will be the same in each tube, independent of the pressure in the tube. One can also imagine a set of thermal reservoirs with different temperatures. In that case the more stringent test for ideal gas behavior is that the ratio pV/nT is the same in each tube.

Experiment shows that for monatomic gases,† such as helium, the ratio pV/nT is independent of the pressure over a wider range of pressures and therefore fits the ideal gas limit better than do polyatomic gases such as O_2, or carbon dioxide, or ammonia. However, *all* gases give precisely the same value of pV/n when this quantity is extrapolated to *zero density* (Fig. 17–15). All gases are indeed ideal in this limit. A more appropriate definition of temperature than that presented in Eq. (17–2) is obtained by *extrapolating the pressure ratio* in Eq. (17–2) to zero density ρ:

▶ **FIGURE 17–15** As the pressure (and hence the density) of any gas drops to zero, the ratio pV/nT goes to the same constant, which is the universal gas constant. This behavior characterizes the ideal gas.

†The molecule of a monatomic gas consists of one atom; the molecule of a polyatomic gas consists of several.

$$T = (273.16\text{K}) \lim_{p \to 0} \frac{p}{p_{tp}}. \qquad (17\text{–}14)$$

KELVIN TEMPERATURE SCALE DEFINED

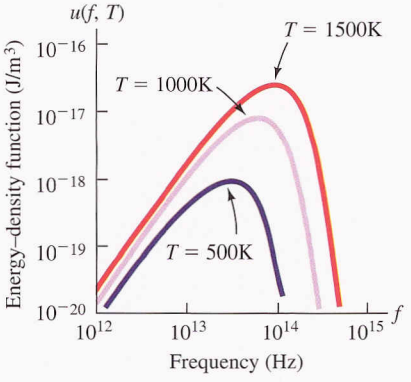
Equation (17–14) provides us with the desired universal definition of temperature because it holds in the domain where *every* gas is ideal.

The van der Waals Equation of State

In 1873 Johannes D. van der Waals proposed an equation of state that describes the properties of many real gases better than the ideal gas law. His formula, known as the *van der Waals equation*, takes the form

$$\left[p + a\left(\frac{n}{V}\right)^2\right]\left(\frac{V}{n} - b\right) = RT. \qquad (17\text{–}15)$$

The constants a and b are both positive and specific to a given gas. The van der Waals equation includes a correction for intermolecular forces through the constant a and a correction for finite molecular size through the constant b. In contrast, the ideal gas law can be derived at the molecular level through assumptions that the gas molecules are noninteracting point particles. (See Chapter 19 for more on this.) We can verify that the van der Waals equation reduces, as it must, to the ideal gas law when the gas is very dilute: In the limit as $n \to 0$, the term $a(n/V)^2$ is small compared to p, and the term V/n is large compared to b. Thus, in this limit, Eq. (17–15) reduces to $pV/n = RT$.



The van der Waals equation of state is a considerable empirical improvement over the ideal gas law for polyatomic gases that are about as dilute as the air we breathe. It describes all gases reasonably well, even when a gas is nearly a liquid; that is, at very low temperatures and at densities approaching those of real liquids.

*17–5 Blackbody Radiation

Most of us have enjoyed an evening before a roaring blaze that slowly dies down during the course of the evening. As the fire dies, its color changes from brilliant white to bright yellow, to orange, and finally to a dull red. The change is more marked if you look into a cavelike hole within the embers, a spot where the temperature is steadier because it is protected from the vagaries of drafts. This phenomenon is the basis of a thermometer called the *optical pyrometer* (Table 17–1). This thermometer works because the color or, rather, the range of colors emitted by a hot object is characteristic of the temperature of that object. This thermometer works best for relatively hot objects with temperatures in the range of several hundred kelvins.

The light emitted by hot objects is **electromagnetic radiation**. Radiation exists in the form of waves, and all frequencies are possible in principle. One small range of frequencies corresponds to visible light, and different frequencies within this range are perceived as different colors, but even if we cannot literally see the radiation at other frequencies, we often use it (radio, infrared, microwave, infrared, X-rays, etc). All matter, at any temperature, absorbs and emits electromagnetic radiation, and across the full range of frequencies. The basic physical emission mechanism is that atoms go into *excited states* when the temperature of the matter they comprise is raised. They then radiate energy when they return to their normal states. For example, the atoms heated by an electric current in a lightbulb filament radiate visible light, from red to orange to yellow to green to blue to violet, as the frequency of the radiation increases from 0.5×10^{15} Hz to approximately 1.0×10^{15} Hz. The filament also radiates a great deal of energy in the form of longer wavelength radiation, and that is why the bulb is hot as well as brilliant.

In some ways, radiation in an enclosure acts like a dilute gas in a bottle; in particular, the radiation has a temperature just as a gas does. However, there is an important difference: Radiation achieves thermal equilibrium through the fact that it is absorbed and emitted by the atoms of the walls of the enclosure rather than through collisions among its components (as do the molecules that make up a dilute gas). The radiation in the enclosure at thermal equilibrium at a given temperature is a mix of *different*

▲ **FIGURE 17–16** The energy density of electromagnetic radiation in thermal equilibrium at the indicated temperatures. The maximum energy density occurs for increasing frequency as the temperature increases. The maximum energy density increases very rapidly with T for a given f; note that this is a log–log plot.

frequencies, and what is important here is that in the mix the proportion of high frequencies to low frequencies rises with temperature. The average frequency of the radiation associated with a white-hot object is greater than the average frequency associated with the object when it is glowing red. We can give a function that describes the radiation at *different* frequencies associated with a given temperature. Such a function is denoted by $u(f, T)$, where $u(f, T)\,df$ *is the radiation energy per unit volume, or energy density, with a frequency between* f *and* $f + df$. We say that the radiation is at a given temperature when it is in thermal equilibrium, meaning that the radiation interacts with an object or system at that temperature over a long period and that the object and the associated radiation is isolated from its surroundings. Radiation of this type is known as **blackbody radiation**, and the object that emits and absorbs such radiation is known as a blackbody. Figure 17–16 shows this function for different values of temperature. *The measurement of* $u(f, T)$ *provides a measurement of* T.

We sometimes refer to this radiation as being "emitted" when we look into the enclosure; that is, we can see the radiation that escapes from the "bottle" of radiation. This picture most exactly describes your looking deeply into a furnace through a small window or a campfire through a little opening in the pile of wood. If the window is large, then so much radiation escapes to the outside that the system may cool down, which is why we refer to a small window. But equivalently, if we have a way to maintain a high temperature, then we just say that the blackbody radiation is emitted from an object at that temperature. An example is provided by the filament of a lightbulb, which would quickly cool if we didn't maintain an electric current through it that holds it at a white-hot temperature.

The form of the energy–density function $u(f, T)$ was a subject of intense study in the latter part of the 19th century. The work of Gustav Robert Kirchhoff, Wilhelm Wien, Lord Rayleigh, and James Jeans set the stage for the breakthrough of Max Planck, who determined in 1900 that

$$u(f, T) = \frac{8\pi h}{c^3} \frac{f^3}{e^{hf/kT} - 1}. \tag{17–16}$$

This formula, known as the **Planck formula**, perfectly fits the data on the energy density of radiation for a wide range of frequencies and temperatures. In addition to Boltzmann's constant, k [introduced in Eq. (17–13)], and the Kelvin temperature, T, the formula contains the speed of light, $c = 3 \times 10^8$ m/s, which is the speed of electromagnetic waves of *every* frequency. A new fundamental constant also appears in this formula. The new constant h, called *Planck's constant*, was found by fitting the formula to the observed energy density, and its value is $h = 6.625 \times 10^{-34}$ J · s. This is an awfully small number, and many of the effects associated with it are visible only on an atomic scale, but its presence in the formula for blackbody radiation shows that it can perfectly well have a macroscopic effect. Note that the quantity hf has dimensions of energy as does the quantity kT. (Indeed, these quantities must have the same dimensions because their ratio is the argument of the exponential function.)

The discovery of the Planck formula was the first step on the path to the basic theory of matter and radiation, called *quantum theory*. This theory is based on a set of ideas that revolutionized the physical sciences in the twentieth century. (The other great revolution in 20th-century physics—Einstein's theory of relativity—also has its origin in the investigation of electromagnetic radiation.)

An interesting consequence of the Planck formula is that the total power radiated through a small hole in an enclosure containing radiation in thermal equilibrium at temperature T is proportional to the fourth power of the temperature. The **Stefan–Boltzmann formula**, which was discovered experimentally by Josef Stefan in 1879 and inferred from thermodynamics by Boltzmann in 1884 before the discovery of the Planck formula, states that the radiated power (energy per unit time) per unit area emitted through the hole is given by $P(T)/A$, usually written as

$$E(T) = \sigma T^4, \tag{17–17}$$

where $\sigma = 5.67 \times 10^{-8}\ \mathrm{W/(m^2 \cdot K^4)}$. The T dependence in Eq. (17–17) can be obtained by integrating Eq. (17–16) over all frequencies f (see Problem 76).

EXAMPLE 17–12 A surface that is "white hot" emits about 10 times more power than a "red hot" surface of the same area. What does this tell us, quantitatively, about the relative temperatures?

Strategy Power and temperature are related through the Stefan–Boltzmann formula, Eq. (17–17). By setting the ratio of the powers to 10, we have an equation for the ratio of the temperatures.

Working It Out From Eq. (17–17),

$$\frac{P(\text{white hot})}{P(\text{red hot})} = 10 = \frac{\sigma T_{\text{white}}^4}{\sigma T_{\text{red}}^4} = \left(\frac{T_{\text{white}}}{T_{\text{red}}}\right)^4$$

This implies that the temperature of the "white hot" surface exceeds that of the "red hot" surface by a factor of

$$\frac{T_{\text{white}}}{T_{\text{red}}} = 10^{1/4} = 1.78.$$

Let's examine the Planck formula for the energy–density function, Eq. (17–16). If the frequencies are small, $hf \ll kT$, then the exponential function in $u(f, T)$ has a small argument, and we can use the expansion

$$\text{for small } x\text{: } e^x \cong 1 + x + \cdots$$

In this case, the denominator of $u(f, T)$ is

$$e^{hf/kT} - 1 \cong 1 + \frac{hf}{kT} - 1 = \frac{hf}{kT},$$

and the function $u(f, T)$ takes the approximate form

$$\text{for } hf \ll kT\text{: } u(f, T) \cong \frac{8\pi h}{c^3} f^3 \frac{kT}{hf} = \frac{8\pi f^2}{c^3} kT. \qquad (17\text{–}18)$$

This expression is independent of Planck's constant and is thus independent of quantum physics. It was, in fact, first found by Lord Rayleigh in 1900 by using a derivation based on classical physics. The energy density in Eq. (17–18) rises with increasing frequency as f^2 and linearly with temperature.

If, however, the frequencies are large, $hf \gg kT$, then the exponential argument in $u(f, T)$ is large and is the exponential function itself. The denominator then becomes

$$e^{hf/kT} - 1 \cong e^{hf/kT}.$$

(Here we have used the fact that for $hf/kT \gg 1$, $\exp(hf/kT) \gg 1$.) Then the energy density is approximately

$$\text{for } hf \gg kT\text{: } u(f, T) \cong \frac{8\pi h}{c^3} f^3 e^{-hf/kT}. \qquad (17\text{–}19)$$

Because the exponential function falls with f much faster than the polynomial factor f^3 grows, $u(f, T)$ decreases as f grows in this range of f. Note that h plays a crucial role in this part of the energy–density function, indicating that quantum physics is important.

As we have seen, the energy–density function increases with f for $hf \ll kT$ and decreases with f for $hf \gg kT$. Such a function has an intermediate maximum, which we can estimate as occurring at about $hf \cong kT$. The underlying physics of the high-frequency side of the curve of the energy–density function in Fig. 17–16 is quantum physics because it involves Planck's constant, but the low-frequency side can be explained by classical physics. The maximum moves to higher values of f as T increases. We can therefore say that the importance of quantum physics decreases as the temperature grows, and this is generally true.

EXAMPLE 17–13 The surface of the Sun is observed to emit light most strongly at a frequency of 2×10^{14} Hz. Estimate the temperature of the Sun's surface (Fig. 17–17).

Setting It Up We can safely assume the radiation is blackbody; thus we want to find the blackbody temperature that gives a maximum in the energy–density function $u(f_0, T)$ at a given frequency f_0.

Strategy As we argued above, the frequency f_0 for which u is a maximum is given by $hf_0/kT \cong 1$. We can solve this for T. (*Alternatively*, we could go beyond this estimate and calculate the maximum of the energy–density function, Eq. (17–16), by taking

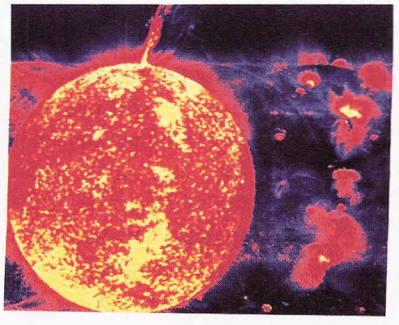


FIGURE 17–17 The temperature of the Sun's surface is not constant but varies somewhat in active areas, such as regions with Sun flares.

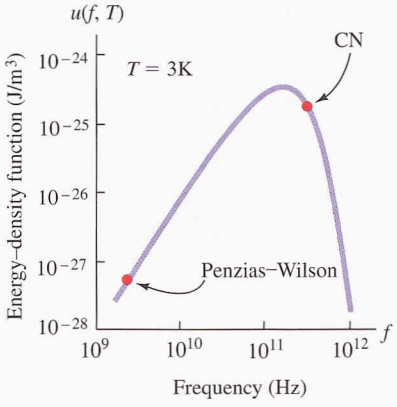
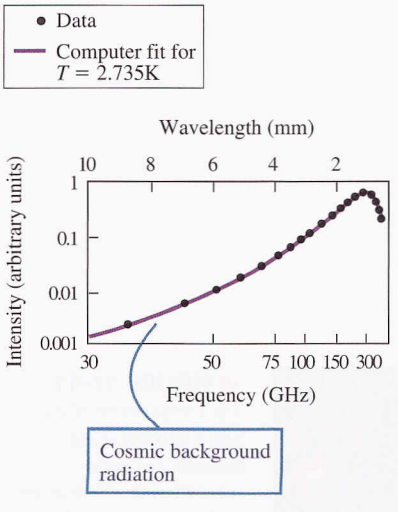
(continues on next page)



the derivative of u with respect to f and setting the derivative to zero. The simpler estimate will be enough here.)

Working It Out We have



$$T \cong \frac{hf_0}{k} = \frac{(6.63 \times 10^{-34}\,\text{J}\cdot\text{s})(2 \times 10^{14}\,\text{Hz})}{1.38 \times 10^{-23}\,\text{J/K}} = 10^4\text{K}.$$

The more precise alternative solution described above gives a solar surface temperature of 6000K (see Problem 80).

What Do You Think? The interior of the Sun is at a much higher temperature than the surface. What happens to the radiation, characteristic of the higher internal temperatures, that must be present in the interior?

▲ **FIGURE 17–18** The energy density of electromagnetic radiation in thermal equilibrium at $T = 3$K. The Penzias–Wilson frequency measurement and the frequency associated with interstellar cyanogen, labeled CN, are marked by red dots.

▲ **FIGURE 17–19** Satellite-based measurements of the cosmic background radiation show remarkable agreement with the Planck formula. The data shown for $T = 2.735$K fit the smooth blackbody curve very well indeed.

The Discovery and Measurement of the Background Radiation of the Universe

In 1964 Arno Penzias and Robert Wilson used a large radio antenna to study the radio waves emitted within our galaxy. They found a puzzling anomaly, which they at first thought might be a problem with their antenna: A background electromagnetic radiation that comes from no particular source is present. Their antenna was sensitive only to the particular frequency $f = 4.08 \times 10^9$ Hz, but later measurements over other frequencies showed that this background radiation was consistent with the Planck formula.

Penzias and Wilson were not aware of work by Ralph Alpher, George Gamow, and Robert Herman in the late 1940s, or of work by James Peebles that was contemporary with their own, in which a cosmological, or large-scale, model of the universe predicted the existence of this radiation. As described by this model, the early universe expanded from an initial catastrophic event—the Big Bang. As the universe expanded, it cooled, maintaining thermal equilibrium between electromagnetic radiation and matter up to a point, some 100,000 years after the Big Bang, when the temperature was about 3000K. At that point, the model shows that electromagnetic radiation and matter decoupled; they were no longer in thermal equilibrium. However, and quite remarkably, as the universe continued to expand, the Planck formula still described the radiation, but with a temperature that dropped as the universe expanded. *A measurement of the present-day temperature of the radiation provides us with a measurement of the rate of expansion of the universe; hence, it provides us with a measurement of the time that has elapsed since the radiation was no longer in thermal equilibrium with matter.* Presently the temperature of the radiation, as characterized by the Planck formula, is about 3K, and this radiation is the oldest directly observable relic of the explosion in which the universe is formed.

A measurement of a single frequency is not a measurement of an entire spectrum! Penzias and Wilson's frequency measurement occurs at one value of frequency on the classical, or low-frequency, side of the Planck formula, as Fig. 17–18, the energy–density function for $T = 3$K, indicates. Since 1964 many other Earth-based measurements have been made by radio antennas sensitive to a great variety of frequencies. Because Earth's atmosphere absorbs radiation of high frequency, these measurements are all made on the classical side of the Planck formula. Fortunately, one other technique can make a measurement on the quantum, or high-frequency, side of the peak of energy density, and measure the amount of light emitted by interstellar cyanogen, the CN molecule. This light is emitted with a strength that can be explained only if the cyanogen is in the presence of background radiation of a certain temperature. The frequency measurement of CN, first made in 1941, is marked on Fig. 17–18. Today we have a series of satellite measurements of the background radiation. Measurements can be made with extraordinary precision across a broad range of the spectrum, including across the maximum of the energy–density curve. We show the results in Fig. 17–19; a temperature of about 2.7K fits the curve perfectly. (The actual temperature can be determined to six significant figures!) Still other measurements reveal that the temperatures in different directions differ ever so slightly from one another. Some regions are somewhat hotter, while others are cooler. These temperature inhomogeneities may well be relics of the instabilities that led to the formation of the great clusters of galaxies present today. Indeed, the precise nature of the inhomogeneities provides further evidence for the Big Bang as well as other cosmological (universe-wide) features. The Big Bang model of the universe, which predicts the presence of this background blackbody radiation, has a remarkable amount of experimental support.

Summary

The temperature of a system in thermal equilibrium is defined on the Kelvin scale by the behavior of the pressure, p, of a dilute gas in a constant-volume gas thermometer:

$$T = (273.16\text{K}) \lim_{p \to 0} \frac{p}{p_{tp}}, \tag{17–14}$$

where p_{tp} is the pressure of the gas in the thermometer at the triple point of water (where the gaseous, liquid, and solid phases coexist); thus 273.16K is chosen to be the temperature at the triple point. The other fixed point of the Kelvin scale is built into the thermometer: $T = 0\text{K}$, absolute zero, is the point where the pressure extrapolates to zero. Two other temperature scales in common use are the Celsius scale and the Fahrenheit scale. The Celsius temperature is given in terms of the Kelvin temperature by

$$t_C = T - 273.15. \tag{17–3}$$

Any sufficiently dilute gas behaves as an ideal gas, meaning that its thermodynamic variables are related by the ideal gas law, an equation of state:

$$pV = nRT = NkT, \tag{17–10, 17–12}$$

where the universal gas constant is

$$R \cong 8.314\ \text{J/mol} \cdot \text{K} \tag{17–11}$$

and Boltzmann's constant is

$$k = \frac{R}{N_A} \cong 1.381 \times 10^{-23}\ \text{J/K}, \tag{17–13}$$

with N_A Avogadro's number. n and N measure the quantity of gas, in moles or in numbers of molecules, respectively. The quantities kT and RT have dimensions of energy.

Real gases are ideal only in the limit that they are very dilute. The small departures from ideal behavior are accurately reflected for many real gases by the empirical van der Waals equation of state,

$$\left[p + a\left(\frac{n}{V}\right)^2\right]\left(\frac{V}{n} - b\right) = RT. \tag{17–15}$$

Materials expand when heated, and they are characterized by a coefficient of thermal expansion, α, defined by

$$\alpha \equiv \frac{1}{L}\frac{dL}{dT}. \tag{17–5}$$

Electromagnetic radiation displays the characteristics of a thermal system. The total power emitted per unit area by radiation in equilibrium with another thermal system at temperature T, which is known as blackbody radiation, is given by the Stefan–Boltzmann formula,

$$P(T)/A = E(T) = \sigma T^4, \tag{17–17}$$

where $\sigma = 5.67 \times 10^{-8}\ \text{W/(m}^2 \cdot \text{K}^4\text{)}$. Blackbody radiation contains a range of frequencies f that have an energy per unit volume (or energy density) per unit frequency, given by

$$u(f, T) = \frac{8\pi h}{c^3}\frac{f^3}{e^{hf/KT} - 1}, \tag{17–16}$$

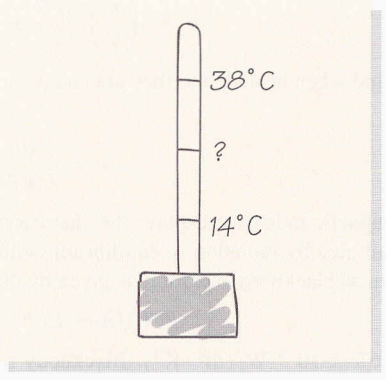
a result known as the Planck formula. The constant h is Planck's constant.

Electromagnetic radiation with this frequency range is observed to occur throughout the universe at a characteristic temperature of 3K. This is strong evidence for the Big Bang theory of the origin of the universe.

Understanding the Concepts

1. Estimate to within an order of magnitude the number of molecules in a breath of air.
2. Why is mercury used in most thermometers rather than a more common liquid such as water?
3. If a scuba diver takes the same volume of air for each breath and breathes at a constant rate, why is the tank of air used up much faster at greater water depths?
4. A student proposes to make a steel sphere in which helium gas can be inserted at various pressures. The student will insert the sphere into various temperature baths (boiling water, ice water, liquid nitrogen, dry ice-methanol) and measure the pressure at each temperature. Then he or she will change the amount of helium in the sphere and do it again. If the student plots pressure vs. temperature for these separate amounts of helium, where, if anywhere, should they intersect?

5. How can a triple point of water exist? If ice, water, and vapor all existed together, would the ice cool the vapor, making it water? Or would the vapor and water melt the ice?
6. Why is it advisable to measure the pressure in automobile tires when the car has not been driven for some time?
7. Devise an experiment to prove the experimental fact that hot objects radiate more energy per unit area than cold objects do.
8. It is well known that chameleons can change their skin color. In this chapter we spoke about the different colors associated with light emitted from objects of different temperature. Is this how a chameleon changes its color—by changing its temperature?
9. Why is it important to check the pressure in automobile tires before the winter season?
10. All gases obey the ideal gas law when they are made sufficiently dilute. Is this true when the temperature is lowered sufficiently?
11. In recent years an attempt has been made to convert Americans to the use of the metric system, so that, for example, two sets of tools would not be necessary for a mechanic who works on both American and European cars. Would it be of equal practical importance to convert Americans from the use of Fahrenheit to Celsius temperature scales?
12. When we observe a fire, we are observing radiation that has escaped the region of the hot fire. Is this a mechanism for cooling the fire? In what way could a fire be enclosed so that it remains hot?
13. In the experiment shown in Fig. 17–10, it often happens that the ball gets stuck in the ring while performing the experiment. Why do you think this happens? Could you dislodge the ball by heating up either the ball or the ring?
14. Suppose that we have no idea that gases consist of molecules. Could we still use the low-pressure limit of a gas to define temperature?
15. Substances in thermal contact reach thermal equilibrium after some time. Can you think of any experimental test that will indicate just when that time will have arrived?
16. Water expands when it freezes. You also have heard that 90% of icebergs are hidden beneath the surface. Why is the latter statement true? Can you estimate by how much water expands on freezing?
17. If the molecules of gases move around a lot, why do we never see a container of gas shake?
18. The pressure of a gas produces an outward force on the walls of a container. Why is there no force at an angle to the walls?
19. The Chamber of Commerce of a town plagued by temperature extremes devises a way to avoid bad publicity: It defines a new temperature scale, the G scale, such that (a) −40°F is defined to be +20°G; (b) +120°F is defined to be −40°G; and (c) the scale is linear. Is there anything wrong with this scale?
20. If a doughnut-shaped piece of a solid that expands under heat is heated, does the hole expand or shrink?
21. Water is one of the relatively rare substances that becomes less dense rather than more dense when it freezes. Describe what might happen to the ocean if ice were denser than liquid water.



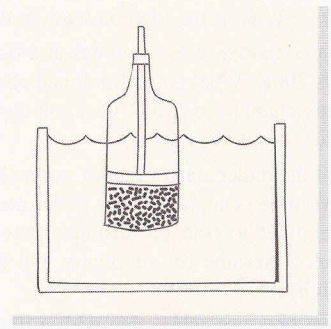
Problems

17–1 Temperature and Thermal Equilibrium

1. (II) Which of these pairs of systems are in thermal equilibrium with one another? (a) A roast reaching the rare stage and the oven in which it sits. (b) The point of a meat thermometer in the roast of part (a) and the roast. (c) A sunbather getting a tan and the air around him. (d) A bather in a hot tub and the water around her. (e) An ice cube in a glass of water at 0°C. (f) Molten iron ore in a blast furnace and the walls of the furnace.
2. (II) You must measure the different temperatures of a series of bottles that contain 1 L of an unknown fluid. Which one of the following techniques would make a suitable thermometer, and why or why not? (a) The time it takes 1L of ice cubes dumped into the fluid containers to melt. (b) The melting time for ice cubes sealed in full 1-L plastic bags that are dumped into the bottles. (c) The melting time for ice sealed in full 1-mL plastic bags that are dumped into the bottles. (d) All of the above techniques, but the fluids in the bottles are gently stirred during the measurement.
3. (II) Thermodynamic variables are either extensive or intensive. A variable is *extensive* if, when two identical thermodynamic systems are combined into one, the variable of the combined system is double its original value in each system; otherwise, it is *intensive*. Which of the following variables are extensive, and which are intensive: (a) volume, (b) temperature, (c) pressure, (d) number of moles?
4. (II) A physicist needs to measure room temperature. Not having anything better at hand, she decides to make use of the thermal expansion of water to construct a thermometer (Fig. 17–20). She calibrates her apparatus to a dependable thermometer at 14°C and 38°C, and divides the range between these temperatures into 24 equal intervals. What will be the true temperature when her equipment reads 28°C? She knows that the volume of water can be described in this temperature range by the formula

$$V = V_0 \times (1 - 2.525 \times 10^{-4} + 4.98 \times 10^{-6}T + 4.94 \times 10^{-6}T^2),$$

where T is the temperature in °C.

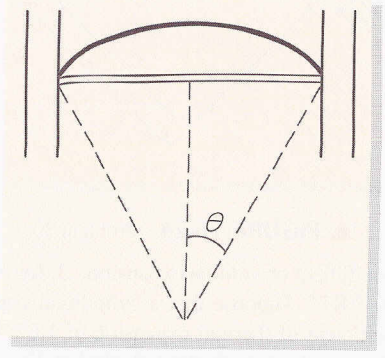


▲ **FIGURE 17–20** Problem 4.

17–2 Ideal Gases and Absolute Temperature

5. (I) At what temperature values are the following scales the same: (a) the Fahrenheit and the Celsius, (b) the Celsius and the Kelvin, (c) the Fahrenheit and the Kelvin?
6. (I) The title of Ray Bradbury's science-fiction novel *Fahrenheit 451* refers to the temperature at which paper ignites. What is that temperature on the Celsius scale?
7. (I) An oral fever thermometer ranges from 35.5°C to 42.5°C. What is the corresponding range on the Fahrenheit scale?
8. (I) An ideal gas in a container is heated from 17°C to 120°C. By what factor does the pressure increase?

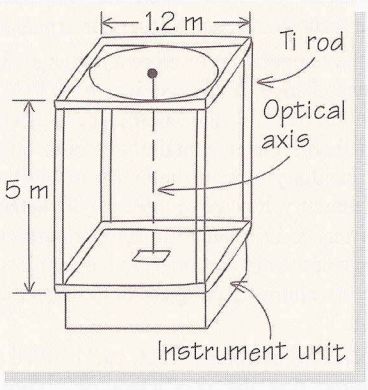
9. (I) A very dilute gas confined to a closed 1-L container is put on the burner of a stove and the temperature is raised from 271K to 349K. By how much does the pressure, which is originally at 1Pa, change?
10. (I) If an ideal gas thermometer could be constructed to measure the temperature of a hot star (see Table 17–2), by what factor would the pressure in the thermometer differ from p_{tp}?
11. (II) (a) Determine the temperature of the surface of Venus (730K) in the Celsius and the Fahrenheit scales. (b) Determine the temperature of the boiling point of liquid nitrogen (77K) in the Celsius and the Fahrenheit scales. (c) A comfortable room temperature is 75°F. Determine this temperature in the Kelvin and Celsius scales. (d) Heat pumps become less efficient than furnaces for heating homes when the temperature drops below 36°F. New laws may require that all temperatures be posted in the Celsius and the Kelvin scales as well as the Fahrenheit scale. What is this temperature in these other systems?
12. (II) In 1701 Isaac Newton proposed a linear temperature scale in which ice water has a temperature of 0°, whereas the human body in good health is assigned a temperature of 12°. In this scale, what is the temperature of someone with hypothermia (chilling)? What is the temperature of boiling water?
13. (II) A temperature scale—the Reaumur scale—developed in the early eighteenth century sets the ice point at 0°R and the boiling point of water at 80°R. Give the conversion formula from the Reaumur scale to the Kelvin scale and to the Fahrenheit scale.
14. (II) For the new temperature scale described in Question 19, what are the general conversion rules from °G to °F and vice versa? What is the conversion rule from °C to °G?
15. (II) The Rankine scale for temperature, named for William Rankine, is used in engineering applications. It has units of °R and is defined by $t_R = 9T/5$, where T is the temperature in the Kelvin scale. Find the value of t_R for the temperatures 100°C, 4.2K, 6000K, 32°F, −30°F, and −25°C.
16. (II) A bottle that has a freely sliding vertical piston and contains an ideal gas is used as a thermometer for water: The bottle is submerged in a water bath (whose temperature is to be measured) until thermal equilibrium is reached (Fig. 17–21). When the bottle is in contact with ice water, the volume inside the bottle is 0.35 L. The bottle is removed from the ice water and put in a second bath. This time, the enclosed volume is 0.38 L. What is the temperature of the second bath, in °C?



▲ FIGURE 17–21 Problem 16.

17. (II) One Sunday morning a family takes an automobile trip to Grandma's. At the start of the trip, the temperature is 288K (15°C), and the gauge pressure in the tires is 32 lb/in^2 (psi). (The gauge pressure is the excess over 14.5 psi, the exterior air pressure.) After an hour's ride over an interstate highway, the gauge pressure in the tires is 38 psi. What is the temperature of the air in the tires, assuming that air behaves as an ideal gas? Neglect any changes in volume of the tires.

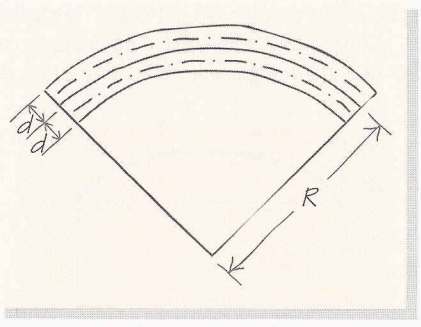
17–3 Thermal Expansion



18. (I) By how much will a steel rod of length 1.5 m and diameter 1.75 cm elongate if it is heated by 100°C?
19. (I) How much farther than a steel rod will a 1 m long aluminum rod expand when each undergoes a temperature increase of 40°C?
20. (I) The coefficient of thermal expansion for Invar is $0.70 \times 10^{-6}\ \text{K}^{-1}$. (Invar is a steel alloy.) Given that an Invar pendulum clock keeps perfect time at a room temperature of 20°C, how much time will the clock gain or lose per day when it is in a room at 30°C? (For the time-keeping properties of a pendulum, see Chapter 13.)
21. (I) The area of the circle formed by a circular loop of metal is found to increase by 1.6% when the temperature changes by 10°C. What is the coefficient of thermal expansion of the metal?
22. (II) When the temperature of mercury changes by ΔT, the fractional volume change, $\Delta V/V$, is given by $\Delta V/V = \beta \Delta T$, where $\beta = 1.8 \times 10^{-4}\ \text{K}^{-1}$ is the coefficient of thermal expansion. Consider a thermometer containing a bulb attached to a thin, cylindrical capillary tube. If the bulb and capillary tube contain 0.2 cm^3 of mercury, how large must the diameter of the capillary tube be so that a 1K change in temperature corresponds to a 2 mm change in the mercury level in the capillary tube? (Neglect the change in volume of the glass bulb when the temperature is raised by 1K.)
23. (II) A copper bowl of volume 1500 cm^3 is filled to the brim with water. Assume that the coefficient of volume expansion is $5.10 \times 10^{-5}\ \text{K}^{-1}$ for copper and $2.07 \times 10^{-4}\ \text{K}^{-1}$ for water. How much water will spill out when the temperature of the system is raised from 20°C to 50°C?
24. (II) Show that the area A of a plate whose coefficient of thermal expansion is α undergoes a fractional change $dA/A \cong 2\alpha\, dT$ when the temperature changes by a small amount dT.
25. (II) Look at the experiment done in Fig. 17–10. (a) How hot do we have to heat the brass ball of 2.028 cm diameter at room temperature to increase the diameter by 0.004 cm, so it will not pass through the ring? (b) What is the coefficient of volume expansion β for brass? (c) By what fraction does the volume expand for this temperature change?
26. (II) A metal bar is 1.75 m long with a coefficient of thermal expansion of $1.34 \times 10^{-5}\ \text{K}^{-1}$. It is rigidly held between two fixed beams. When the temperature rises, the metal bar takes on the shape of the arc of a circle (Fig. 17–22). What is the radius of curvature of the circle when the temperature rises by 40°C? [*Hint*: Use the small-angle approximation $\sin\theta \cong \theta - \theta^3/6$.]

▲ FIGURE 17–22 Problem 26.

27. (I) In the design of a mercury thermometer, it is desirable for each °C change to correspond to a 1 cm expansion of the metal. What is the cross section of the mercury column if the mercury at the lowest reading on the thermometer is contained in a bulb whose volume is 0.7 cm^3? Ignore any possible expansion of the glass tube.



28. (II) In space, where heat transfer by air is missing, large temperature differences can develop. A space telescope (Fig. 17–23) consists of a main mirror and an instrument unit, held together by titanium rods. The optical axis of the mirror (perpendicular to the mirror, through its center) hits the middle of the receiving window of the instrument unit. Suppose that the temperature of two neighboring rods increases by 20°C due to direct sunlight, with the temperature of the other two remaining unchanged. How far will the optical axis of the mirror move on the instrument unit, given that the rods are 5 m long and that $\alpha = 8.5 \times 10^{-6}\ K^{-1}$?

▲ **FIGURE 17–23** Problem 28.

29. (II) As we know from Chapter 13, the time expressed by a grandfather clock depends on the length of the pendulum. (a) Which is the best material for the pendulum of a clock to be used outdoors: aluminum, copper, or steel? (See Table 17–3.) (b) If the temperature of the clock ranges from −20°C to +30°C over the course of a year, and if the clock ticks with frequency $f = 1.00000$ Hz at 5°C, what is the yearly frequency range for each of the three materials?

30. (III) A strip of brass 1.5 mm thick and 12 cm long is glued back-to-back to a strip of Invar with the same dimensions. When the temperature is increased by ΔT, the composite strip tends to curl into an arc of a circle (Fig. 17–24). Find the radius of curvature of this circle for $\Delta T = 8°C$, given that the coefficient of thermal expansion is $19 \times 10^{-6}\ K^{-1}$ for brass and $0.7 \times 10^{-6}\ K^{-1}$ for Invar.

▲ **FIGURE 17–24** Problem 30.

31. (II) The coefficient of volume expansion, β, for ethyl alcohol is $1.12 \times 10^{-3}\ K^{-1}$. Suppose that a cylindrical copper container, with a coefficient of thermal expansion of $1.67 \times 10^{-5}\ K^{-1}$, is filled to the very brim with ethyl alcohol at 5°C. What percentage of the alcohol will spill if the temperature is raised to 25°C?

17–4 The Equation of State of Gases

32. (I) A container holds gas at a pressure of 1.0 atm and a temperature of 300K. Half the gas leaks out while the temperature is raised to 340K. What is the pressure in the container?

33. (I) A dilute gas in a container fitted with a piston occupies a volume of 2500 cm^3. If the pressure is increased by 50% and the temperature in kelvin is decreased by 15%, what volume will the gas occupy?

34. (I) A 1000 L container is filled with an ideal gas at 1.2 atm and 310K. How many moles are in the container? How many gas molecules?

35. (I) What is the volume occupied by three moles of an ideal gas at 30K and 10^{-7} atm in the upper atmosphere?

36. (I) What is the mass density of steam at a temperature of 100°C and a pressure of 1 atm, given that the molecular weight (the number of grams of 1 mol of the material) of water is 18 g/mol?

37. (I) What is the mass density of air (average molecular weight 29 g/mol), at a pressure of 0.31 atm and a temperature of −43°C? (These conditions correspond roughly to those at the top of Mount Everest.)

38. (I) A helium balloon is filled with 150,000 cm^3 of helium gas at *STP* (standard temperature and pressure: 0°C and 1 atm). How many moles and molecules of helium (molecular weight 4.0 g/mol) are contained in the balloon?

39. (I) A container of ideal gas whose volume can be changed by the movement of a plunger is placed in a large bath that maintains the temperature of the gas at a fixed value of 295K. The plunger is pulled out so that the volume is increased by a factor of 1.78. By what factor is the pressure changed in the vessel, if at all?

40. (I) The atomic weight A of an elemental substance is closely related to the mass of the atoms of that substance. Atoms consist of electrons, of negligible mass, and a total of A protons and neutrons, which each have nearly the same mass M. The total mass of an atom is therefore approximately AM, and N_A atoms have a total mass AMN_A. By the definition of Avogadro's number, N_A, this mass is A g. Given the value of N_A, what is M in grams?

41. (I) A container at 0°C holds a mixture of gases: 80% nitrogen (N_2 molecular weight 28 g/mol) and 20% oxygen (O_2 molecular weight 32 g/mol) by weight. Assuming that for a dilute gas each constituent behaves as if it alone occupied the volume, what is the partial pressure due to each constituent of the mixture, given that the total mass of gas in the container is 8.0 g and that the volume is 4.0 L? What is the total pressure in the container?

42. (I) Consider a container of an ideal gas at a fixed pressure. The temperature is 290K. What is the fractional change in volume if the temperature changes to 296K? Can you derive a general formula that holds for all ideal gases?

43. (II) Given that the molecular weight of water (H_2O) is 18 g/mol and that the volume occupied by 1.0 g of water is $10^{-6}\ m^3$, use Avogadro's number to find the distance between neighboring water molecules. Assume for simplicity that the molecules are stacked like cubes.

44. (II) The lowest pressure achievable with a rotary vane pump is on the order of $10^{-2}\ N/m^2$. What is the number density of molecules of the gas in a chamber that holds gas at this pressure and at a temperature of 20°C?

45. (II) The pressure of an ideal gas in a closed container is 0.60 atm at 35°C. The number of molecules is 5.0×10^{22}. (a) What are the pressure in pascals and the temperature in kelvins? (b) What is the volume of the container? (c) If the container is heated to 120°C, what is the pressure in atmospheres?

46. (II) Freon has van der Waals values of $a = 1.08\ \text{J}\cdot\text{m}^3/\text{mol}$ and $b = 10^{-4}\ \text{m}^3/\text{mol}$. (a) Calculate the pressure inside a 0.40 L container of 1 mol of freon at 15°C. (b) What is the percentage difference between this pressure and the pressure you would have found had Freon been ideal? (c) What would your answers be if there were 100 mol inside the container?

47. (II) The Dieterici equation of state is

$$p\left(\frac{V}{N} - b\right) = kT \exp\left(-\frac{aN}{kTV}\right).$$

(a) Find the equation of state to which this reduces if $a = b = 0$. (b) By expanding the exponential function, find the equation of state to first order in a. (c) Sketch the isothermal curve on a p–V diagram, together with the corresponding curve for the ideal gas. In making your sketch, you can assume a and b are small.

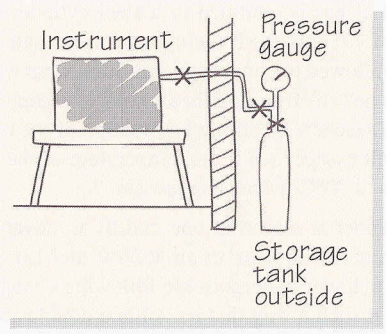
48. (II) The molecular weight of H_2 is 2.0 g/mol. Consider H_2 gas in a container at STP (see Problem 38). (a) What volume is occupied by 30 g? (b) What mass and volume are occupied by 0.50 mol and 10 kmol?

49. (II) Use the ideal gas law to calculate the volume occupied by 1 mol of ideal gas at 1 atm pressure and 0°C. Given that the average molecular weight of air is 28.9 g/mol, calculate the mass density of air, in kg/m^3, at the above conditions.

50. (II) Use the result of Problem 49 and Avogadro's number for the number of molecules in 1 mol, 6.02×10^{23}, to estimate the number of molecules in your lecture hall.

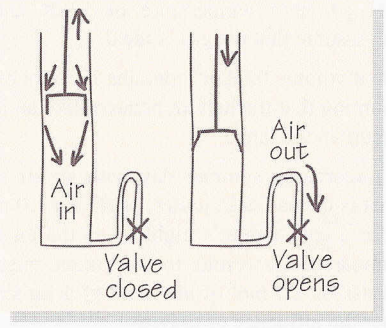
51. (II) What is the mass density of helium gas (atomic weight 4.00 g/mol) at 1 atm pressure and a temperature of 8K?

52. (II) A child takes 20 puffs of air to blow up a spherical balloon. The diameter of the balloon is 23 cm. The temperature is 23°C, and the exterior atmospheric pressure is 1 atm. (a) How many molecules are in each of the child's puffs? (b) If the surrounding air and the balloon are heated to 28°C, what size will the balloon be?



53. (II) In an experiment, a vacuum of 10^{-10} atm is achieved in a bottle. If the bottle is at room temperature (30°C), what is the number of molecules in the bottle per cubic centimeter?

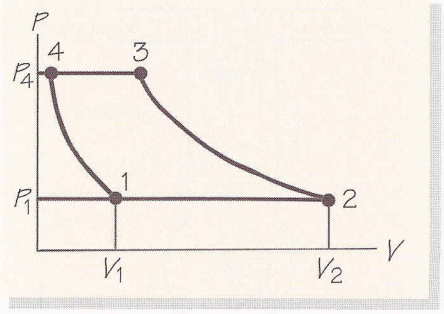
54. (II) At altitudes above 14,000 ft, pilots must breathe air with enriched oxygen because the density of the atmosphere is decreased. The pressure of air is only about 0.26 atm at a typical height for flying of 32,000 ft. If the airplane is not pressurized, what must the fraction of oxygen in the air be in order for a pilot to breathe the same amount of oxygen as at sea level?



55. (II) An ideal gas is contained in a tank at 120 atm of pressure and 263K. (a) If half the mass of gas is drawn off and the temperature then rises by 50K, what is the new pressure? (b) Suppose instead that the temperature first rises by 50K and then half the mass of the gas is drawn off. What is the new pressure?

56. (II) For safety reasons, compressed gases for laboratory use are often stored outdoors and transferred to where they are needed via a system of tubes and valves (Fig. 17–25). Suppose that a 150 L tank contains hydrogen at 25 atm at −5°C at the beginning of an experiment. If 190 L are used at 25°C and 1 atm pressure, what is the pressure of the remaining hydrogen? The temperature outside does not change during the measurement.

57. (II) The cylinder of a manual bicycle tire pump is 35 cm long; its inside diameter is 2.5 cm. When the piston is pulled up, the valve to the tire is closed and air at atmospheric pressure enters the cylinder through the gap between the piston and the wall of the cylinder, which acts like another valve (Fig. 17–26). When the piston is pushed down, the air in the cylinder is compressed. The valve to the tire opens when the pressure in the tire is reached, and air is transferred to the tire during the rest of the stroke. The last 5% of the volume of air remains in the cylinder and the hose. Suppose that you are pumping up a tire that already contains air at 2.5 atm gauge pressure. How much air is transferred to the tire at this pressure? What is the volume of this air at atmospheric pressure? Sketch a p–V diagram of the process. Assume that the temperature is constant.



▲ **FIGURE 17–25** Problem 56.

▲ **FIGURE 17–26** Problem 57.

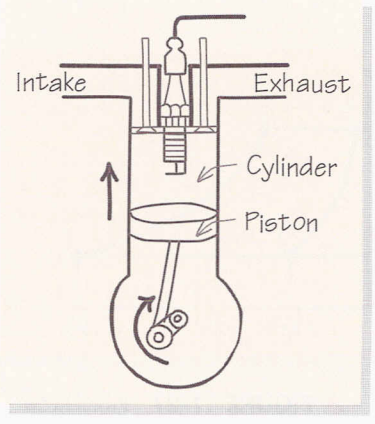
58. (II) Figure 17–27 represents the variation of the volume and pressure of gas contained in a cylinder with a movable piston. The curved sections of the curve are isotherms. Calculate the temperature, pressure, and volume at the points 1, 2, 3, and 4 given that $p_1 = 1.00$ atm, $V_1 = 1.00$ L, $T_1 = 0.0$°C, $V_2 = 3.5V_1$, and $p_4 = 3p_1$.

▲ **FIGURE 17–27** Problem 58.

59. (II) The specific volume of a gas is its volume per unit mass; that is, the inverse of the density. Compute the specific volume and density of oxygen gas, O_2, at $T = 15$°C and 1.0 atm of pressure, assuming that oxygen gas is ideal.

60. (II) An ideal gas is confined in a steel cylinder at 25°C and a pressure of 7.0 atm. (a) If the cylinder is surrounded by boiling water and allowed to come to equilibrium, what will the pressure of the gas be? (b) If the gas is allowed to escape until the pressure again reaches 7.0 atm, what fraction of the original gas, by weight, will escape? (c) If the temperature of the remaining gas now drops to 20°C, what is its pressure?

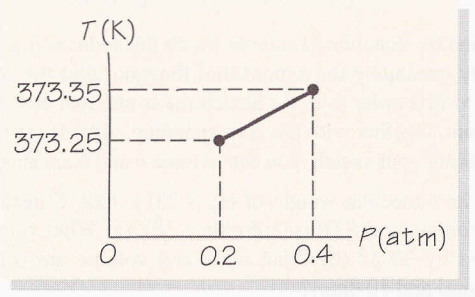
61. (II) A cylinder is closed at one end by a movable piston. The cylinder contains 300 cm^3 of air at 20°C and 1.0×10^5 Pa pressure. The cylinder undergoes the following changes: (a) the gas is heated in such a way that its volume doubles but its pressure remains constant; (b) the volume is kept constant and the temperature is changed until the pressure increases by 30 percent; (c) the gas cools, and the piston position is adjusted to keep the pressure constant until the initial volume is reached. Calculate the volume, pressure, and temperature after each step.



62. (II) The law of Joseph Gay-Lussac and Jacques Charles (1802) states that any ideal gas undergoes the same fractional increase in the product of pressure, p, and volume, V, when the gas is brought from one temperature to another. What is the fractional increase in pV for an ideal gas brought from the temperature of ice melting at 1 atm of pressure to the temperature of water boiling at the same pressure?

63. (II) Calculate the volume of 24 g of the gaseous form of ethyl ether, $C_4H_{10}O$, at a temperature of 120K and pressure of 0.080 atm. Assume that the gas is ideal.

64. (II) A tank of volume 0.80 m^3 contains 125 mol of helium gas at 25°C. Assuming that the helium behaves like an ideal gas, what is the pressure in the tank?

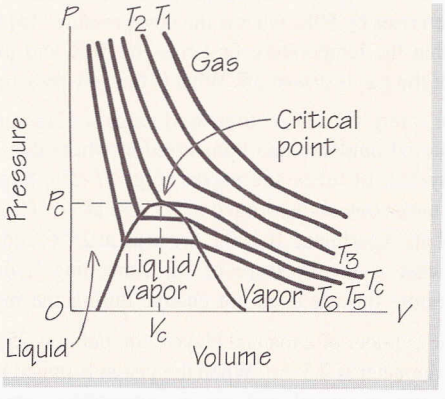


65. (II) It is a scorching summer day with an air temperature of 308K. What is the value, in joules, of RT for 1.0 mol of air? Repeat this for a cold winter's night when the air temperature is 258K. Compare these results to the kinetic energy that a ball with the mass of 1.0 mol of air (28.9 g) acquires when it falls 1.0 m under the influence of gravity.

66. (II) At the beginning of a compression stroke, the cylinder in a combustion engine contains 1.0 L of air at atmospheric pressure and a temperature of 20°C (Fig. 17–28). At the end of the stroke, the air has been compressed to a volume of 60 cm^3, and the total pressure is 35 atm. What is the temperature of the air when it is so compressed?

▲ **FIGURE 17–28** Problem 66.

67. (II) The steam point of water is the point where water vapor (steam) and boiling water coexist at a pressure of 1.00 atm. When a constant-volume gas thermometer calibrated to read a temperature of 273.16K at the triple point of water is used to measure the temperature of the steam point, the result depends slightly on the pressure of the gas in the thermometer because the gas is not precisely ideal (Fig. 17–29). In particular, if oxygen is used in the thermometer, the temperature of the steam point is determined to be 373.35K when the gas pressure is 0.40 atm, and 373.25K when the pressure is reduced to 0.20 atm. What is the temperature of the steam point?



▲ **FIGURE 17–29** Problem 67.

68. (II) Carbon dioxide obeys the van der Waals equation of state with $a = 5.96 \times 10^6$ atm · cm^6/mol^2 and $b = 98.6$ cm^3/mol. We know that 0.30 moles of CO_2 occupies 2.5×10^3 cm^3 at 1.7 atm of pressure. (a) Find the temperature of the gas. (b) Redo your calculation, but this time assume that CO_2 is an ideal gas. What is the percentage difference between the two answers?

69. (II) There is a certain temperature T_B (the *Boyle temperature*) for which a van der Waals gas behaves as if it were ideal. (a) Show that an expression for this temperature is $T_B = (a/bR)[1 - (bn/V)]$. (b) The constants a and b of the van der Waals equation of state are $a = 0.140$ $m^6 \cdot Pa/mol^2$ and $b = 4.00 \times 10^{-5}$ m^3/mol for argon gas. What is the value of the Boyle temperature of argon gas when the gas is so dilute that the term bn/V in the expression for the Boyle temperature can be ignored?

70. (III) An isotherm of 1 mol of a gas that obeys the van der Waals equation of state and is plotted on a p–V curve falls monotonically for large T. As T is decreased and new isotherms are plotted, the curve begins to show a kink, and at a temperature known as the *critical temperature*, T_c, there is a flat spot in the curve, where the slope is zero (Fig. 17–30). At this point, $p = p_c$ and $V = V_c$. Find T_c, p_c, and V_c in terms of the constants a and b.

▲ **FIGURE 17–30** Problem 70.

*17–5 Blackbody Radiation

71. (I) According to the Stefan–Boltzmann formula, the energy of radiation emitted by a blackbody per unit area per unit time is proportional to T^4, where T is the temperature in the Kelvin scale. Compare the energy emitted by a tungsten filament at 3200°C and the same filament at room temperature (25°C).

72. (I) The intensity of radiation from a small source decreases with the square of the distance from the source. Consider the energy of radiation that reaches your face after being emitted by solid aluminum at room temperature (25°C). At what distance will this energy of radiation be the same as the energy emitted by the same amount of molten aluminum (800°C) that reaches your face when you are 20 m from the aluminum? (Your answer will surprise you. Can you explain why? A look at Fig. 17–16 should help.)

73. (I) The dominant frequency of radiation emitted by an object is related to its temperature by $hf \cong kT$. Find the dominant radiation frequency emitted by (a) an object in interstellar space at 3K; (b) a body of water at 280K; (c) an electric stove heating unit (800K); (d) melting tantalum (3000K).

74. (I) The human eye is most sensitive to yellow light with a wavelength of approximately 550 nm. What is the temperature of an incandescent bulb filament that radiates most of its energy as a blackbody at this wavelength?

75. (II) The temperature of your skin is about 35°C. Calculate the wavelength at which the Planck radiation curve has a maximum for this temperature, and therefore the wavelength at which your body radiates the most energy. Use the more acccurate estimate indicated in Example 17–13.

76. (II) Show that the integral over all frequencies of the Planck formula given by

$$U(T) = \int_0^\infty \left(\frac{8\pi hf^3}{c^3}\right)\frac{1}{e^{hf/kt} - 1}df$$

gives a result that is of the form (a constant) $\times T^4$. [*Hint*: Change variables from f to hf/kT.] The energy emitted per unit area per unit time, $P(T)$, is proportional to $U(T)$, and thus $P(T)$ is also proportional to T^4, as in the Stefan–Boltzmann formula, Eq. (17–17).

77. (II) The surface of the Sun is at a temperature of 6000K. At what rate is energy radiated from the whole surface of the Sun, given that the radius of the Sun is $R = 6.95 \times 10^8$ m?

78. (II) Assume that the radiation emitted from the Sun moves radially outward from the Sun and that no radiation is absorbed between the Sun and Earth. How much energy in the form of radiation will fall per second on an area of 1 m^2 on Earth, if that area is perpendicular to the straight-line path of the radiation? The distance from the Sun to Earth is 1.5×10^{11} m.

79. (II) The average surface temperature of Earth is 290K. How much energy per second is radiated by Earth's surface, assuming that Earth simulates a blackbody. Compare this result with the amount of radiative energy that reaches Earth from the Sun. Use the result of Problem 78.

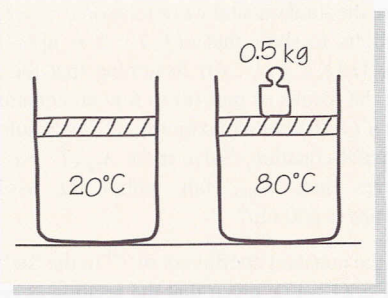
80. (III) The energy density per unit frequency in the frequency range from f to $f + df$ in blackbody radiation is $u(f, T)\,df$, where $u(f, T)$ is given by Eq. (17–16). An alternative way to express the blackbody radiation is to give $u'(\lambda, T)\,d\lambda$, the energy density per unit wavelength in the wavelength range from λ to $d\lambda$. (a) Use the fundamental wave relation $c = \lambda f$, where c is the speed of light, to show that $u(f, T)\,df = u[(c/\lambda), T]c\,d\lambda/\lambda^2$, so $u' = u[(c\lambda), T]c/\lambda^2$. (b) Assuming that the temperature is fixed, use the results of part (a) to find an equation for the λ_{max} for which $u'(\lambda, T)$ has a maximum. (c) The result of part (b) is a transcendental equation. Solve it for $\lambda_{max}T$. For what range of temperatures does λ_{max} fall within the visible spectrum, $\lambda \cong 450$ nm to 650 nm?

81. (III) Find the constant coefficient of T^4 in the Stefan–Boltzmann formula, Eq. (17–17), given that the relation between $P(T)$ and the total energy density $U(T)$ calculated in Problem 76 is $P(T) = cU(T)/4$, where c is the speed of light. [*Hint*: An appropriate entry in a table of integrals is

$$\int_0^\infty [x^3/(e^x - 1)]\,dx = \pi^4/15.]$$

General Problems

82. (II) Some astronomers estimate that toward the center of the galaxy, the average interstellar gas is molecular hydrogen, at a density of roughly 1 molecule per cubic centimeter and a temperature of between 10 and 20K. Estimate the pressure of this gas. Compare this with atmospheric pressure (1 atm = 760 torr) and very good laboratory vacuums (10^{-10} torr) that are achieved only with some difficulty.



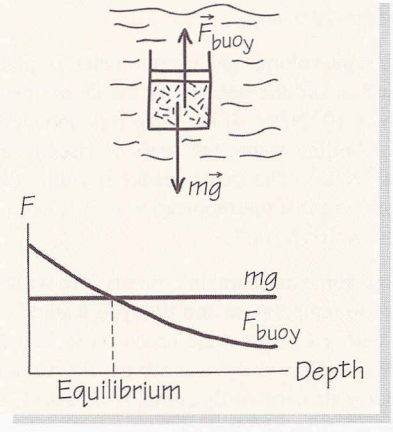
83. (II) Use Archimedes' principle (Section 16–4) to estimate how much helium is needed for a balloon to lift a payload of 230 kg (including the mass of the balloon) in air at 1.0 atm pressure and 10°C. You will need the molecular weight of helium (4.00 g/mol) and that of air (29 g/mol).

84. (II) A constant-volume gas thermometer is placed in contact with ice water, and the pressure in the thermometer is observed to be 0.76×10^5 N/m^2. If the same thermometer is then placed in a pot of boiling water, the pressure rises to a new value of 0.90×10^5 N/m^2. The thermometer is calibrated in °C. What temperature will this thermometer read if it has a pressure reading of 0.84×10^5 N/m^2?

85. (II) Suppose some measurable property Z of a material you have is sensitive to temperature and that you wanted to make a thermometer with a Celsius scale based on it. You therefore write $T_C = a + bZ$. How do you establish the values of a and b? Would your scale necessarily coincide with the Celsius scale that you would get from an ideal gas?

86. (II) The human eye can detect colors over the electromagnetic wavelength range of about 300 to 700 nm. (a) Use the results of Section 17–5 to calculate what temperatures correspond to the maximum energy densities ($hf \cong kT$) for this range of frequencies? (b) The answer to Problem 80 is $\lambda_{max}T = 2.9 \times 10^{-3}$ m · K. Calculate the temperatures using this relation. (c) What is the percentage difference, if any, for the ends of the range in the two calculations?

87. (II) A cylindrical vessel with a tight but movable piston is placed in a vertical position so that the piston, whose area is 70 cm^2, is subject to atmospheric pressure. When the gas in the vessel is heated from a temperature of 20°C to 80°C, a 0.5 kg mass must be placed on top of the piston to hold the piston at the position it occupied at the lower temperature (Fig. 17–31, see next page). What is the volume of 0.2 mol of the gas?



▲ **FIGURE 17–31** Problem 87.

88. (II) An air bubble of volume 8 cm^3 rises from the bottom of a lake 15 m deep. The temperature at the bottom is 8°C. The bubble rises to the surface, which is at 20°C and at atmospheric pressure. Assuming that the bubble is in thermal equilibrium with the surroundings at all times, calculate the volume of the bubble at the surface.

89. (II) In Chapter 14 we stated that the speed of sound in air is given by $v_{\text{sound}} = \sqrt{\gamma p/\rho_0}$, where the constant $\gamma \cong 1.4$ for air near STP (see Problem 38), p is the pressure, and ρ_0 is the density of the air. Reexpress the speed of sound in terms of the temperature. What is the difference in the speed of sound at the coldest and hottest times of day in a desert?

90. (II) A bottle containing air is closed with a watertight yet smoothly moving piston. The bottle with its air has a total mass of 0.30 kg. At the surface of a body of water whose temperature is a uniform 285K throughout, the volume of air contained in the bottle is 1.5 L (Fig. 17–32). Recall that the pressure of water increases with depth below the surface, D, as $p = p_0 + \rho g D$, where p_0 is the surface pressure and $\rho = 1.0$ kg/L. The bottle is submerged. (a) What is the volume of the air in the bottle as a function of depth? (b) Calculate the buoyant force on the bottle as a function of depth. (c) At what depth do the buoyant force and the force of gravity cancel? (d) Is the depth at which the force on the bottle is zero, calculated in part (c), a stable or an unstable equilibrium?

▲ **FIGURE 17–32** Problem 90.

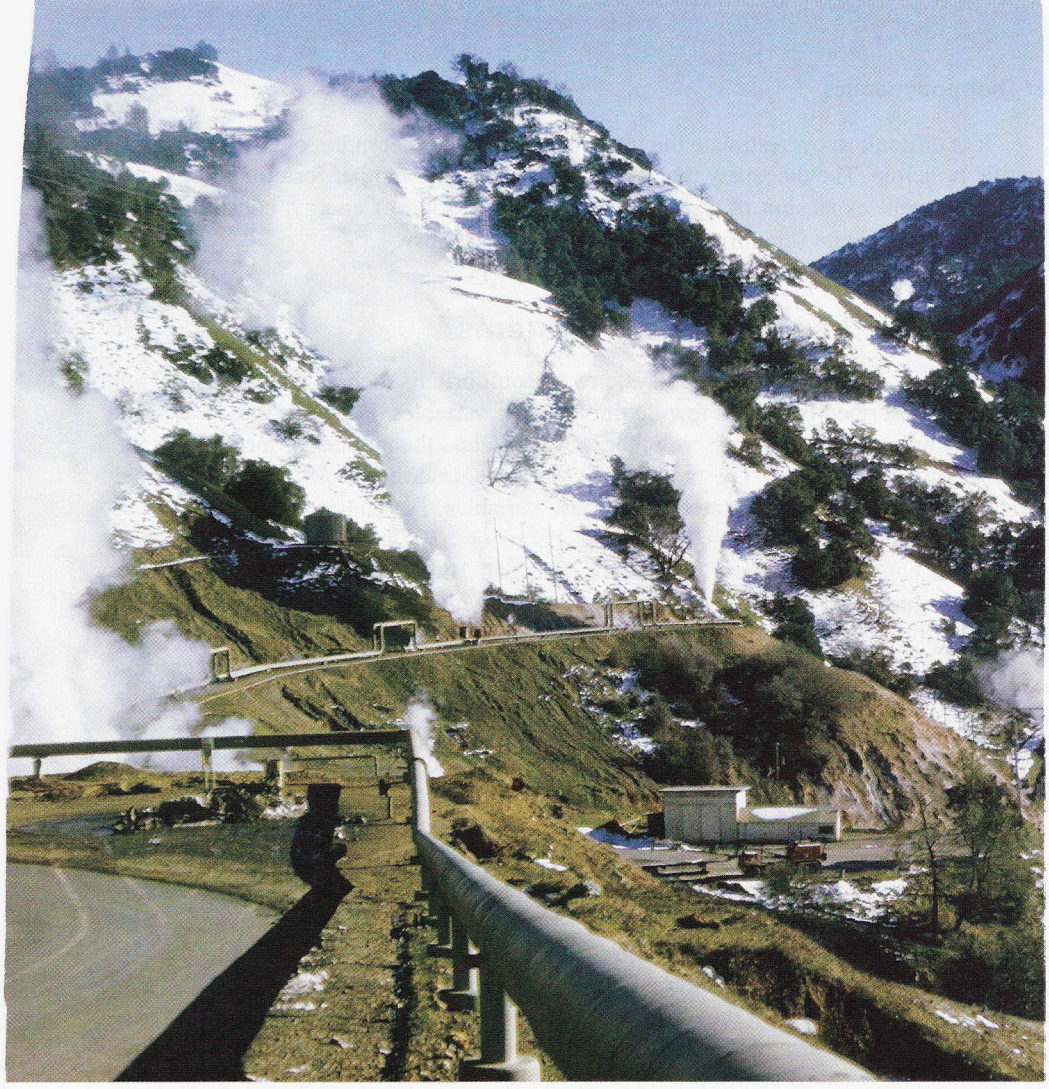
91. (II) Suppose that, instead of the Kelvin scale, an alternative temperature scale—call it the Kelvin′ scale, with the units K′—were defined in which the zero level remains unaffected but the temperature at the triple point of water is taken to be 500K′. Calculate the value of Boltzmann's constant in units of J/K′.

92. (II) Consider the radiation emitted from a furnace through a hole of area 1 cm^2. Assume that all the radiation is absorbed by a beaker that contains 42 g of water. Given that it takes 4.2 J of energy to raise the temperature of 1 g of water by 1°C, how long will it take for the water to be heated by 8°C if the furnace temperature is 1600K? Assume that there are no energy losses due to the beaker.

93. (III) The van der Waals equation of state, Eq. (17–15), can be put into a form that is an expansion in powers of the density. Dividing by RT and then by $[(V/n) - b]$ in Eq. (17–15), we can write

$$p + \frac{\alpha(n/V)^2}{RT} = \left(\frac{V}{n} - b\right)^{-1} = \frac{n}{V}\left(1 - b\frac{n}{V}\right)^{-1}.$$

(a) Show that, for $bn/V < 1$, this equation has the approximate form



$$\frac{p}{RT} = \frac{n}{V} + b\left(\frac{n}{V}\right)^2 - \frac{\alpha}{RT}\left(\frac{n}{V}\right)^2.$$

(b) The result in part (a) is of the general form

$$\frac{p}{RT} = \frac{n}{V} + B_2(T)\left(\frac{n}{V}\right)^2,$$

where, in this case, the function $B_2(T)$ is $B_2(T) = b - (a/RT)$. This is an example of a *virial expansion* for the equation of state, and the function $B_2(T)$ is known as a *virial coefficient.* Show that $B_2(T)$ starts out negative as T increases from some small value, passes through zero, and then becomes positive. The value of T at which $B_2(T)$ is zero is the Boyle temperature, where a real gas satisfying the van der Waals equation behaves as though it were ideal (see Problem 69).

Chapter 18

◀ Part of a large plant near Geyserville, in northern California, that uses thermal energy from within Earth to do work and generate electric power. While such a plant does not require a separate fuel source that must be replenished, any electric energy that it has produced has depleted at least that much thermal energy from the underground thermal source.

Heat Flow and the First Law of Thermodynamics

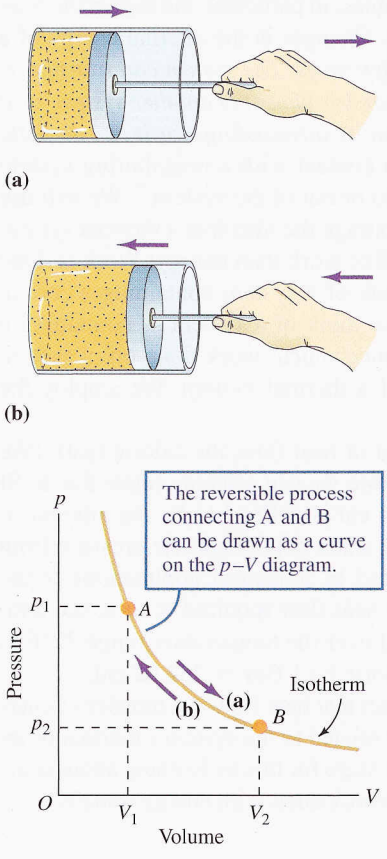
Steam contains thermal energy, and as a result steam can push a piston in a cylinder or turn a turbine and can thereby do work. The observation that we can transfer thermal energy to a mechanical system and do work is important. In this chapter we will see how thermal energy is related to other forms of energy with which we are familiar and how it can be used to do mechanical work. We will see that as the temperature of a thermal system increases, so does the amount of thermal energy in the system.

Changes in the energy of thermal systems (thermal energy) and its relation to changes in the energy of the systems' surroundings is summarized in two important laws of physics—the first and second laws of thermodynamics—which we examine here and in Chapter 20, respectively. The first law of thermodynamics describes thermal energy as just another form of energy—like kinetic energy or potential energy. The principle of the conservation of energy that we developed in Chapter 7 is now expanded to include the thermal energy of a system. This energy can be accounted for in mechanical form: It is the kinetic and potential energy of the system's microscopic atomic constituents (Chapter 19). In other words, the first law of thermodynamics is nothing more than the conservation of energy principle applied to thermal systems. The second law of thermodynamics states limitations on how much of a system's thermal energy can be converted to other forms of energy.

It is difficult to overestimate the importance of the conservation of energy as a scientific principle. The discovery that thermal energy is just another form of energy, and the consequent expansion of the principle of conservation of energy, constitutes one of the truly important scientific advances of the 19th century.

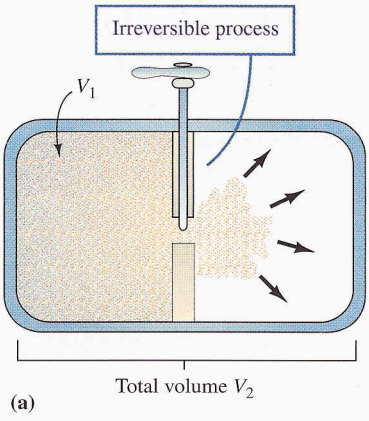
18–1 Changes in Thermal Systems

As we saw in Chapter 17, thermal systems in equilibrium, such as a container of hot steam, are described by only a few thermodynamic variables. For a gas these variables are the temperature T, the pressure p, the volume V, and the number of moles n (or the number of molecules, N). Thermodynamic variables describe the *state* of the thermal system, and an equation of state relates these variables. For example, the equation of state for an ideal gas [Eqs. (17–7) and (17–9)] is $pV = nRT = NkT$, where R is the universal gas constant and k is Boltzmann's constant. But other equations of state are equally possible and can all be handled the same way. If we assume that n is fixed, the remaining three variables are connected by an equation of state, and we can very usefully describe the state as a point on a two-dimensional plot, such as a p–V diagram, a p–T diagram, or a V–T diagram. Changes, or transformations, in the state of a thermal system can be represented as curves on such diagrams—at least if thermal equilibrium is established at every stage of the transformation. We have already described and used such curves in Section 17–4 (see Example 17–11).

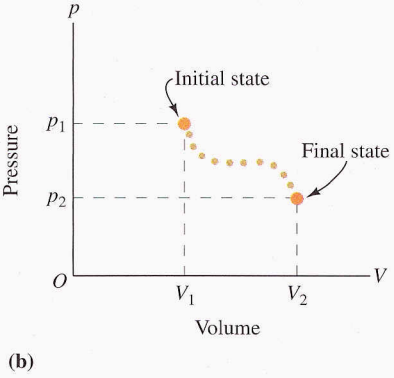


To maintain thermal equilibrium at each step of a transformation, changes must be made slowly. Just how slowly depends on the internal dynamics that lead to equilibrium. For example, it is not difficult to compress a gas in such a way that it maintains thermal equilibrium at each stage. To see why, consider a piston compressing a gas. When molecules bounce from the inward-moving piston, they are speeded up (thereby gaining energy) and distribute their additional energy to other molecules through collisions. The time required for the effect of the push to be evenly spread through the gas is characterized by the size of the container divided by the *speed of sound* in the gas. That is because the speed of sound is a measure of the spread of an organized disturbance through the gas through successive collisions. The speed of sound is large compared to typical mechanical motion, such as the movement of the piston; equivalently, the intermolecular collision time is short compared to the time for mechanical motion.

Reversible and Irreversible Processes



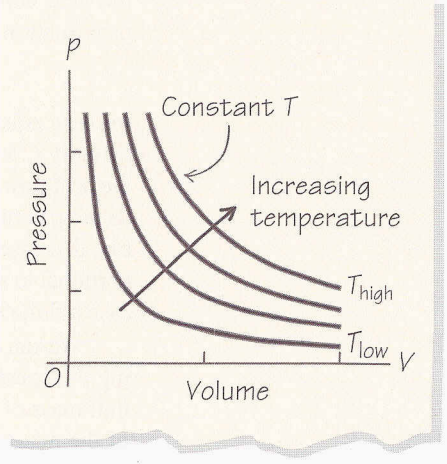
A change in which thermal equilibrium is maintained throughout, such as the sufficiently slow compression of a piston in an insulated cylinder, or the cooling of a bottle of soda in a refrigerator, is called a **reversible process**. Such changes can always be reversed by changing the external conditions in such a way that the thermodynamic variables return to their original values following the same path, only reversed, on the graph of thermal variables. As an example, the volume of a cylinder of gas held at a fixed temperature is increased from V_1 to V_2 in a controlled way when a piston slowly moves out of the cylinder with an external force balancing the pressure, as in Fig. 18–1a. If the piston is slowly pushed back in, as in Fig. 18–1b, the external conditions are reversed, and the thermodynamic variables of the gas recover their initial values. These changes are reversible, and Fig. 18–1c shows the transformation as a curve on a p–V diagram. Because the thermal system remains in equilibrium throughout a reversible process, reversible processes always connect equilibrium states.



Conversely, a gas expanding to fill a vacuum through an open stopcock (Fig. 18–2a) provides an example of an **irreversible process**, a process in which the thermal system's changes cannot be retraced. The expansion from V_1 to V_2 occurs rapidly and without control. Nothing you do with the stopcock will cause the released gas to reverse itself and reconcentrate within the original volume. We can mark the original and final points on a p–V diagram (Fig. 18–2b), but we cannot mark the points in between, because the system is not in thermodynamic equilibrium during the expansion. The particular irreversible process described here, in which the gas expands freely, is known as **free expansion**. Other examples of irreversible thermal transformations include the

melting of ice cubes in lemonade and the heating of a brake shoe as it rubs against the brake drum. Unless we state otherwise, in this chapter *we consider only reversible changes of state.*

◀ **FIGURE 18–1** The volume of a gas in a cylinder is reversibly changed when a piston is (a) slowly pulled or (b) slowly pushed. The temperature is held fixed during the transformations. (c) Constant-temperature reversible transformation of a gas between V_1 and V_2 on a p–V diagram. The curve is an *isotherm.*



▶ **FIGURE 18–2** (a) A gas initially confined to the left-hand side of a container expands to fill the container's total volume when a stopcock is opened. (b) Irreversible expansion of a gas from V_1 to V_2. The path is not well defined, and the dots serve only to indicate that there has been some irreversible change.

CONCEPTUAL EXAMPLE 18–1 A gas in contact with a thermal reservoir at temperature T is expanded reversibly from V_1 to V_2. The trace of points made by this change on a p–V diagram is an isotherm. Describe the isothermal curve if the gas is ideal.

Solution Because we have a gas in contact with a thermal reservoir, the temperature T must remain constant. Therefore, the ideal gas law, $pV = nRT$, reveals that the product of p times V must be a constant, because nRT is constant. We can see that as the volume increases from V_1 to V_2, the pressure must decrease from p_1 to p_2 in order to keep the product pV constant as shown in Figure 18–1c. The curve that corresponds to pV = a constant is a hyperbola. Figure 18–3 shows a family of hyperbolas, each curve corresponding to a different constant temperature.

What Do You Think? What would such a curve look like on a p–T diagram? *Answers to* ***What Do You Think?*** *questions are given in the back of the book.*

▲ **FIGURE 18–3** An isotherm for an ideal gas is a hyperbola, $p \propto TV^{-1}$. The isotherms corresponding to different temperatures are indicated.

18–2 Heat Flow

We suggested in Section 17–3 that the temperature of a system is closely related to its **internal energy**, or **thermal energy**. We will learn here that the internal energy of a thermal system is a function of the thermodynamic variables; in particular, the higher the temperature of a system, the higher the internal energy. Changes in the internal energy of a thermal system can manifest themselves in only a few ways: *The system can transfer its internal (thermal) energy by changing the temperature (or phase) of another system, or it can use its internal energy to do mechanical work on its surroundings, or it can do both.*

When the temperature of a thermal system in contact with a neighboring system changes, we say that there has been a **heat flow** into or out of the system.[†] We will use the term *heat flow* rather than *heat* in order to discourage the idea that a thermal system has a certain amount of "heat." Heat flow is more like work than energy: Work is done *on* or *by* a mechanical system, and we do not speak of a system containing a certain amount of work. It would be equally misleading to think of a system as containing a certain amount of "heat." Heat flow into, and/or mechanical work done on, a system may each contribute to raising the temperature of a thermal system. We employ the symbol Q for heat flow or, often, ΔQ.

As far as units, we start with the historical unit of heat flow, the calorie (cal). (We are going to have to learn some further physics before we can sensibly relate this to SI units with which we are familiar.) Provisionally, 1 cal is defined to be the amount of heat flow required to raise the temperature of 1 g of water at atmospheric pressure from 14.5°C to 15.5°C. Another unit for heat flow used in industrial applications is the *British thermal unit* (Btu), which is defined as the heat flow required to raise the temperature of a 1-lb weight of water by 1°F, averaged over the temperature range 32°F to 212°F. The British thermal unit is related to the calorie by 1 Btu = 252.02 cal.

A major aim of this chapter is to establish the fact that heat flow is a transfer of energy and that thermal systems have an internal energy related to the system's thermal properties. In the remainder of this section we will set the stage for this by learning about some properties of heat flow that are independent of its identification with energy transfer.

Heat Capacity

When there is a heat flow to or from a thermal system, the temperature of the system changes. The connection between heat flow and temperature change is the **heat capacity**, C. A *small* heat flow, dQ, *into* a thermal system will change the temperature by a small amount dT, with a proportionality constant that is the heat capacity C:

$$dQ = C\,dT. \tag{18–1a}$$

This can also be written for a *finite* heat flow ΔQ and a *finite* temperature change ΔT if the heat capacity does not depend on the temperature—a situation that is a good approximation for many physical situations:

$$\Delta Q = C\Delta T. \tag{18–1b}$$

In these equations the heat flow, whether large or small, can be positive or negative. The quantity C is always positive; thus, the sign of the temperature change indicates the sign of the heat flow. Equations (18–1a, b) state that there is a positive heat flow into a system when its temperature increases and there is a negative heat flow into the system when its temperature decreases. The value of the heat capacity depends on the particular material and is proportional to the amount (mass) of material. It may also depend on the temperature, in which case a finite heat flow is related to a finite temperature change through an integral.

We can eliminate the dependence of heat capacity on the amount of material by defining the **specific heat**, c, as the heat capacity of 1 g of the material—the heat capacity per unit mass of the material—and the **molar heat capacity**, c', as the heat capacity of 1 mol of the material. If the mass in grams of a thermal system consisting of n moles is m, then

$$C = mc = nc', \tag{18–2}$$

[†]We will see later that we can also have a heat flow without a temperature change when the system does work or undergoes a phase change.

and if A is the molecular weight (the mass of 1 mol, in grams), then

$$c' = Ac. \tag{18–3}$$

The units of heat capacity are cal/K; those of specific heat are cal/g · K; and of molar specific heat, cal/mol · K.

CONCEPTUAL EXAMPLE 18–2 You have a substance with a large specific heat—water is an example. For a given positive heat flow out of a given amount of the substance, the temperature will (a) rise a lot; (b) rise a little; (c) fall slightly; (d) fall a lot.

Answer If we remove energy (heat flow) from a substance with a large specific heat capacity, the temperature of the substance will fall only slightly. The substance has a "large capacity" for holding its temperature. (The word "slightly" should take into account the amount of the substance.) Water has a relatively large specific heat, which is why large bodies of water have strong moderating effects on the climate in their vicinity.

Path Dependence of Heat Flow

The heat capacity is defined in Eq. (18–1) in terms of a temperature change. But the conditions for a temperature change are not unique—for example, the volume or the pressure, or neither, can be held constant during the temperature change. The heat capacity generally depends on how the temperature change is made and on the values of the thermodynamic variables p, V, and T. This dependence is indicated by writing $C = C(p, T)$ or $C = C(V, T)$. We cannot use Eqs. (18–1a, b) to find a net heat flow unless we know more about how either pressure or volume changes as temperature changes. We say that the heat flow *depends on the path* along which temperature changes.

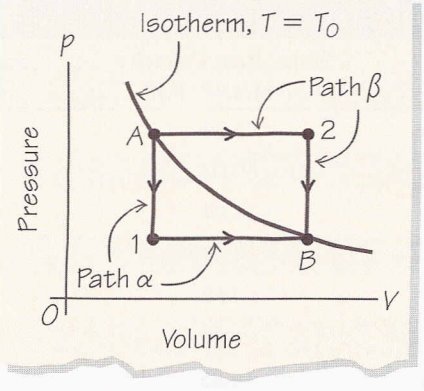
Let us examine two cases of special interest: In the first case the volume is kept constant, and in the second the pressure is held constant. For these cases, we label the heat capacity with the subscript V or p, and Eq. (18–1a) becomes

$$\text{for constant volume: } dQ = C_V\, dT; \tag{18–4}$$

$$\text{for constant pressure: } dQ = C_p\, dT. \tag{18–5}$$

Generally, C_V differs from C_p, as we will see later when we find C_V and C_p for an ideal gas. If these quantities are independent of temperature, then the generalizations of the finite change Eq. (18–1b) applies. Indeed, the heat capacities do turn out to be independent of temperature for monatomic ideal gases, which describe at least roughly all gases that are not too hot, and that will simplify things. Note that the subscript must be used on c and c' as well. (The volume change with temperature for liquids is insignificant compared with that of gases; for solids, pressure is not a useful variable. Therefore, the subscript is not used for these cases.)

One can show (to see why, see Section 18–7) that the heat capacity for constant pressure is larger than the heat capacity for constant volume:



$$C_p \geq C_V. \tag{18–6}$$

This inequality holds even for nonideal gases.

EXAMPLE 18–3 An ideal gas undergoes transformations that take it from point A to point B on a p–V diagram by the two different paths, α and β, shown in Fig. 18–4. Points A and B have the same temperature, $T = T_0$ (they lie on an isotherm). Assuming that C_V and C_p are constants, what is the heat flow into the gas (a) for path α (through point 1 at temperature T_1) and (b) for path β (through point 2 at temperature T_2)?

Strategy Figure 18–4 labels the various thermodynamic variables. We can use Eqs. (18–4) and (18–5) to find the heat flow along the various legs of the transformation. But because both C_V and C_p are constants, we can use these equations in "Δ" form, that is, we can use them for finite heat flows and finite temperature changes.

(continues on next page)

▲ **FIGURE 18–4** An ideal gas undergoes a transformation between points A and B by two different paths.

Working It Out (a) Along path α, there are two contributions: from point A to point 1 (constant volume), and from point 1 to point B (constant pressure). Thus

$$\Delta Q_\alpha = C_V\,\Delta T_{A\to 1} + C_p\,\Delta T_{1\to B}$$
$$= C_V(T_1 - T_0) + C_p(T_0 - T_1) = (T_0 - T_1)(C_p - C_V).$$

(b) For path β, there are also two contributions: from point A to point 2 (constant pressure), and from point 2 to point B (constant volume).

$$\Delta Q_\beta = C_p\,\Delta T_{A\to 2} + C_V\,\Delta T_{2\to B}$$
$$= C_p(T_2 - T_0) + C_V(T_0 - T_2) = (T_2 - T_0)(C_p - C_V).$$

The factor $(T_0 - T_1)$ is not equal to the factor $(T_2 - T_0)$. Thus the two answers are different, and the heat flow depends on the path that is followed.

What Do You Think? There is no temperature difference between points A and B. Why isn't the heat flow zero?

Calorimetry

The measurement of heat capacities is called **calorimetry**. Calorimetry, or more properly *adiabatic calorimetry*, is based on the fact that *when a system is mechanically and thermally isolated, heat flow is conserved within the system.* (A system is said to be *mechanically isolated* if it cannot do mechanical work on its surroundings.) A heat flow into one part of such a system must be matched with a corresponding heat flow out of another part. In such circumstances, heat flow is present only as long as there is a temperature difference between parts of the system; it ceases when equilibrium is established throughout the system.

Our definition of the calorie shows that the specific heat for water at 15°C and at 1 atm of pressure is

$$c_{H_2O} = 1\ \text{cal/(g}\cdot\text{°C)}.$$

The measurement of the specific heats of other substances is based on that of water, as in Example 18–4.

EXAMPLE 18–4 A block of iron (mass 100 g) is heated in an oven to 500K and then plunged into a closed, thermally insulated container of 500 g of water at 292K. The block and the water come to an equilibrium temperature of 297K. What is the specific heat of iron, c_{Fe}? Assume that the specific heats of water and iron do not vary significantly over the temperature ranges in question.

Strategy There is a positive heat flow ΔQ_{water} into the water—it is positive because the iron is initially hotter than the water and the water temperature increases. Similarly the iron cools, so the heat flow into it, ΔQ_{Fe}, is negative. The entire system of iron and water together is isolated, so that

$$\Delta Q_{system} = 0 = \Delta Q_{water} + \Delta Q_{Fe}.$$

We next relate the heat flows to the specific heats. There are two things to keep in mind: First, the heat capacities C are independent of temperature here, so we can use Eq. (18–1b) for finite temperature shifts. These temperature changes are all specified in the problem statement. Second, we are interested in the specific heats c, so we can use the relation $C = mc$, where m is the amount of material, also specified. These two facts allow us to write $\Delta Q = mc\Delta T$ for both water and iron in the equation above, and that is enough to solve for c_{Fe}.

Working It Out We have

$$0 = \Delta Q_{water} + \Delta Q_{Fe}$$
$$= m_{water}c_{water}(\Delta T)_{water} + m_{Fe}c_{Fe}(\Delta T)_{Fe}$$
$$= (500\ \text{g})(1\ \text{cal/g}\cdot\text{K})(297\text{K} - 292\text{K})$$
$$+ (100\ \text{g})c_{Fe}(297\text{K} - 500\text{K})$$
$$= 2500\ \text{cal} + (-2.03\times 10^4\ \text{g}\cdot\text{K})c_{Fe}.$$

We solve for c_{Fe} to find that

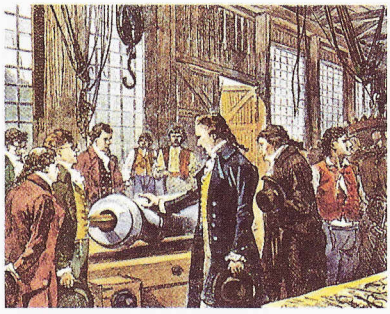
$$c_{Fe} = \frac{2500\ \text{cal}}{2.03\times 10^4\ \text{g}\cdot\text{K}} = 0.12\ \text{cal/g}\cdot\text{K}.$$

What Do You Think? What if we had used an aluminum block instead of iron in this experiment? Would the final system temperature be (a) higher, (b) lower, (c) no change? (Look at Table 18–1 for the specific heat of aluminum.)

TABLE 18–1 • Molar Heat Capacities and Specific Heats of Some Materials at Constant Volume†

Material	Molar Heat Capacity (cal/mol·K)	Specific Heat (cal/g·K)	Material	Molar Heat Capacity (cal/mol·K)	Specific Heat (cal/g·K)
Helium gas	3.00	0.75	Silicon	4.78	0.17
Argon gas	30.00	0.75	Aluminum	5.82	0.22
N_2 gas	4.94	0.176	Copper	5.85	0.092
O_2 gas	4.97	0.155	Iron	6.00	0.107
SO_2 gas	7.52	0.118	Lead	6.32	0.031
Diamond	1.46	0.12	Water	18.0	1.00
Beryllium	3.85	0.43	Mercury	6.7	0.033

† *Gases at standard temperature and pressure.*

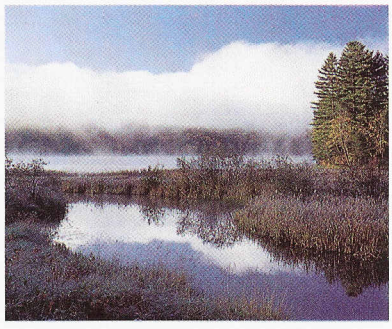


Example 18–4 shows how the specific heat of iron (or of many materials) can be measured. Calorimetry is used most often in the opposite sense: Given the specific heats, temperature changes are calculated in situations where there is a heat flow from one system to another. Table 18–1 gives the molar heat capacities and specific heats *at constant volume* for a variety of materials at room temperature. In this table, the gases are at standard pressure. In Chapter 19 we will see that the values in Table 18–1 can be explained in terms of the microscopic constituents and structure of the material.

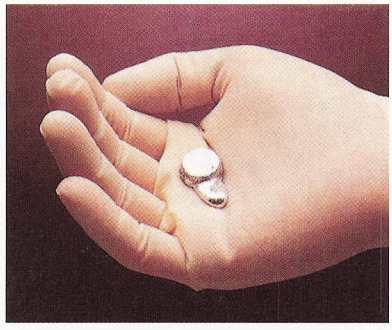
THINK ABOUT THIS . . .

WHAT ARE THE ORIGINS OF THE TERMS CALORIE, CALORIMETRY, CALORIC?

The prefix "calor" is derived from the Latin word *calor*, meaning heat in its colloquial sense. The French scientist Lavoisier coined the term "caloric" in his caloric theory of 1787; this theory proposed that a massless substance (a fluid) flows from one material to another when an object is heated. The fluid was called the *caloric*. The unit of heat flow was later called the *calorie*. Caloric was thought never to be created or destroyed, and all substances had caloric that could be absorbed or released. The term calorimetry refers to the science of measurements associated with heat flow; the term is still used today even though we know the idea of the caloric is wrong. A calorimeter is a device used to measure heat flow.



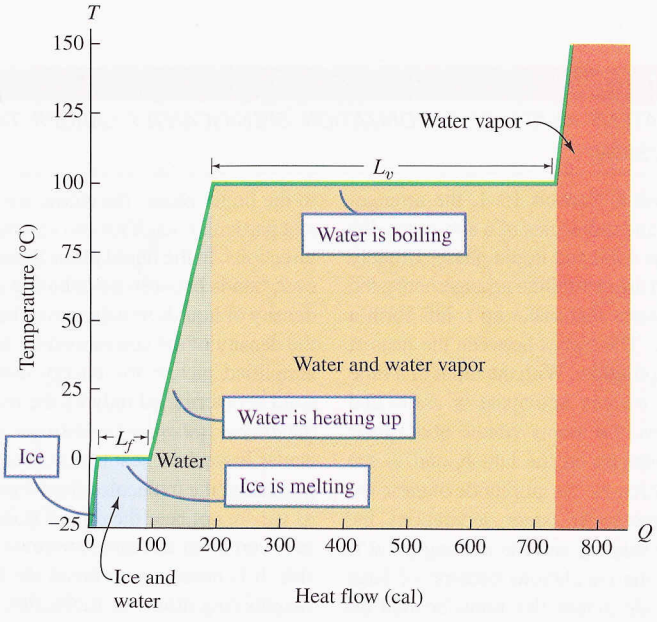
Count Rumford (Benjamin Thompson) played an important role in discrediting the caloric theory. While he was supervising the boring of cannon barrels in Bavaria in 1798, Rumford observed and quantified the continual heating of the metal (Fig. 18–5). He reasoned that if the heating were due to the transfer of a fluid—as proposed by the caloric theory—then the fluid eventually would be used up and no more heating should occur. He found that heat was caused by the process of friction and that there was a continual heat flow as long as the boring continued. He even used the hot chips of metal that were bored out to boil water!



▲ **FIGURE 18–5** Count Rumford observed that the temperature of cannon barrels rose steadily as they were being hollowed out. He concluded that the caloric theory could not be correct.

Phase Changes and Heat Flow

When there is a **change of phase** in a system, there is no temperature change even though there is a heat flow. For example, a solid state may change to a liquid state by melting, or a gaseous state may change to a liquid state by condensation (Fig. 18–6). It takes a certain heat flow to convert 1 g of ice at its melting temperature of 0°C to liquid water at 0°C (Fig. 18–7). The heat flow necessary to bring about the transformation is called the **latent heat of fusion**, L_f. Measurements show that $L_f = 79.6$ cal/g for ice.



(a)

(b)

▲ **FIGURE 18–6** (a) Mist forms when water droplets condense from water vapor. (c) Gallium melts at the temperature of the human body. When it does so, it absorbs heat flow from its surrounding environment.

▲ **FIGURE 18–7** Phase changes for 1 g of water. Note that the temperature remains constant as heat flow is added during melting and vaporization.

During the melting process, there is no change of temperature and, to a good approximation, there may be little change of pressure or volume. The heat flow goes into changing the molecular arrangement of the substance (see Fig. 16–1). Similarly it takes a certain heat flow to convert 1 g of water at its vaporization temperature, 100°C (at 1 atm pressure), to 1 g of steam. The heat flow necessary for this is called the **latent heat of vaporization**, L_v, whose value for water is 540 cal/g. Most of this heat flow goes into overcoming the intermolecular forces that hold the molecules close together and make a liquid much denser than a gas. Some latent heats are given in Table 18–2.

TABLE 18–2 • Some Latent Heats

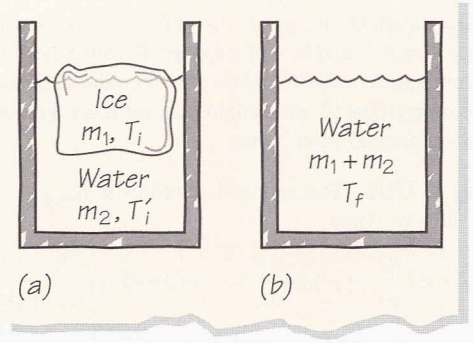
Material	Melting Temperature (K)	Latent Heat of Fusion (kJ/mol)
H_2	14	0.12
O_2	54	0.44
Water (H_2O)	273	6.0
Ethyl alcohol (CH_3CH_2OH)	159	4.8
Mercury	234	2.3
Lead	600	4.8
Copper	1357	13

Material	Boiling Temperature† (K)	Latent Heat of Vaporization (kJ/mol)
H_2	20	0.92
O_2	90	6.8
Water (H_2O)	373	41
Ethyl alcohol (CH_3CH_2OH)	351	39
Mercury	630	59
Lead	2023	178
Copper	2839	300

† *Boiling takes place at atmospheric pressure.*

THINK ABOUT THIS . . .

WHY ARE LATENT HEATS OF VAPORIZATION SIGNIFICANTLY LARGER THAN LATENT HEATS OF FUSION?



As we described in Section 16–1, the arrangement of atoms and molecules of a substance differs between the solid and liquid phase. Broadly speaking, solids are crystalline arrangements; the atoms or molecules that make up solids form a lattice structure. The forces between the nearest neighbors are springlike. With the input of a little energy, which we can anticipate is associated with a heat flow, the atoms vibrate about their equilibrium positions on the lattice, and as the energy input increases, the amplitude of these oscillations increases. At larger separations the forces become weaker, and the melting point is reached when the oscillations become of large enough amplitude to take the atoms beyond the point where the forces are springlike. At this point, which is where the substance has gone to the liquid phase, the atoms are no longer tied to a particular neighbor and can move in random directions. In the liquid phase there are still, however, bonds between neighboring atoms, and the density of liquids remains essentially the same as the density of the corresponding solid. So in this simplified picture the energy needed to melt a solid is determined only by the requirement that the *directional order* be destroyed—that the molecules leave their neat lattice arrangement. In vaporization the molecules form a gas, and (as long as we are not near the critical point) the distance between them increases enormously. To achieve this, it is necessary to *break the bonds* between neighboring atoms or molecules, and this takes much more energy than a rearrangement without actual separation.

CONCEPTUAL EXAMPLE 18–5 One of the games that children used to play was to take a toy tin soldier, put it in a spoon over a flame till the soldier melted, and then drop it into a pan of water. The shape of the solid mass was then used to cast shadows or to "read," like tea leaves. The temperature of the water naturally rose. Would it have risen more, less, or the same if the tin soldier had been heated to the point of almost melting and then dropped in the water?

Answer The just-melted tin and the not-quite-melted tin are at very nearly the same temperature. Nevertheless, they have quite different effects on the water. The water temperature rises because there is heat flow to it from the hot tin. But when a liquid solidifies (freezes), as does the melted tin, there is heat flow in the form of a latent heat of fusion. The not-quite-melted soldier does not have this additional thermal energy. There is thus more heat flow in the case of the melted tin soldier than in the case of the solid tin soldier, and the temperature of the water will rise higher when the melted soldier is dropped in rather than the not-quite-melted one.

EXAMPLE 18–6 One hundred grams of ice at 0°C is dropped into 200 g of liquid water at 49°C. The system is thermally isolated (see Chapter 17). After a period of time, the ice is entirely melted, leaving 300 g of water at 6°C. Assume that the specific heat of liquid water has the constant value $c = 1\ \text{cal/g}\cdot\text{°C}$. Calculate the latent heat of fusion of water.

Setting It Up As in Fig. 18–8, we label the mass of ice as m_1, its initial temperature as T_i, the initial mass of liquid water as m_2, and its initial temperature as T_i'. The final temperature of the system is T_f. All these quantities are given.

▲ **FIGURE 18–8** Ice dropped into water changes the temperature of the system.

Strategy With the system thermally isolated, the temperature cannot change as a result of thermal contact with the surroundings. Any heat flow must occur within the system between the water and the melting ice, and the net heat flow to the outside must be zero. We can summarize this condition as

$$\Delta Q_1 + \Delta Q_2 + \Delta Q_3 = 0,$$

where ΔQ_1 is the heat flow needed to melt the ice, ΔQ_2 is the heat flow necessary to raise the temperature of an amount m_1 of liquid water (from the melted ice) to the T_f, and ΔQ_3 is the heat flow necessary to cool an amount m_2 of liquid water (the initially present liquid) to T_f. The specific heat of water is assumed to be a constant, so we can use the finite heat-flow version of Eq. (18–1). By definition the latent heat of fusion, L_f, is the heat flow necessary to melt 1 g, so if m_1 is measured in grams, we have

$$\Delta Q_1 = m_1 L_f,\ \Delta Q_2 = cm_1(T_f - T_i),\ \Delta Q_3 = cm_2(T_f - T_i').$$

The only unknown is L_f, so to solve for it, we use the condition that $\Delta Q = 0$ for the system.

Working It Out Let's calculate ΔQ_2 and ΔQ_3:

$$\Delta Q_2 = (1\ \text{cal/g}\cdot\text{°C})(100\ \text{g})(6\text{°C} - 0\text{°C}) = 600\ \text{cal}$$
$$\Delta Q_3 = (1\ \text{cal/g}\cdot\text{°C})(200\ \text{g})(6\text{°C} - 49\text{°C}) = -8600\ \text{cal}.$$

Now we have

$$m_1 L_f + \Delta Q_2 + \Delta Q_3 = 0$$

or

$$L_f = \frac{-\Delta Q_2 - \Delta Q_3}{m_1} = \frac{-600\ \text{cal} + 8600\ \text{cal}}{100\ \text{g}} = 80\ \text{cal/g}.$$

You can find $\Delta Q_1 = L_f \times (100\ \text{g}) = 8.00 \cdot 10^3\ \text{cal}$. This is much larger than the value associated with raising the temperature of the melted ice; we have $L_f/c = 80$. Latent heats are typically quite significant.

What Do You Think? Describe what would be different if the latent heat of fusion of water were (a) much larger, (b) much smaller than it is. Think about lakes in Minnesota or about iced drinks for your answer.

18–3 Heat Flow in Materials

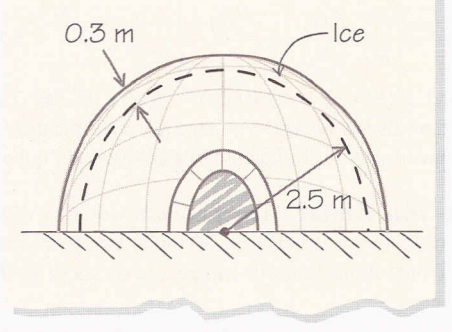
When one end of a solid beam of length L is maintained at a temperature T_1 and the other end is kept at a lower temperature T_2, there will be a steady heat flow from the higher-temperature end to the lower-temperature end. Experiment shows that the rate of heat flow is proportional to the cross section A of the beam and to the temperature difference $\Delta T = (T_1 - T_2)$ between the two ends; it is inversely proportional to the length of the beam L. This rate is thus described by an equation of the type

$$\frac{\Delta Q}{\Delta t} \propto A\frac{\Delta T}{L}. \qquad (18\text{–}7)$$

Heat flow is only linearly dependent on the temperature difference ΔT if ΔT is small. This poses no difficulty if we think about the rate of heat flow for a thin slice of length

TABLE 18–3 • Thermal Conductivities for Various Materials

Material	κ (kW/m • K)
Aluminum	0.21
Copper	0.39
Lead	0.035
Silver	0.42
Water (at 0°C)	5.65×10^{-4}
Water (at 20°C)	5.99×10^{-4}
Air	2.6×10^{-5}
Asbestos	0.80×10^{-4}
Brick	6.3×10^{-4}
Glass	10.5×10^{-4}



Δx rather than for the entire beam at once. In that case ΔT is small and the linear relation between ΔT and the rate of heat flow is valid. In this "thin-slice limit" we replace L by Δx and rewrite Eq. (18–7) in derivative form as

$$\frac{dQ}{dt} = -\kappa A \frac{dT}{dx}. \tag{18–8}$$

The coefficient κ is the **thermal conductivity**, a constant that varies from material to material and may have a temperature dependence. The SI units of κ are W/(m • K), or J/(m • s • °C). (Note that a difference of 1°C is identical to a difference of 1K. The appearance of watts in the units of κ anticipates that heat flow is an energy transfer.) We present some typical values of thermal conductivity in Table 18–3. When κ is large, the material is said to be a good thermal conductor, and when κ is small, the material is a poor thermal conductor. The minus sign in Eq. (18–8) indicates that if the *temperature gradient* dT/dx is negative (i.e., the temperature is lower for larger values of x), there is positive heat flow toward larger x. In other words, heat flow goes from a hot region to a cold region. The differential equation Eq. (18–8) applies to liquids and gases as well as to solids, and Table 18–3 lists values of κ for materials of all three states.

EXAMPLE 18–7 An igloo, a hemispherical enclosure built of ice ($\kappa = 1.67$ J/m • s • °C), has an inner radius of 2.50 m. The thickness of the ice is 0.30 m. At what rate must thermal energy be generated to maintain the air inside the igloo at 5°C when the outside temperature is −40°C? Ignore all thermal energy losses through the ground or by air currents.

Setting It Up Given the configuration and dimensions of an igloo, as in Fig. 18–9, we want the rate of heat flow out of it for a given inside-outside temperature difference. This much heat flow has to be supplied from a heater to keep the inside temperature steady.

▲ FIGURE 18–9

Strategy The right-hand side of Eq. (18–8) tells us the rate at which heat flow must be supplied to the interior of the igloo. The temperature gradient is given by $(T_{in} - T_{out})/(\text{ice thickness})$. The surface area A is that of half a sphere. Because the ice thickness is small compared to either the inner or outer radius, we could use either radius or anything in between; in fact, we'll use a radius halfway between the inner and outer radius.

Working It Out The appropriate radius is $R_{med} = 2.50\text{ m} + 0.15\text{ m} = 2.65\text{ m}$. Then

$$\begin{aligned}\frac{dQ}{dt} &= -\kappa A \frac{dT}{dx} = -\kappa A \frac{\Delta T}{\Delta x} = -\kappa(2\pi R_{med}^2)\frac{T_{in} - T_{out}}{\text{ice thickness}} \\ &= -2\pi(1.67\text{ J/m} \cdot \text{s} \cdot °\text{C})(2.65\text{ m})^2 \frac{(5°\text{C}) - (-40°\text{C})}{0.30\text{ m}} \\ &= -1.1 \times 10^4\text{ J/s} = -11\text{ kW}.\end{aligned}$$

This igloo requires an 11 kW heater just to keep things at a chilly 5°C. Note the use of units involving joules rather than calories. For comparison, a room-size kerosene heater puts out some 5 kW.

What Do You Think? Purely from a thermal point of view, why is it best to make igloos hemispherical?

Thermal Resistance

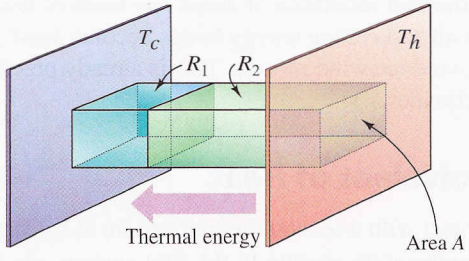
The **thermal resistance**, or **R value**, is used as an alternative to the thermal conductivity rating; it is inversely proportional to thermal conductivity. For a slab of a given material of thickness L, R is defined by

$$R \equiv \frac{L}{\kappa}. \tag{18–9}$$

Whereas κ depends only on the type of material, *R depends also on the thickness of the material*. Therefore, R characterizes the effectiveness of a thermal barrier of given thickness. A large R value corresponds to a small thermal conductivity and/or a large thickness; a piece of material with such characteristics is a good *thermal insulator*, whereas a piece of material

with a low R value is a poor insulator. The R value has SI units of $m^2 \cdot K/W$. When it is used in connection with insulation in construction in America, however, it is often quoted in units of $ft^2 \cdot h \cdot °F/Btu$, where $1\ ft^2 \cdot h \cdot °F/Btu = 0.18\ m^2 \cdot K/W$. The R value of a 6-in piece of fiberglass insulation is $22\ ft^2 \cdot h \cdot °F/Btu$, compared to $0.32\ ft^2 \cdot h \cdot °F/Btu$ for a 3/8-in piece of plasterboard.

In terms of R, the relation between thermal energy flow and temperature difference from Eqs. (18–8) and (18–9) is



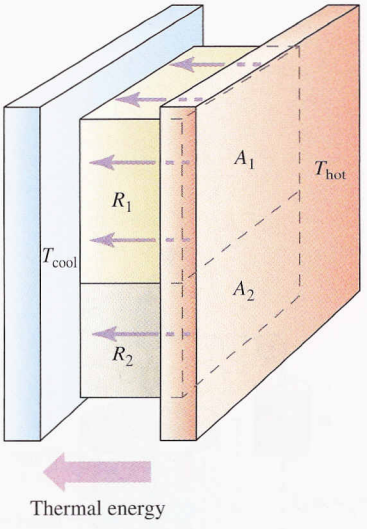
$$\frac{\Delta Q}{\Delta t} = \frac{1}{R} A\, \Delta T, \tag{18–10}$$

where A is the area across which thermal energy is transported. Because R refers to a given material of a given thickness, it is interesting to study the effective R values of different pieces of material combined in different ways—after all, that is how a house is constructed.

Thermal Resistance in Series: Let's first consider combining two conducting materials of the same area A *in series*, as shown in Fig. 18–10. Suppose that the left-hand piece has an R value of R_1 and the right-hand piece R_2 and that the temperature varies from T_c (cold) on the left to T_h (hot) on the right. We want to find the effective R value of the combined piece, R_{eff}. When thermal energy flows at a steady rate through the two materials, as shown in Fig. 18–10, then energy conservation implies that the rate of transport of thermal energy across one piece must equal the rate of transport across the second piece, and hence also the rate across the combined piece. Application of this idea (see Problem 25) implies that

$$\text{for two solids in series: } R_{\text{eff}} = R_1 + R_2. \tag{18–11}$$

This result generalizes for many slabs of material that are combined in series.

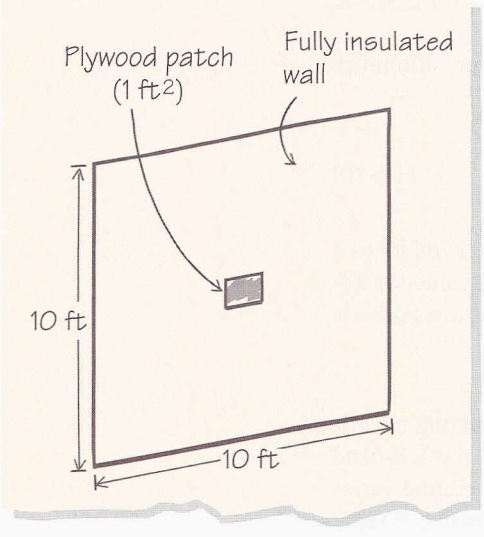


◀ **FIGURE 18–10** Thermal resistance, or R values, for two materials placed "in series"—one behind the other. Thermal energy passes through the materials as shown.

Thermal Resistance in Parallel: Now suppose that instead of being placed in series, two slabs are placed *in parallel*, as shown in Fig. 18–11. In this case the temperature difference on the right-hand and left-hand sides of both slabs is the same, and the total rate of transport of thermal energy is the sum of the transport rates through the two slabs. In Problem 27, this fact gives the result

$$\text{for two solids in parallel: } \frac{1}{R_{\text{eff}}} = \frac{1}{A_1 + A_2}\left(\frac{A_1}{R_1} + \frac{A_2}{R_2}\right). \tag{18–12}$$

This result generalizes for more than two slabs placed in parallel.



▲ **FIGURE 18–11** Thermal resistance, or R values, for two materials placed "in parallel." Thermal energy passes through the materials as shown.

EXAMPLE 18–8 A hole in a wall has been temporarily patched on the inside with a 1 sq-ft piece of plywood for which $R = 1\ ft^2 \cdot h \cdot °F/Btu$. The rest of the wall is insulated with fiberglass insulation for which $R = 22\ ft^2 \cdot h \cdot °F/Btu$. What is the R value of the repaired wall, whose total area is $100\ ft^2$?

Setting It Up The sketch of this situation, Fig. 18–12, shows that we have two materials placed in parallel. We know A_1 and R_1, the area and R value of the plywood, and A_2 and R_2, the area and R value of the fiberglass, respectively. We want R_{eff}, the R-value of the wall formed as in the figure.

(continues on next page)

Strategy This is an application of the formula for materials in parallel; Eq. (18–12) applies. We require only a numerical evaluation.

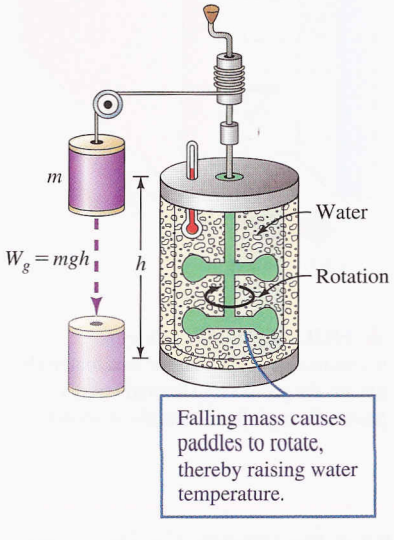
▲ **FIGURE 18–12** Hole in wall is patched with plywood.

Working It Out We have

$$\frac{1}{R_{\text{eff}}} = \frac{1}{A_1 + A_2}\left(\frac{A_1}{R_1} + \frac{A_2}{R_2}\right)$$
$$= \frac{1}{100\ \text{ft}^2}\left(\frac{1\ \text{ft}^2}{1\ \text{ft}^2 \cdot \text{h} \cdot {}^\circ\text{F/Btu}} + \frac{100\ \text{ft}^2 - 1\ \text{ft}^2}{22\ \text{ft}^2 \cdot \text{h} \cdot {}^\circ\text{F/Btu}}\right)$$
$$= \frac{1}{18\ \text{ft}^2 \cdot \text{h} \cdot {}^\circ\text{F/Btu}}.$$

Thus

$$R_{\text{eff}} = 18\ \text{ft}^2 \cdot \text{h} \cdot {}^\circ\text{F/Btu}.$$



Note that because the R values already take the thickness of the materials into account, the plywood is not necessarily the same thickness as the fiberglass insulation. In fact, plywood is only a fraction of an inch thick, whereas the fiberglass is 6 in thick. The rest of the thickness may be taken up by air, but because this air will be continuous with the outside environment, we have ignored its insulating properties.

What Do You Think? Having 1% of the area in plywood changed the R value by almost 20%. If instead of 1% the plywood area were 10%, the R value would have changed by about a factor of 3. Why such a big effect?

In Example 18–8 a hole in a wall that is patched with little insulation and takes up only 1% of the area of the wall reduces the R value by some 18%. This effect is typical of thermal insulators combined in parallel. In particular, if one of the elements of a set of insulators combined in parallel has a very small R value, Eq. (18–12) shows that the effective R value is very small. Small holes can be very costly sources of thermal energy loss. Indeed, the best window has a thermal resistance of about one-tenth of normal wall and ceiling insulation. Thus once wall and ceiling energy losses become small, the only way to conserve energy further is to reduce window area. This is already practiced in many commercial buildings in cold climates.

18–4 The Mechanical Equivalent of Heat

Placing a thermal system in thermal contact with a second thermal system at a different temperature is one way to produce a temperature change in the first system, via heat flow in this case. For example, we can heat water by placing it in a pot on a hot stove. In this case a heat flow is responsible for the temperature change. In the first half of the nineteenth century the major discovery was made that the temperature of a thermal system can also be raised by performing mechanical work on that system. For example, when an object is rubbed so that work is done on it by friction, its temperature is raised, just as in Count Rumford's late 18th century observation (Fig. 18–5). Such observations and the realization of their significance took place through a slow buildup of data rather than through a single breakthrough experiment. The history is thus rather tangled, with many participants. Rumford argued that Lavoisier's caloric theory could not be correct. Rumford's result was not widely accepted at the time, but in the mid-19th century the careful experiments of James Joule established with precision that a given amount of mechanical work done on a thermal system produces a temperature rise that corresponds to a given heat flow, as defined by Eq. (18–1).

▲ **FIGURE 18–13** Schematic diagram of the apparatus used in Joule's classic experiments. Churning paddles raise the temperature of a thermally isolated container of water.

Joule's Experiments

In an idealized version of Joule's experiments, the temperature of a thermally isolated quantity of water is measurably raised by a set of paddles that churn the water (Fig. 18–13). We know that a drag force is present to resist the motion of the turning paddles,

and work must be performed to keep them rotating. The amount of work done can be measured precisely by attaching the paddles to a falling mass that keeps the paddles moving, and then measuring the distance the mass falls.

When the paddles have done a certain amount of work on the water, the temperature of the system (water plus paddles) will have risen by a definite amount. And once the temperature has been raised, *there is no way to tell* whether the temperature increase occurred because work has been done on the system or because of heat flow into it. A series of experiments of this type establishes that there is a specific temperature rise for a specific amount of work; therefore, there is a precise equivalent between work done on a system, W, and the heat flow into it, ΔQ. Because *no* experiment can be performed that can tell whether a given temperature change was produced by mechanical work or by heat flow, we can assert that *heat flow, like work, is an energy transfer*. This result is known as the **mechanical equivalent of heat**. It means that the unit of heat flow, the calorie, must be convertible to the unit of energy—that is, there is a direct relation between the SI unit of work, the joule, and the unit of heat flow, the calorie, and Joule's experiment allows one to find the numerical relation:

$$1 \text{ cal} = 4.185 \text{ J}. \qquad (18\text{–}13)$$

THE MECHANICAL EQUIVALENT OF HEAT

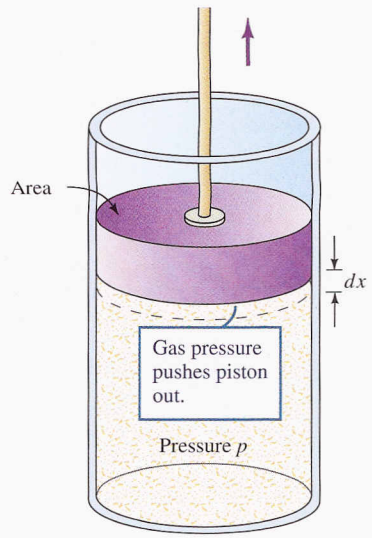
This relation may seem to be a simple unit conversion; however, it is far more. Until Joule's experiment, the calorie was unrelated to any other units familiar to us. Once his work was completed, one could say that the calorie has the dimensions of energy and that the SI unit of heat flow is the joule. Equation (18–13) thus states the crucial result of a basic experiment. It should not be confused with, say, the statement that 1 Btu is 252.00 cal, which is merely the relation between different units.

Today the *numerical definition* of the calorie is taken to be Eq. (18–13); it is no longer based on a measurement of the temperature change of water, as it was in Section 18–2. Such a definition is possible only because of the physical equivalence between heat flow and work. The calorie continues to be a widely used unit.

CONCEPTUAL EXAMPLE 18–9 Two *very* thin-walled (but unbreakable and undentable!) containers are dropped from a tall building. One of them holds water, the other an equal mass of mercury. Which of the liquids inside will be warmer after the container hits the ground?

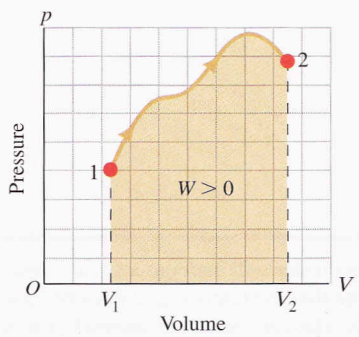
Answer When the containers land, *kinetic energy* is converted into thermal energy in each case. The mass of each container is the same, so each has the same kinetic energy just before landing. But since the specific heat of water is higher than that of mercury (by a factor of 30; see Table 18–1), the water will undergo a smaller temperature change as a result. Note that the temperature does not rise gradually as the container falls; the conversion to thermal energy takes place rapidly when the container hits the ground and the fluid is strongly shaken.

What Do You Think? Would the heating be the same if the containers were flung from the height of about 1 m, with a velocity comparable to the one they reach in falling from the building?



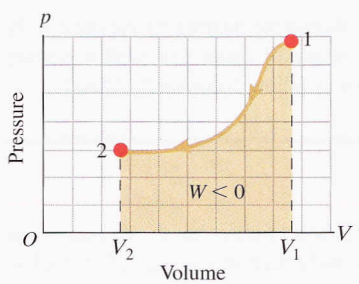
EXAMPLE 18–10 The paddles of the apparatus shown in Fig. 18–13 are driven by a mass m of 0.50 kg falling at a constant speed. The mass of the thermally isolated water in the apparatus is 250 g. How much is the temperature of the water raised if the driving mass falls a distance $h = 2.0$ m? Ignore the mass of the paddles.

Strategy According to the work–energy theorem, the work W done on the water is the change in energy of the falling mass m. Since the mass falls at constant speed, that change is the change in the potential energy of m, namely mgh. But this work is equivalent to a heat flow, $\Delta Q = W$, and if we note that ΔQ is related to the temperature change ΔT by the specific heat (which we assume constant) according to Eq. (18–1), we can solve for ΔT.



Working It Out The specific heat of water has the constant value $c_{H_2O} = 1.00 \text{ cal/g} \cdot ^\circ\text{C}$, so Eq. (18–1) reads $m_{H_2O}c_{H_2O}\Delta T = mgh$, or

$$\Delta T = \frac{mgh}{m_{H_2O}c_{H_2O}} = \frac{(0.50 \text{ kg})(9.8 \text{ m/s}^2)(2.0 \text{ m})}{(250 \text{ g})(1.00 \text{ cal/g} \cdot ^\circ\text{C})}(4.185 \text{ cal/J})$$
$$= 0.16^\circ\text{C}.$$



What Do You Think? It looks as though you could reverse the entire process: You turn the crank in Fig. 18–13 in reverse and thereby raise the weight. Will the thermal process also reverse, leaving you with cooler water?

▲ **FIGURE 18–14** The volume of a cylinder increases when a piston of area A moves out a distance dx under the influence of the pressure, p, of the gas contained in the cylinder.

(a)

(b)

▲ **FIGURE 18–15** The work done by a gas on its surroundings (like that of the piston–cylinder system of Fig. 18–14) in moving reversibly from point 1 to point 2 is the area under the curve of p versus V. (a) If the volume V_2 is greater than V_1 (the gas expands), the work the gas does on its surroundings is positive. (b) If the volume V_1 is greater than V_2, the gas is compressed, and the work it does on its surroundings is negative.

18–5 Work Done by Thermal Systems

In the last section, we saw that work can be done on a thermal system. By a simple sign reversal, we can think of this as work done by the thermal system on its surroundings—negative work, in the case of the churning paddles of Joule's experiments. Thermal systems, particularly gases, which can expand greatly, can also do *positive* work on their surroundings.

Consider a piston of area A pushed out by the pressure p of the gas contained in a cylinder (Fig. 18–14). By the definition of pressure, the magnitude of the force F on the piston is pA. Moreover, if the piston moves out, this force acts in the direction of the displacement, which we take to have infinitesimal magnitude dx. The infinitesimal work done by the gas in moving the piston is

$$dW = \vec{F} \cdot d\vec{x} = pA\,dx. \tag{18–14}$$

Because $A\,dx = dV$ (the infinitesimal change in the volume of the gas), this expression can be rewritten as

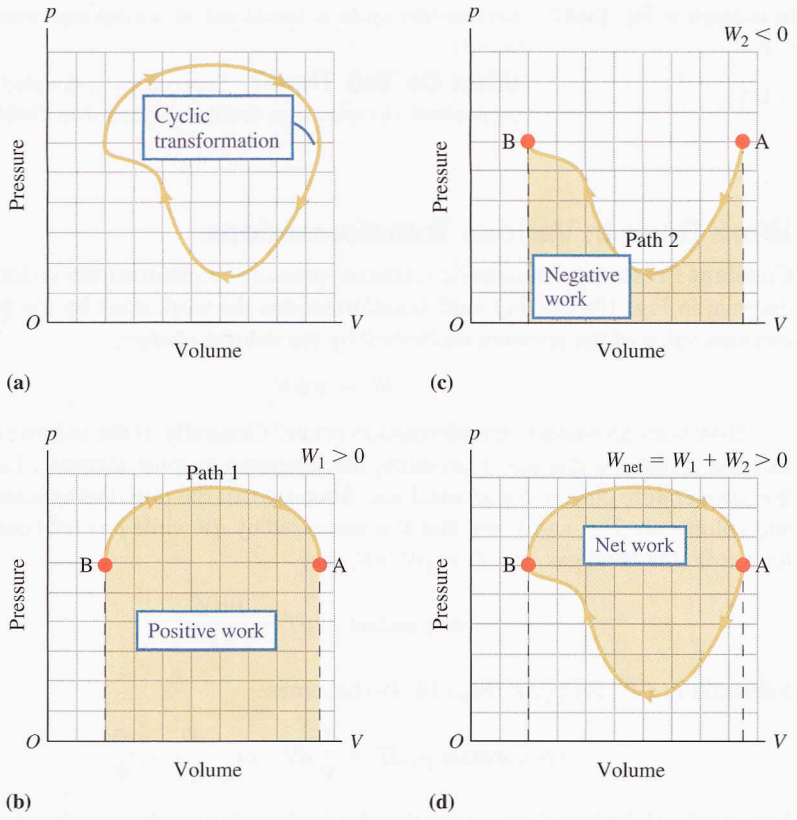
$$dW = p\,dV. \tag{18–15}$$

Equation (18–14) is specific to the linear motion of a piston with the geometry of Fig. 18–14, but Eq. (18–15) is a more general form that holds when a gas changes its volume by dV in pushing against its surroundings in any direction. Note the sign carefully: dW, the work the gas does *on* its surroundings, will be positive or negative according to whether dV is positive or negative.

As for the heat flow, we must specify the way in which the finite volume change is made in the integration of Eq. (18–15). Thus, *the net work done by the gas depends on the path in a p–V, p–T, or V–T diagram.* The integral expressing the work done in going from some state 1 to another state 2 is

$$W = \int_{V_1}^{V_2} p\,dV. \tag{18–16}$$

This integral is defined only when the path $1 \rightarrow 2$ is specified, meaning that how p is changing as we follow the path has to be specified.



If the path of the transformation $1 \rightarrow 2$ is drawn on a p–V diagram, as in Fig. 18–15a, then the work done by the gas has a simple interpretation: *It is the area under the curve of p versus V*, which is shaded in the figure. The sign of the work done by the gas is determined by whether V_2 is larger than V_1, as in Fig. 18–15a, or smaller than V_1, as in Fig. 18–15b. In Fig. 18–15b, the net work done *by* the gas is negative; in other words, there is positive work done *on* the gas to compress it. All this follows the normal rules of calculus, where $\int_{x_1}^{x_2} F(x)\,dx$ is the area under a curve of $F(x)$ versus x.

If we think of the work done by a thermal system as the area under a curve of p versus V, the fact that the work done depends on the path of the change becomes evident. The path describes the curve between two states, 1 and 2, and the area under different curves may certainly differ.

Cyclic Transformations

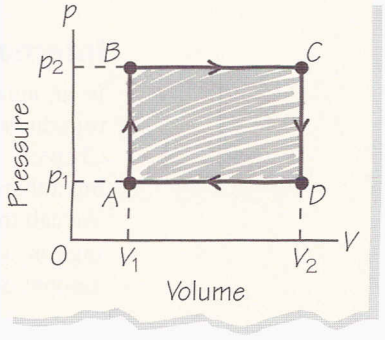
The operation of the pistons in an automobile engine is repetitive.† This is an example of a **cyclic transformation**: a change in which a thermal system follows a path that takes it back to its original state. The importance of such processes rests on the fact that all engines work in cycles. The net work done by the thermal system in a cyclic transformation can be calculated by starting anywhere along the path shown on a p–V diagram (Fig. 18–16a). (Note that we are assuming that all the changes treated here are reversible ones; the very fact that we are tracing the path indicates that.) Let's divide the cycle of Fig. 18–16a into two parts, as in Fig. 18–16b and c. The first part is the change $B \rightarrow A$,

†If you are not familiar with the details of such an engine, the only important aspect here is the repetitive nature of an engine's action. But you can also peek ahead to Chapter 20 if you are curious.

◀ **FIGURE 18–16** In a closed cycle, the work done by a gas on its surroundings is the area enclosed by the curve of p versus V. To show this, the full cycle is broken into two paths.

along path 1 (Fig. 18–16b), and the second part is $A \rightarrow B$, along path 2 (Fig. 18–16c). The net work W_{cycle} adds algebraically (Fig. 18–16d) and is thus given by

$$W_{\text{cycle}} = \underset{\text{path 1}}{W_{B\rightarrow A}} + \underset{\text{path 2}}{W_{A\rightarrow B}}.$$



As we saw in Chapter 6 during our discussion of work, $\int_{x_1}^{x_2} f(x)\,dx = -\int_{x_2}^{x_1} f(x)\,dx$, when the two integrals are taken over the same path. Thus the integral over path 2, which goes from larger to smaller values of x, is the negative of the area under that path. The net work is then the area under path 1 minus the area under path 2:

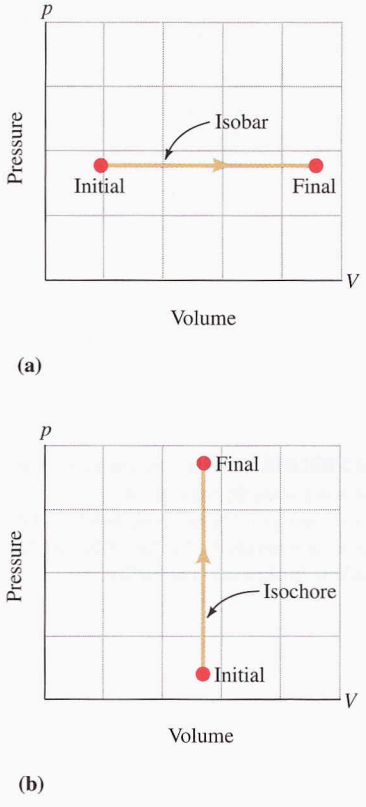
$$W_{\text{cycle}} = \text{area enclosed by cyclic path.} \qquad (18\text{–}17)$$

Because the cycle is traced in a clockwise direction, the work done by the gas along path 1 is larger than the work done on the gas along path 2. The net work done on the surroundings is positive; if this cycle were traced in a counterclockwise direction, the net work done would be negative.

EXAMPLE 18–11 A thermal system is taken around the cycle shown in Fig. 18–17. Along the paths $A \rightarrow B$ and $C \rightarrow D$, the volume is held fixed at V_1 and V_2, respectively. From $B \rightarrow C$ and from $D \rightarrow A$, the pressure is held fixed at p_2 and p_1, respectively. What is the work done by the thermal system in tracing out one cycle?

Strategy We can solve the total work around the cycle by calculating the work over each step using Eq. (18–16) and summing the work done in each step, or we can do what is suggested in Eq. (18–17) and evaluate the area enclosed by the p–V diagram. We shall use the second method, which is simpler because it summarizes the steps of the first method. Nevertheless, it is useful to make one comment on the first method. Two steps of the cycle, the ones from $A \rightarrow B$ and the ones from $C \rightarrow D$, are constant volume segments. For these legs the differential element $dV = 0$, and the integral is zero, as there is no area beneath a vertical line on the p–V diagram.

▲ **FIGURE 18–17** A thermal system undergoes a cyclic transformation.



(continues on next page)

Working It Out The area enclosed by the rectangle in Fig. 18–17 is the width $(V_2 - V_1)$ times the height $(p_2 - p_1)$:

$$W_{\text{cycle}} = (p_2 - p_1)(V_2 - V_1).$$

Because the cycle is traced out in a clockwise manner, W_{cycle} is positive.

What Do You Think? Suppose p_2 is doubled. The work is (a) doubled; (b) more than doubled; (c) less than doubled.

▲ **FIGURE 18–18** (a) An isobar, which represents a constant-pressure transformation. (b) An isochore, which represents a constant-volume transformation.

Work Done in Various Transformations

Constant Pressure: An isobaric (constant-pressure) transformation is drawn on a p–V diagram in Fig. 18–18a. For such transformations the work done by the gas is just the constant value of the pressure multiplied by the volume change,

$$W = p\Delta V. \tag{18–18}$$

How does an isobaric transformation occur? Generally, if the volume of a gas is to increase without a change in pressure, the temperature must increase. Let's calculate this temperature change for an ideal gas. Suppose that the initial temperature, pressure, and volume are T, p, and V and that V is increased by dV while p is held constant. It follows from the ideal gas law, $T = pV/nR$, that

$$\text{for constant } p\text{: } dT = \frac{p\,dV}{nR}. \tag{18–19}$$

Substituting T/V for p/nR, Eq. (18–19) becomes

$$\text{for constant } p\text{: } dT = \frac{T}{V}dV \quad \text{or} \quad \frac{dT}{T} = \frac{dV}{V}. \tag{18–20}$$

Conversely, if the heat flow is such that the fractional increase in temperature is equal to the fractional increase in volume, as in Eq. (18–20), then for an ideal gas the pressure must be constant, and the heat flow is $C_p\,dT$.

Constant Volume: When the volume is kept fixed, the curve of the transformation is said to be an **isochore** (Fig. 18–18b). Thermal systems do no work—positive or negative—in an isochoric transformation because there is zero area under the curve on a p–V diagram. The pressure and temperature both change, however, so such a transformation must be accompanied by a heat flow, just as for the isobaric and the isothermal transformations. In this case the heat flow is $dQ = C_V\,dT$.

Adiabatic: Finally, there is a particular curve that will be followed if the gas does work while it is thermally isolated from its environment. Imagine a cylinder of gas enclosed in a thermal insulator, such as Styrofoam, with only the mechanical movements of a piston connecting it to its surroundings. Because of the thermal isolation, there is no heat flow dQ into or out of the system. When $dQ = 0$, the temperature can change only if work is done on the system. Reversible transformations of a thermal system in which there is no heat flow to the system are called **adiabatic** transformations. In Section 18–8 we will explore the precise curve followed by adiabatic transformations for ideal gases.

Internal Energy

In an adiabatic transformation a thermal system has no thermal contact with its surroundings but does work on them. The work–energy theorem, as formulated in Chapters 6 and 7, can be applied to the system, which we can accordingly view as having a thermal (or internal) energy that can change if work is done on or by the system. We call this thermal energy[†] U. In particular, when a system does work on its surroundings in an adiabatic transformation, *it changes its internal (thermal) energy* by the amount of work it does:

$$\text{for an infinitesimal adiabatic transformation: } dU = -dW; \tag{18–21}$$

$$\text{for a finite adiabatic transformation: } U_B - U_A = -W_{A\to B}. \tag{18–22}$$

[†]Don't confuse U with a potential energy!

In other words, any changes in a thermal system's internal energy are matched by mechanical work done if a transformation is adiabatic. If we want to study how the internal energy of a thermal system changes when we go from one thermodynamic state to another, we should look at adiabatic transformations because then we can avoid the complications of heat flow. *The adiabatic process allows us to learn just how the internal energy depends on the thermodynamic variables.*

The thermal (internal) energy is a function of p and V, p and T, or T and V. The thermal energy is associated with the energy of the molecules of a thermal system; it is simply a function of the thermodynamic variables of the system, not of how those variables might have changed. Changes in internal energy, like changes in the potential energy of a conservative mechanical system, are *not* path dependent. This contrasts sharply with work or heat flow, which *are* path dependent.

In Eq. (18–21) both dU and dW are written as differentials. The symbol dU has its usual meaning as a differential, in that a finite change in internal energy is

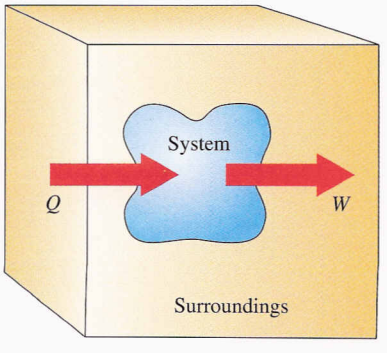
$$\int_A^B dU = U_B - U_A, \tag{18–23}$$

which is independent of the path between A and B. There is no equivalent expression for work, because the integral of dW *does* depend on the path taken. In a strict mathematical sense, dW is not a true differential, but there is no need for a more complicated notation, provided we keep in mind that the integral of dW is path dependent.

The minus signs on the right-hand sides of Eqs. (18–21) and (18–22) occur because W always denotes the work done *by* the system *on* its surroundings. When the system does positive work in an adiabatic transformation, its internal energy U decreases; when the work done is negative, the internal energy increases.

Let's now reconsider the Joule experiments that determined the mechanical equivalent of heat (Section 18–4). The water whose temperature is raised by the churning paddles is thermally isolated. The transformation is irreversible; it is not possible to "unchurn" the water and use it to raise the fallen weight. Nevertheless, the (positive) net work done by the paddles does indeed determine the (positive) change in the internal energy of the water. *How* a change is made is irrelevant for the internal energy, because the internal energy is purely a function of state. Thus Eq. (18–22) holds for both reversible and irreversible transformations of thermally isolated systems.

18–6 The First Law of Thermodynamics



The **first law of thermodynamics** is a statement of the conservation of energy for thermal systems. It is essential in understanding any thermal system—particularly those in which fuel is burned and work is done, such as engines or power plants. We have seen that heat flow and work are equivalent ways to change a system's internal, or thermal, energy. The first law simply recognizes this by stating that the change in the internal energy of a thermal system in going from one state to another is the negative of the work that the system does on its surroundings, plus the heat flow into the system, during that transformation. In other words, if we label our initial and final states by A and B, respectively,

$$\Delta U = U_B - U_A = -W_{A\to B} + Q_{A\to B}. \tag{18–24}$$

FIRST LAW OF THERMODYNAMICS

This equation is the primary result of this chapter. The minus sign in front of W indicates that W is the work done *by* the thermal system, and the plus sign in front of Q indicates that Q is the heat flow *into* the system. In Fig. 18–19 we give another view of the meaning of these terms.

We should mention that there is no universal agreement as to the sign convention for work W. Engineers and physicists tend to use the convention stated here; engineers and physicists are primarily interested in what the system does to its surroundings—for example, how much work an engine is capable of doing. But chemists prefer to say that W is positive when it is done *on* the system, a convention that makes the sign in Eq. (18–24) + instead of −. That is because chemists are more interested in the thermal system itself than its effects on its surroundings.

▲ **FIGURE 18–19** In the first law of thermodynamics, W represents the work done by the system, while Q represents the heat flow into the system. Either term can be negative or positive, depending on the transformations involved.

Because U is a function of state only, ΔU is the same whether the transformation $A \rightarrow B$ is reversible or irreversible. Similarly, the work done by the system can be measured by observing its effect on its surroundings—for example, how high the system lifts a mass—independently of whether the transformation $A \rightarrow B$ is reversible or irreversible. The heat flow $Q_{A \rightarrow B}$ can be determined from the first law of thermodynamics if the transformation is irreversible or determined independently by making a calorimetric measurement.

The first law of thermodynamics is often written as

$$\Delta U = -\Delta W + \Delta Q \tag{18–25a}$$

or in a differential form as

$$dU = -dW + dQ. \tag{18–25b}$$

While both dW and dQ depend on the path, dU is independent of path. Remarkably, the path dependence of the two separate terms cancels in the difference $-dW + dQ$.

The First Law of Thermodynamics in Closed Cycles

Engines operate and perform work in closed cycles. Thus it is of practical importance to be able to apply the first law of thermodynamics to a closed cycle. There is no change in internal energy over a cycle, because the system comes back to its original state. The work done by the thermal system over the cycle must then match the heat flow into the system, by the first law:

$$Q_{\text{cycle}} = W_{\text{cycle}}. \tag{18–26}$$

Here Q_{cycle} and W_{cycle} are the net heat flow into, and net work done, by the system over the entire cycle.

CONCEPTUAL EXAMPLE 18–12 Suppose that a thermal system follows the cycle $A \rightarrow B \rightarrow C \rightarrow D \rightarrow A$, as drawn in Fig. 18–17 and treated in Example 18–11. What is the total heat flow into the system after one cycle is completed?

Answer To repeat the argument above, the internal energy change over one cycle is zero because the initial point is the same as the final point. The fact that the system passes through a complicated succession of intermediate states is irrelevant. Then we apply Eq. (18–26), $Q_{\text{cycle}} = W_{\text{cycle}}$, together with the results of Example 18–11, where the work done for this cycle is calculated:

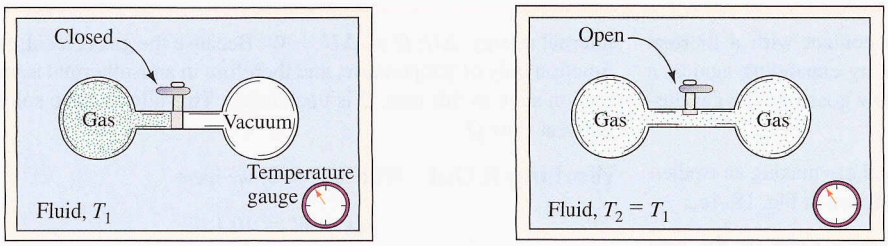
$$Q_{\text{cycle}} = (p_2 - p_1)(V_2 - V_1).$$

What Do You Think? Suppose that instead of the rectangular path of Fig. 18–17, an arbitrary closed curve were followed. What can you say about the sign of the heat flow into the system?

How the Energy Changes in Constant-Volume and Constant-Pressure Transformations

No work is done in reversible changes under constant volume ($dW = pdV$, and $dV = 0$), so Eq. (18–25) becomes

$$\text{for constant volume: } dU = dQ_V = C_V\, dT. \tag{18–27}$$



We have emphasized the fact that the volume is constant by the subscript on dQ. No subscript is necessary for dU, because the change in U is independent of the path taken. Similarly, we can express the first law of thermodynamics for reversible changes under constant pressure as

$$\text{for constant pressure: } dU = -dW_p + dQ_p = -pdV + C_p\, dT. \tag{18–28}$$

Equations (18–27) and (18–28) can both be integrated over paths with constant V and constant p, respectively, to find the net internal energy change under a finite volume or pressure change. Keep in mind that in such an integration the heat capacities may depend on temperature, so they cannot be removed from under the integral sign.

18–7 Internal Energy of Ideal Gases

Joule performed an experiment in 1845 to study the properties of U for ideal gases. He demonstrated that *for ideal gases, the internal energy is a function of temperature alone*: $U = U(T)$. The equation of state adds to this by saying that U is equivalently a function only of the product pV.

◀ **FIGURE 18–20** Schematic diagram of Joule's experiment. When Joule opened the stopcock to allow free expansion, he observed no temperature change for a dilute (ideal) gas.

Joule's experiment is as follows: Fill one part of a two-part container with a dilute sample of gas (if it is sufficiently dilute, we can be sure it is ideal). The other part of the container is evacuated, and the two parts are connected by a tube with a stopcock (Fig. 18–20a). The container as a whole is sealed and does no work on the outside world. The container is submerged in a thermally isolated container of water or some other fluid whose temperature can be monitored. This fluid, initially at temperature T_1, acts as a calorimeter: If its temperature changes because of some change in the state of the gas in the container, then there has been a heat flow into or out of the gas.

The stopcock is now opened, and the gas undergoes free expansion into the previously empty part of the container. The crucial feature of free expansion is that the gas does no work, because it does not cause mechanical movement in its surroundings. The new temperature of the fluid, T_2, is then measured. When the gas is sufficiently dilute, the experiment shows that $T_2 = T_1$ (Fig. 18–20b). *The temperature of an ideal gas undergoing free expansion remains constant.* This result means that there has been no heat flow into the gas. There is no work done and no heat flow in free expansion. Thus, according to the first law of thermodynamics, the internal energy, U, remains unchanged. But because the volume of the gas does change, U must be independent of volume. Therefore, for an ideal gas, U is a function only of temperature:

$$U_{\text{ideal}} = U(T). \tag{18–29}$$

ENERGY OF AN IDEAL GAS

This result follows directly from experiment, but it can also be derived from the second law of thermodynamics, which we will explore in Chapter 20.

For real gases—which are not perfectly ideal—there is a deviation from the result of Eq. (18–29), and temperature changes during free expansion. In other words, U is a function of density as well as temperature. We typically ignore this effect.

Let's now couple the fact that the internal energy of an ideal gas depends only on the temperature with Eqs. (18–27) and (18–28). Because U depends *only* on T, the integral of Eq. (18–27) gives

$$U(T_B) - U(T_A) = \int_{T_A}^{T_B} C_V \, dT. \tag{18–30}$$

This equation must hold for *all* values of the volume because the left-hand side of the equation is independent of volume. Hence Joule's experiment shows that C_V must itself be independent of volume. Equation (18–30) expresses only a *change* in energy, so it is equivalent to the form

$$U(T) = \int_0^T C_V \, dT + \text{a constant}. \tag{18–31}$$

The constant is arbitrary because only *changes* in U matter, not the actual values of $U(T)$ and $U(0)$. We therefore take the constant to be zero. Finally, we can use the experimental fact that over a wide temperature range, C_V is independent of temperature. We can remove C_V from behind the integral sign and find

$$\text{for } C_V \text{ independent of temperature: } U(T) = C_V T. \tag{18–32}$$

The internal energy of an ideal gas is simple indeed, as long as C_V is constant with temperature.

EXAMPLE 18–13 An ideal gas in contact with a thermal reservoir at temperature $T = T_0$ does work by expanding against a piston. That work is 10 J. How much heat flow goes into the gas during its expansion?

Setting It Up The path, which for an ideal gas making an isothermal transformation is a hyperbola, is already drawn in Fig. 18–1c.

Strategy The first law of thermodynamics gives us the heat flow, Q, in terms of the work W done by the system and the change in internal energy, ΔU: $Q = \Delta U + W$. Because the gas is ideal, U is a function only of temperature, and therefore in an isothermal transformation such as this one, U is unchanged. This allows us to solve for the heat flow Q.

Working It Out With $\Delta U = 0$, we have

$$Q = W = 10\text{ J}.$$

What Do You Think? Where does the heat flow come from?

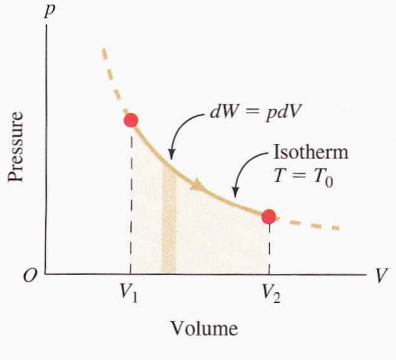
A Relation Between C_p and C_V for Ideal Gases

We can express C_p in terms of C_V. Equations (18–27) and (18–28) (respectively $dU = C_V\,dT$ and $dU = -p\,dV + C_p\,dT$) are two differential expressions for the energy change, dU. Because Eq. (18–28) specifies constant pressure, the term $p\,dV$ that occurs on the right-hand side can also be written for an ideal gas as $p\,dV = nR\,dT$. Then both Eqs. (18–27) and (18–28) involve only terms proportional to dT on the right-hand side. Because the energy shift dU is independent of whether the infinitesimal transformation is made at constant V or at constant p, the two expressions for dU must be equal:

$$C_V\,dT = -nR\,dT + C_p\,dT.$$

We cancel the common factor dT from this equation to find that

$$C_p = C_V + nR, \tag{18–33}$$



RELATION BETWEEN C_p AND C_V

which is a result that applies to ideal gases. As C_V is a function of T only, C_p is also; and to the extent that C_V is in fact constant with T, so is C_p. Equation (18–33) is supported by experiment for ideal gases and is a good approximation for real gases. To go further than this relation—actually to compute quantities such as C_V—it is necessary to consider the microscopic dynamics of gases. This calculation will be made in Chapter 19.

18–8 More Applications for Ideal Gases

In order to understand the behavior of engines or, more generally, of gaseous thermal systems, we want to express the changes that occur in terms of the thermodynamic variables. In principle, this is possible as long as the transformations are reversible. Better, if we can approximate real gases by ideal gases, then all the transformations we have discussed can be expressed mathematically, as can the corresponding work done, heat flow, energy changes, and related quantities. Some of these mathematical expressions have already been given. For example, the shape of the p–V curve that represents an isothermal transformation at $T = T_0$ is a hyperbola, $p = nRT_0/V$. The relation $C_p = C_V + nR$ [Eq. (18–33)] is a consequence of the fact that the gas is ideal.

Of the four reversible transformations we discussed earlier—constant-volume (isochoric), constant-pressure (isobaric), constant-temperature (isothermal), and adiabatic transformations—the first two are simple to treat. Let's now look at the other two in more detail.

▲ **FIGURE 18–21** An ideal gas expands from V_1 to V_2 while its temperature is held fixed, and in doing so does work on its surroundings.

Isothermal Transformations of an Ideal Gas

When the temperature is constant, the work done by an ideal gas is simple to compute. We see from Fig. 18–21 that

$$W = \int_{V_1}^{V_2} p\,dV = \int_{V_1}^{V_2} \frac{nRT_0}{V}\,dV = nRT_0 \int_{V_1}^{V_2} \frac{dV}{V}. \tag{18–34}$$

The integral of $1/x$ is the natural logarithm, $\ln x$ (see Appendix IV-6). Because $\ln x_1 - \ln x_2 = \ln(x_1/x_2)$, we have, for the work done by an ideal gas in an isothermal transformation:

$$W = nRT_0 \ln\left(\frac{V_2}{V_1}\right). \tag{18–35}$$

As expected, W is positive when the gas expands ($V_2 > V_1$) and negative when the gas contracts ($V_2 < V_1$).

EXAMPLE 18–14 Suppose that 0.12 mol of an ideal gas, in contact with a thermal reservoir that holds the temperature fixed at $T_0 = 9.8°C$, has an initial volume of 1.3 L and does 14 J of work. What is the final volume, and what is the final pressure?

Strategy We can use Eq. (18–35) to find the final volume V_f because every other quantity in the equation is known. (We'll need to convert T_0 to the Kelvin scale.) Then we can use the ideal gas law, $pV = nRT_0$, to find the final pressure of the gas.

Working It Out To start, we have $T_0 = 9.8 + 273.15 \cong 283\text{K}$. Then from Eq. (18–35)

$$\ln\left(\frac{V_f}{V_i}\right) = \frac{W}{nRT_0} = \frac{14\text{ J}}{(0.12\text{ mol})(8.314\text{ J/mol}\cdot\text{K})(283\text{K})} = 0.050,$$

or

$$\frac{V_f}{V_i} = \exp(0.050) = 1.05;$$

$$V_f = 1.05\,V_i = 1.05 \times (1.3\text{ L}) = 1.4\text{ L}.$$

The final pressure is given by the equation of state:

$$p_f = \frac{nRT_0}{V_f} = \frac{(0.12\text{ mol})(8.314\text{ J/mol}\cdot\text{K})(283\text{K})}{(1.4\text{ L})(10^{-3}\text{ m}^3/\text{L})} = 2.0 \times 10^5\text{ Pa} = 2.0\text{ atm}.$$

The pressure has decreased from an initial value of $p_i = p_f(V_f/V_i) = 2.2$ atm.

What Do You Think? Did (positive) thermal energy come out of the reservoir, or did it go into the reservoir, or was there no thermal energy flow at all?

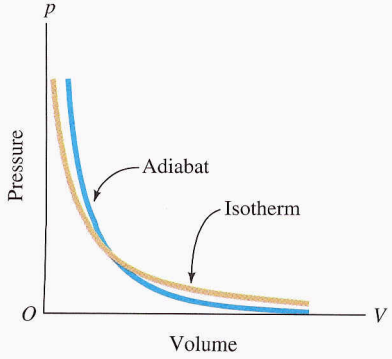
The internal energy of an ideal gas is unchanged in an isothermal transformation. Thus by the first law of thermodynamics, Eq. (18–35) also expresses the heat flow into the gas during an isothermal transformation.

Adiabatic Transformations of an Ideal Gas

In an adiabatic expansion, the first law of thermodynamics becomes $dU = -dW$. Because dW is positive, dU is negative. U is proportional to T, so the temperature will fall in an adiabatic expansion and rise in an adiabatic compression. When a gas expands in a thermally isolated container, it cools; when it is compressed, it heats up (as you can feel when you compress a bicycle pump).

The curves that describe this transformation are derived in the next subsection. They are given by

$$pV^\gamma = p_0V_0^\gamma = \text{a constant}, \tag{18–36}$$



where (p_0, V_0) are the initial values of pressure and volume, respectively, of the ideal gas that undergoes an adiabatic transformation to new values (p, V). The constant γ is given by

$$\gamma \equiv \frac{C_p}{C_V} = \frac{C_V + nR}{C_V} = \frac{c'_V + R}{c'_V}, \tag{18–37}$$

where c' is the molar heat capacity, from Eq. (18–2). We have used Eq. (18–33), which relates C_p to C_V. Because $C_p > C_V$, γ is greater than unity (a result that is true even for nonideal gases). In terms of V and T, the transformation follows the curves

$$TV^{\gamma-1} = \text{a constant}. \tag{18–38}$$

Compare Eq. (18–36) with the curve that describes an isothermal transformation, $pV =$ a constant, or $p \propto V^{-1}$. Figure 18–22 contains an isotherm and an adiabatic curve for a monatomic ideal gas, for which $\gamma = 1.67$. The isothermal curve is a hyperbola, $p \propto V^{-1}$. The adiabatic curve $p \propto V^{-\gamma}$ falls more steeply than the hyperbola as V increases, because $\gamma > 1$.

▲ **FIGURE 18–22** For ideal gases, adiabatic curves ($p \propto V^{-\gamma}$), called adiabats, are steeper than isotherms ($p \propto V^{-1}$) on a p–V diagram.

*How to Derive the Adiabatic Transformation of an Ideal Gas on a *p–V* Diagram

To derive the curves that are described by Eq. (18–36), we start with the first law of thermodynamics in its differential form [Eq. (18–25)], with the heat flow, dQ, set to zero: $dU = -dW$. The infinitesimal work done is still given by $dW = p\,dV$. We also know that dU is proportional to the temperature change, dT. In particular, dU can be calculated by differentiating Eq. (18–31) with respect to the temperature, T. Because C_V is constant for an ideal gas, we have $dU/dT = C_V$, or

$$dU = C_V\,dT.$$

Thus the adiabatic transformation satisfies

$$C_V\,dT = -p\,dV. \tag{18–39}$$

All three thermodynamic variables appear here, but because of the ideal gas law, $nRT = pV$, only two are independent. To find the curve of p versus V, we eliminate T in favor of p and V. The ideal gas law implies that

$$nR\,dT = p\,dV + V\,dp.$$

(See Appendix IV–7.) Equation (18–39) can thus be rewritten as

$$C_V\frac{p\,dV + V\,dp}{nR} = -p\,dV.$$

Solving for $V\,dp$, we find

$$V\,dp = -\frac{C_V + nR}{C_V}p\,dV. \tag{18–40}$$

The numerator on the right-hand side of Eq. (18–40) is the heat capacity at constant pressure, C_p, as Eq. (18–33) shows. Thus the right-hand side may be written as $-(C_p/C_V)p\,dV = -\gamma p\,dV$, with γ defined in Eq. (18–37).

With the definition of γ, we rewrite Eq. (18–40) in the form

$$\frac{dp}{p} = -\gamma\frac{dV}{V}.$$

Each side of this equation may be integrated separately, with the lower limits on the integrals determined by the initial state (p_0, V_0, T_0). Thus

$$\int_{p_0}^{p}\frac{dp}{p} = -\gamma\int_{V_0}^{V}\frac{dV}{V}.$$

Each integral gives a logarithm, and

$$\ln\left(\frac{p}{p_0}\right) = -\gamma\ln\left(\frac{V}{V_0}\right).$$

Because $A\ln x = \ln(x^A)$, it follows that

$$\ln\left(\frac{p}{p_0}\right) + \ln\left[\left(\frac{V}{V_0}\right)^{\gamma}\right] = 0.$$

We use $\ln x_1 + \ln x_2 = \ln(x_1x_2)$ to find

$$\ln\left[\left(\frac{p}{p_0}\right)\left(\frac{V}{V_0}\right)^{\gamma}\right] = 0.$$

We now take the exponential of both sides of the equation to find

$$pV^{\gamma} = p_0V_0^{\gamma} = \text{a constant}.$$

This is Eq. (18–36). By using the ideal gas law, we can show that the corresponding equation in terms of T and V is Eq. (18–38).

Variation of Atmospheric Temperature with Height

If you have taken a long-distance commercial flight, you know that the air high up is quite a bit colder than the air at ground level. Adiabatic transformations explain the variation of atmospheric temperature with height rather well. Air is transported from high altitude to low altitude and vice versa by large atmospheric wind currents. Air is a sufficiently good thermal insulator, so the transport of air between different altitudes is, to a good approximation, adiabatic. When air rises, the pressure decreases, so that the air undergoes adiabatic expansion; its temperature therefore falls. When air is carried to lower altitudes, it undergoes adiabatic compression, and its temperature rises.

If we assume that air is an ideal gas, we can quantify these concepts. Suppose that pressure and temperature are related by an adiabatic transformation. The adiabatic curve for p versus T is derived from, for example, Eq. (18–36) with $V \propto T/p$. For the p-versus-T adiabatic curve, this gives the equation $p^{1-\gamma}T^{\gamma} =$ a constant. If we raise both sides to the power $1/\gamma$ and solve for T, we find that

$$T = (\text{a constant})p^{(\gamma-1)/\gamma}. \tag{18–41}$$

If we know how pressure varies with height, then Eq. (18–41) can tell us how temperature varies with height. But how does pressure vary with height? In Chapter 16 we found that pressure decreases linearly with increasing height for an *incompressible* fluid, such as water. Air, which is assumed to obey the ideal gas law in this case, is certainly not incompressible, but we can use the methods of Section 16–3 to find an equation for the way pressure varies with height. There we considered an imaginary horizontal slab cut out of the fluid, with its base at height h, where the pressure is p. The top of the slab, where the pressure is $p + dp$, is at height $h + dh$. Note that we expect dp to be negative because pressure should decrease with height. According to Eq. (16–5),

$$\frac{dp}{dh} = -\rho g,$$

where ρ is the density of the fluid. From this equation, we see that as h decreases, p increases due to the increasing weight of the overlying fluid (in this case, air). For water, ρ is constant. For air, ρ is not constant but is given by

$$\rho = \frac{m}{V} = \frac{nM}{V} = M\left(\frac{p}{RT}\right),$$

where M is the mass of 1 mol of air (its molecular weight). The equation for pressure as a function of height becomes

$$\frac{dp}{dh} = -\left(\frac{Mg}{RT}\right)p. \tag{18–42}$$

Rather than solving this equation directly (see Problem 61), we can convert it into an equation for temperature as a function of height (see Problem 77). This is done by using the adiabatic curve, Eq. (18–41). Temperature is thus found to change linearly with height as

$$T = T_0 - \left(\frac{mgh}{R}\right)\left(\frac{\gamma - 1}{\gamma}\right). \tag{18–43}$$

Because $\gamma > 1$, temperature does indeed drop with increasing height—as anyone who has been to the mountains can appreciate.

How does Eq. (18–43) compare with observation? The molecular weight of air is approximately 0.029 kg/mol, $\gamma_{\text{air}} \cong 1.4$, and $g \cong 9.8\ \text{m/s}^2$. Then if we take the derivative of T [Eq. (18–43)] with respect to h, we find that

$$\frac{dT}{dh} = -\frac{(0.029\ \text{kg/mol})(9.8\ \text{m/s}^2)}{8.3\ \text{J/°C}\cdot\text{mol}}\left(\frac{1.4 - 1}{1.4}\right) = 0.010°\text{C/m}.$$

We have estimated that temperature drops about 10°C/km. The experimental result is approximately 6.5°C/km. The main sources of error in our calculation are the neglect of the effects of water condensation and, closer to the surface, the effects of local topography, such as mountain ranges. In the vicinity of flat deserts and high in the atmosphere, the value calculated is a fairly good approximation.

Summary

Reversible changes of state are changes that are made sufficiently slowly that the temperature, T, the pressure, p, and the volume, V—the thermodynamic variables that describe a thermal system such as a gas—are well defined at all times. The three variables are related by the equation of state of the gas. Reversible transformations, in contrast with irreversible transformations, can be traced out on a plot of any one of the three variables versus either of the other two. In this chapter we dealt with isothermal, isobaric, isochoric, and adiabatic changes.

When the temperature of a system changes, then the internal energy of the system will have changed. This may happen because the system has done work on its surroundings—for example, it pushed a piston and raised a weight—and/or because there has been a heat flow into the system. Infinitesimal heat flow into a system, dQ, is related to the infinitesimal temperature change of the system, dT, by the heat capacity, C, which depends not only on the system's composition but on how the temperature change is made:

$$\text{for constant volume: } dQ = C_V\, dT; \tag{18–4}$$

$$\text{for constant pressure: } dQ = C_p\, dT. \tag{18–5}$$

It is generally true that

$$C_p \geq C_V. \tag{18–6}$$

Because dQ depends on how a transformation is made, the net heat flow in a finite transformation is path dependent. Heat flow is measured in calories. Calorimetry, the measurement of heat capacities, is based on the fact that heat flow is conserved in a mechanically and thermally isolated system.

The specific heat of a material, c, is the heat capacity of 1 g of the material; its molar heat capacity, c', is the heat capacity of 1 mol of the material.

Solids conduct thermal energy in a characteristic way. The rate of transport of thermal energy depends on the temperature drop per unit length and the area of the material through which the thermal energy flows. The thermal conductivity, κ, is defined by

$$\frac{dQ}{dt} = -\kappa A \frac{dT}{dx}, \tag{18–8}$$

where the left-hand side represents the flow of thermal energy per unit time, A is the area, and dT/dx is the temperature drop per unit length. The reciprocal of κ is related to the thermal resistance, or R value, of the insulating material, with

$$R \equiv \frac{L}{\kappa}. \tag{18–9}$$

where L is the thickness of the material. The R values of two insulating slabs of the same area are additive when the slabs are connected in series, whereas the quantities area/R are additive when the slabs are connected in parallel.

Heat flow, like work, is an energy transfer. Any transformation of a thermal system caused by a heat flow can be made equally well by doing work on the system. This means that heat has an exact mechanical equivalent and that the calorie can be expressed as an energy unit:

$$1 \text{ cal} = 4.185 \text{ J}. \tag{18–13}$$

A gas undergoing an infinitesimal transformation does an infinitesimal amount of work on its surroundings, given by

$$dW = p\, dV. \tag{18–15}$$

As for heat flow, the net work done in a finite transformation is path dependent. If the path is adiabatic ($dQ = 0$), the work done by the system is the negative of the internal energy change,

$$\text{for an infinitesimal adiabatic transformation: } dU = -dW; \tag{18–21}$$

$$\text{for a finite adiabatic transformation: } U_B - U_A = -W_{A\to B}. \tag{18–22}$$

An adiabatic transformation is a reversible transformation in which there is no heat flow between a system and its surroundings.

The internal energy (thermal energy), U, is a function of state. Any changes U undergoes in thermal transformations are path independent. The first law of thermodynamics specifies that the change in the internal energy of a thermal system in going from state A to state B is the negative of the work it does on its surroundings, plus the heat flow into the system:

$$\Delta U = U_B - U_A = -W_{A\to B} + Q_{A\to B}. \tag{18–24}$$

The work in this equation, W, is the work done *by* the thermal system, and Q is the heat flow *into* the system. The differential form of the first law of thermodynamics is written as

$$dU = -dW + dQ. \tag{18–25}$$

The internal energy of ideal gases is a function of temperature alone:

$$U_{\text{ideal}} = U(T). \tag{18–29}$$

To the extent that C_V is independent of temperature, the dependence is linear,

$$\text{for } C_V \text{ independent of temperature: } U(T) = C_V T. \tag{18–32}$$

It is also true that for an ideal gas

$$C_p = C_V + nR. \tag{18–33}$$

The curve of an adiabatic transformation can be calculated for an ideal gas by using the ideal gas law. It is given on a p–V diagram by

$$pV^\gamma = \text{a constant}, \tag{18–36}$$

where

$$\gamma \equiv \frac{C_p}{C_V} = \frac{C_V + nR}{C_V} = \frac{c'_V + R}{c'_V}. \tag{18–37}$$

This equation can be used to predict the variation of temperature with height in the atmosphere.

Understanding the Concepts

1. When a bicycle tire is pumped up, the end of the pump near the valve feels hotter. What is happening?
2. A gas expands adiabatically, doing 500 J of work. By how much does the internal energy of the gas change?
3. We stated that the system of Example 18–6 was thermally isolated. Shouldn't we have added that it is mechanically isolated as well?
4. If a bucket of water is carried uphill, raising the water's potential energy, will its temperature change?
5. Which of the following are reversible processes: (a) the slow inflation of a balloon with a bicycle pump; (b) the heating up of a drill bit used to bore a hole in a log; (c) the slow stretching of a wire by an external force, carried out at a constant temperature?
6. Thermopane windows are windows made of two glass panes with air between them. Explain why they are better thermal insulators than a simple window pane of twice the thickness.
7. You want to make a reversible transformation between 2 points A and B on a p–V diagram. Assume that $V_B > V_A$. On what path is the least amount of work done by the gas?
8. To survive a cold night in the woods, you are advised to make a thick bed of dry leaves to sleep on and a thick cover of dry leaves to sleep under. Why does this work?
9. Why are cross-country skiers told to wear several layers of clothing rather than a single, thick coat?
10. Why is free expansion not an example of an adiabatic process?
11. Would it make sense for you to shake a container of soup in order to heat it? Would the fact that the soup is in an insulating container change your answer?
12. Should the cooling fluid for an engine have a large or a small heat capacity?
13. What use can you think of for fluids with very large specific heats? With very small specific heats?
14. You glue together two strips of metals that have different coefficients of thermal expansion, back-to-back. What will happen to such a composite strip when it is heated or cooled? Can you propose some technological use for such strips?
15. When a mass m_1 of water at temperature T_1 is mixed with a mass m_2 of water at temperature T_2, with $T_1 > T_2$, the temperature change of the hotter mass, ΔT_1, is related to the temperature change of the colder mass, ΔT_2, by $\Delta T_1/\Delta T_2 = -m_2/m_1$. In an experiment in which water and mercury are mixed, it was found that 100 g of mercury acts like 3.3 g of water. Explain both the formula and the observation about mercury.
16. A well-insulated container is divided into two separate compartments by an adiabatic wall. One compartment contains gas at a pressure p_1 and temperature T_1; the other contains gas at a pressure p_2 and temperature T_2. What happens when the partition is removed?
17. Why is the latent heat of vaporization for water so much larger than the latent heat of fusion?

18. When a freeze threatens, how can spraying fruit trees with water protect the fruit from frost damage?
19. A cyclic transformation shows up as a closed curve in a p–V plot. Suppose a cyclic transformation differs from the first one only in that the value of V is double at every step. How are the values of the net work related for the two transformations?
20. Why does perspiring during exercise help you to cool off?
21. For an ideal gas, the heat capacities are independent of temperature, and it is easy to relate temperature change to heat flow. Would it be impossible to relate temperature change to heat flow if the heat capacities varied with temperature?
22. Can all thermodynamic transformations be plotted on a graph of one thermodynamic variable versus another?
23. A change in a thermal system is reversible if (a) there is no friction and (b) the change is carried out slowly. Explain these constraints.
24. In the evening, after a hot summer day, why is it much cooler in the suburbs than downtown?
25. In Example 18–10 you have an apparatus that is capable of measuring ΔT to 0.02°C. If you want a better than 20% accuracy measurement, you need at least a 0.10°C temperature increase. Would you be better off with mercury instead of water in the experiment? (See Table 18–1.)
26. The center of a continent has more temperature extremes than do coastal areas at the same latitude. What effect contributes significantly to this?
27. People who drive cars in cold climates observe that the car's engine sometimes overheats if they keep the engine idling. This does not happen while they are driving, even though the engine puts out much more power then. Why?

Problems

18–1 Changes in Thermal Systems

1. (II) Are the following thermal transformations reversible or irreversible? Show the changes on a diagram when one is requested. (a) The sudden release of a gas from one portion of a container, of volume V_1, into a second portion, previously under vacuum. The total final volume, the volume of the whole container, is V_2 (p–V diagram). (b) As in part (a), but rather than a sudden release, the release is made a little at a time until there is no further flow of gas (p–V diagram). (c) The compression of a gas in thermal contact with a heat reservoir by loading weights, a little at a time, onto a piston connected to the gas (V–T diagram). (d) The slow heating of a gas by the release, a little at a time, of a warmer gas into the original sample of gas (p–T diagram). (e) The slow heating of a gas by placing it in thermal contact with a series of ever hotter thermal reservoirs (p–T diagram). (f) The slow rusting of a nail. (g) The release of electrical energy as lightning. (h) The release of chemical energy in the operation of a rechargeable battery to lift a weight.

18–2 Heat Flow

2. (I) (a) Using Table 18–1, calculate the heat capacity of a 5.7-kg aluminum rod. (b) Assuming that heat capacity is constant with temperature, how much heat flow is required to raise the temperature of the rod from 14°C to 58°C?
3. (I) A water heater heats 0.8 L of water/min from 20°C to 50°C. If the efficiency of the heater is 80%, how much power is consumed by the heater?
4. (I) The latent heat of fusion of oxygen (O_2) is 0.44 kJ/mol. Given that the atomic weight of molecular oxygen is 32 g/mol, find the latent heat of fusion in units of (a) kJ/kg and (b) cal/g.
5. (I) Consider an ideal gas initially in a state (p, V) and finally in a state $(p, 2V)$. If the transformation occurs at a constant pressure, what is the heat flow into the gas in terms of p and V?
6. (II) A 16 kg lead brick is at room temperature, 25°C. The melting point of lead is 327°C. Using the specific heat for lead, given in Table 18–1, calculate the heat flow to the brick needed to bring the brick to the melting temperature.
7. (II) A 300 cm^3 glass is filled with 100 g of ice at 0°C and 200 g of water at 25°C. (a) Characterize the content of the glass after equilibrium has been reached. Neglect heat transfer to and from the environment. (b) Repeat your calculations for 50 g of ice and 250 g of water.
8. (II) In Example 18–4 an experiment in calorimetry was described in which the assumption is made that the heat capacity of water and iron are constant over the temperature range of the experiment. Describe a series of experiments that would establish whether or not these heat capacities are indeed constant.
9. (II) The quantity 0.60 kg of thermally isolated water at an initial temperature of 291K serves as a calorimeter. Into it can be placed 1.20 kg of metal that has been heated to 373K. Find the specific heats and molar heat capacities of the metals if the equilibrium temperature is (a) 316K; the metal is aluminum. (b) 305K; the metal is iron. (c) 297K; the metal is lead.
10. (II) A calorimeter consists of 400 g of water at 25°C. A 500 g piece of copper at 100°C is thrown into the water, and the equilibrium temperature is found to be 28.3°C. What are the specific heat of copper in cal/g · K and the molar heat capacity, given that 1 mol of copper has a mass of 63.5 g?
11. (II) The quantity 200 g of thermally isolated water at an initial temperature of 293K serves as a calorimeter. Into it are placed, *successively*, 200 g of iron, then 200 g of silver, each of which has been heated to 400K. Using the known specific heats of iron and silver, find the final equilibrium temperature. (Use $c_{Ag} = 0.0557$ cal/g · K and $c_{Fe} = 0.112$ cal/g · K.)
12. (II) An axe head consisting of 1.8 kg of iron is left outdoors one cold winter's night and is brought indoors when the outside temperature is a brisk 240K. The room into which it is brought is initially at a nice, comfortable 293K and 1.0 atm of pressure. The volume of the room, which is well insulated, is 38 m^3. Assuming that the axe head comes to thermal equilibrium with the air in the room, by how much is the temperature of the room lowered? (Ignore the thermal interaction with furniture, walls, and so forth. Use $c_{air} = 0.172$ cal/g · K, $c_{Fe} = 0.112$ cal/g · K, and 28.8 g/mol for the molecular weight of air.)
13. (II) A thermally isolated system consists of 1 mol of helium gas at 100K and 2 mol of a solid at 200K; the gas and the solid are separated by an insulating wall of negligible mass. If the wall is removed, what is the equilibrium temperature of the system? Assume that at the given temperatures, the heat capacity of the solid is given by $3R/2$ per mole.

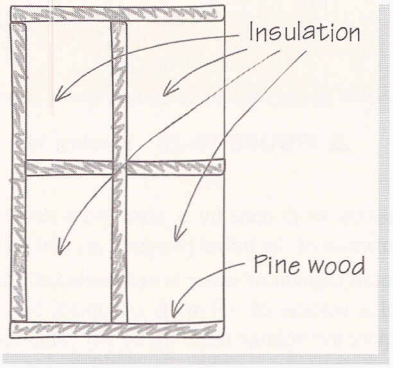
18–3 Heat Flow in Materials

14. (I) A single window pane of thickness 6.0 mm has an area of 1.0 m^2. The inside and outside temperatures are 73°F and 13°F,

respectively. Calculate the rate of thermal energy loss through the window. (See Table 18–3.)

15. (I) Compare the rate of thermal energy transfer across a piece of asbestos that is 1.0 m^2 in area and 1.0 cm thick with that of a piece of glass of the same dimensions for a temperature difference of 60°C.

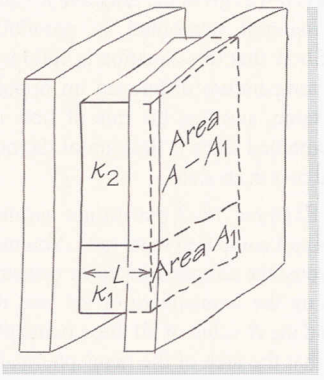
16. (I) The glass from a basement window is replaced by a sheet of asbestos that is 0.80 cm thick. The window is 60 cm wide and 35 cm high, and there is no air leakage around the edges. Given that the heat loss through the surface is 0.006 J/s, what is the temperature difference between the outside and the inside of the basement?



17. (I) A brick wall 5.0 m by 5.0 m in size and 0.10 m thick separates the inside of a house from the outside, where the temperature is 285K (12°C). A heater supplies energy inside at a rate of 0.35 kW. What is the inside temperature? Ignore all surfaces except the brick wall in question.

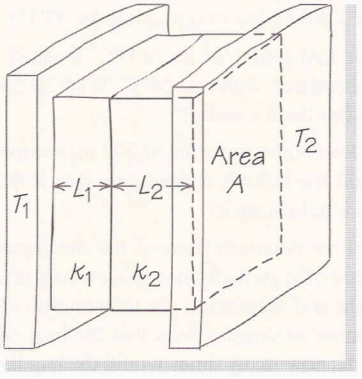
18. (I) Your refrigerator can be thought of as a box with six sides of total area 2.5 m^2. The effective R value of the walls is 1.5 $m^2 \cdot K/W$. The temperature inside is 5°C, while the temperature outside is 25°C. Calculate the rate of heat loss.

19. (I) A house of dimensions 36 ft × 21 ft × 9 ft is built of bricks that are 9.0 in thick. The inside and outside temperatures are 76°F and 25°F, respectively. Calculate the rate of thermal energy loss through the brick wall. (See Table 18–3.)



20. (II) The R value of brick is about 1.1 $ft^2 \cdot h \cdot °F/Btu$ across the brick's width. A dog who expends 57 W of energy lives in a brick doghouse of total effective area 1.6 m^2. How much temperature variation between the inside and outside of the doghouse can the dog withstand if only its body heat warms the house? Assume that the door locks out drafts and that the heat conduction through the door is identical to that through the walls.

21. (II) Pine wood 1 in thick has an R value of 1.3, compared with 3.0 for fiberglass insulation of the same thickness. (The units of R are $ft^2 \cdot h \cdot °F/Btu$.) Calculate the rate of thermal energy loss of a 6-in thickness of these same materials across a 4.0 ft × 8.0 ft section of wall for a temperature difference across the wall of 35°F. If 10 percent of the wall section is made of wood studs and the space between studs is filled with fiberglass, calculate the effective R value of the wall section (Fig. 18–23).



▲ **FIGURE 18–23** Problem 21.

22. (II) Consider a wall of thickness L and area A. Part of the area, A_1, consists of a material with thermal conductivity κ_1 and the remaining area, $A - A_1$, consists of a material with thermal conductivity κ_2 (Fig. 18–24). Calculate how much thermal energy flows through each part of the wall, and calculate an effective thermal conductivity for the wall as a whole.

▲ **FIGURE 18–24** Problem 22.

23. (II) A wall of area A consists of two slabs: one of thickness L_1 and thermal conductivity κ_1, the other of thickness L_2 and thermal conductivity κ_2, as shown in Fig. 18–25. The temperatures are T_1 and T_2, respectively, on the left-facing side and the right-facing side of the wall. (a) Calculate the effective thermal conductivity of the wall in terms of the parameters given. (b) Calculate the temperature at the interface of the two slabs.

▲ **FIGURE 18–25** Problem 23.

24. (II) Two pieces of material are arranged in series as in Fig. 18–10. If the temperature to the left is T_1 and the temperature to the right is T_2, find the temperature between the pieces, T_{int}, as a function of T_1, T_2, and the R values of the two pieces.

25. (II) Equation (18–11) states that when two slabs of conducting material are combined in series, as pictured in Fig. 18–10, their R values are additive. Show that this is so by using the principle that the rate of flow of thermal energy is the same for each slab and for the two slabs combined:

$$\frac{dQ}{dt} = \frac{1}{R_1}A(T_1 - T_{int}) = \frac{1}{R_2}A(T_{int} - T_2)$$
$$= \frac{1}{R_{eff}}A(T_1 - T_2).$$

26. (II) A trapper lives in a cave. At the cave's entrance, the trapper has constructed an exterior wall from lumber 6.0 cm thick. The wood has a thermal conductivity, κ, of 0.35 $W/m \cdot K$. Assume that all thermal energy loss occurs through the wall, which forms a rectangle of dimensions 2.5 m × 2.0 m. This wall, together with a stove, is capable of maintaining the cave's interior at a temperature of 8°C when the outside temperature is −25°C. What is the power output of the stove?

27. (II) Equation (18–12) gives the effective R value for two slabs of conducting material combined in parallel, as pictured in Fig. 18–11. Show that this equation is valid by using the principle that the temperature difference on opposite sides of both slabs is the same, and that the rate of flow of thermal energy across the combined slabs is the sum of the rate of flow of thermal energy across each slab.

28. (III) Repeat Example 18–7 but do not assume that the igloo's thickness is small compared to its radii. You may assume that the surfaces of constant temperature form concentric hemispheres. [*Hint*: Break up the hemisphere of ice into thin hemispherical shells and find the R value of all these hemispheres combined in series. Note that the area of the hemispherical shells is not constant, so Eq. (18–8) must be modified appropriately.]

29. (III) A long, cylindrical hot-water pipe of radius R_1 is at temperature T_1. It is wrapped with insulation of thickness α and of thermal conductivity κ; the outer surface of the insulation is at temperature T_2. Derive an expression for the rate of heat loss per unit length of insulated pipe. [*Hint*: The temperature within the insulation varies with radial position r. Break the insulation into thin cylindrical shells and find the areas of these shells as a function of their radii.]

18–4 The Mechanical Equivalent of Heat

30. (I) How many kilojoules of energy are required to raise the temperature of a 3.0 kg bar of aluminum by 32°C?

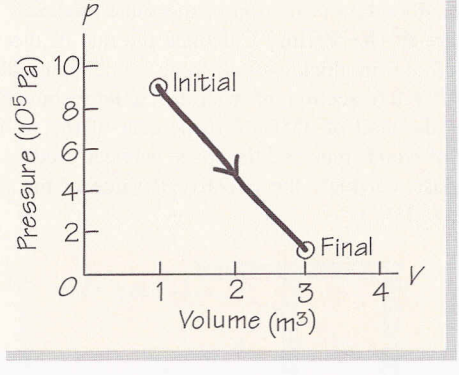
31. (I) One hundred grams of ice at 0°C is added to 500 grams of thermally insulated water at 24°C. What is the temperature of the water after the ice melts?

32. (I) A 50 g lead bullet traveling at 200 m/s stops in a target. How much would the bullet's temperature rise if 80% of the energy were to go into heating it?

33. (I) A primitive demonstration of the mechanical equivalent of heat consists of repeatedly dropping a bag of lead shot from a given height and measuring the temperature change in the bag after a number of drops. Given that the heat capacity of lead is 128 J/kg · K, how many times would the bag have to be dropped from a height of 2.0 m to change its temperature by 5°C? Neglect all heat flows from the lead.

34. (II) Suppose that a kilogram of water drops, starting from rest, from a height of 13 m. When the water hits the ground suppose that half of the kinetic energy it attains in falling is converted into thermal energy within the water. By how much will the temperature of the water rise? Neglect the effect of air resistance.

35. (II) Julius Robert Mayer, who first enunciated the principle of the conservation of energy, estimated the mechanical equivalent of heat by considering a quantity of air confined in a cylinder by a movable piston. If the volume is fixed, 0.172 cal must be supplied to raise the temperature of 1 g of air by 1.0°C. If the piston is not fixed but exerts a constant pressure of 1 atm ($= 1.01 \times 10^5$ N/m^2), 0.241 cal are needed to raise the temperature of 1 g of air by 1°C. If the volume change experienced by 1 g of air when the temperature changes by 1°C at constant pressure is 2.83×10^{-6} m^3/g · K, what is the relation between the calorie and the joule?



36. (II) The amount of solar energy delivered to a horizontal surface in Washington, D.C., averaged over a full year, is 160 W/m^2. Assuming a 10% efficiency for absorption and conversion to usable heating, how many liters of water can be heated from 0°C to 20°C in a 24 h period by a 3 m^2 solar panel?

37. (II) Angel Falls, in Venezuela, has the highest free waterfall in the world, at 2,648 ft. The water at the top of the falls is at a temperature of 10°C. (a) What is the temperature of the water in the pool at the base of the falls? As a first approximation, ignore the effects of air resistance, so that there is no terminal velocity. Also, ignore the effects of evaporation. [*Hint*: The kinetic energy that the water gains in falling, thereby losing potential energy, goes into turbulent motion at the base of the falls.]The exact terminal velocity is a complicated function of the precise configuration of the waterfall, such as whether it forms a tight tube or whether it is a broad, dispersed spray. (b) Repeat part (a) for Niagara Falls, which is approximately 50 m high. (c) Return to Angel Falls. Discuss the effect of air resistance and the fact that there is a terminal velocity. Would you expect the water to be heated as much as in part (a)? (d) It takes a positive heat flow into a liquid, the latent heat of vaporization, to cause it to evaporate. What is the sign of the temperature change in the waterfall, when you take into account the effect of evaporation of the falling droplets?

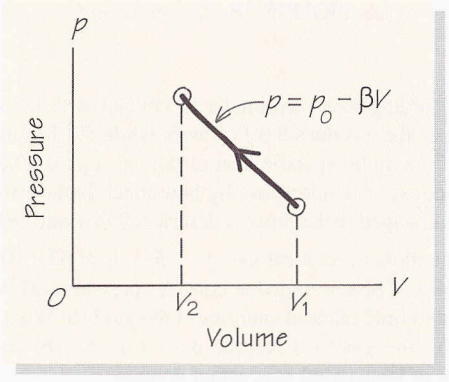
38. (II) Work is done on a thermally isolated container of 1.5 kg of water under 1 atm of pressure, initially at a temperature of 295K. Assume that the specific heat of water does not vary with temperature, and that churning paddles do work on the water at a rate of 40 W. How long must the paddles continue to turn to bring the water to its boiling point, 373K?

18–5 Work Done by Thermal Systems

39. (I) The volume of a gas in a cylinder slowly increases by a factor of 3 while its pressure decreases from 9×10^5 Pa to 1×10^5 Pa, as shown in Fig. 18–26. How much work is done on the piston by the gas during the expansion?

▲ **FIGURE 18–26** Problem 39.

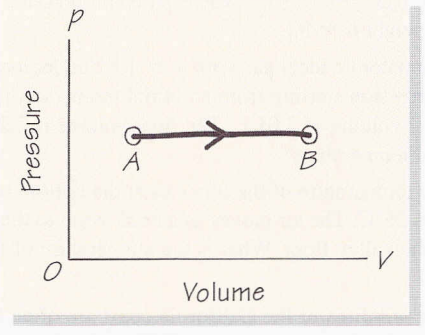
40. (I) Express the work done by an ideal gas at constant temperature T_0 as a function of the initial pressure, p_i, and final pressure, p_f.



41. (I) If a small amount of water is evaporated at atmospheric pressure until a volume of 3.0 m^3 is occupied, how much work is done? Ignore the volume taken up by any remaining liquid water.

42. (I) Gas in a cylinder is allowed to expand from a volume of 0.85×10^{-3} m^3 to a volume of 0.95×10^{-3} m^3, while the pressure changes linearly with the volume from an initial pressure of 4.8 atm to a final pressure of 4.2 atm. What is the work done by the gas?

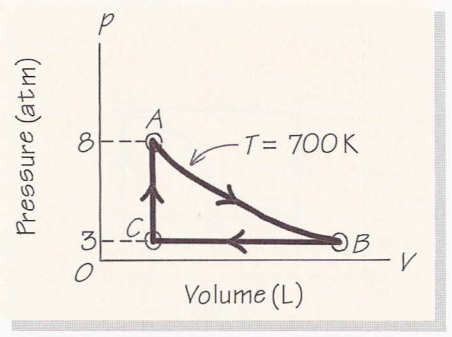
43. (II) Half a mole of an ideal gas is compressed isothermally at 293K so that the pressure is increased from 1.0 atm to 3.6 atm. What are the initial and final volumes of the gas, and how much work is done by the gas during the compression?



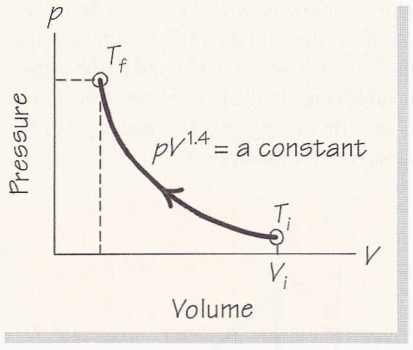
44. (II) Two liters of nitrogen gas at an initial temperature of 320K expand at a constant pressure of 5 atm against a piston, thereby doing work to raise a total mass of 100 kg. The gas is allowed to expand to a volume of 5.0 L. (a) How high can the mass be lifted? (b) What is the final temperature of the gas?

45. (II) A gas is compressed from V_1 to V_2 by reversibly following the path shown in Fig. 18–27, $p = p_0 - \beta V$, where β is a constant. (a) What is the dimension of β? (b) Determine the work done by the gas during the transformation by integrating the infinitesimal work along the path, $dW = p\,dV$. (c) Check your answer by evaluating the area under the p–V curve in the figure.

▲ **FIGURE 18–27** Problem 45.



46. (II) Figure 18–28 shows a reversible path for a gas being taken from state A to state B. Both states have the same pressure. (a) What is the work done in taking this path? (b) Draw a second reversible path that connects the same points by which no work is done. If the gas is ideal, to what minimum temperature is the gas taken on this path? (Real gases cannot be taken to this temperature.) (c) Draw a third path in which the work done is greater than the work done in following the original path.



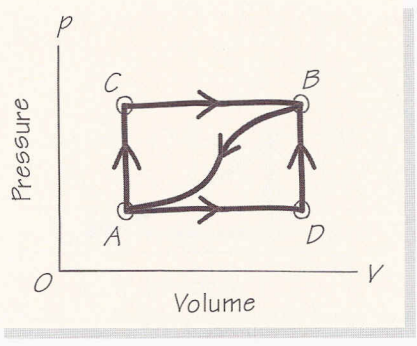
▲ **FIGURE 18–28** Problem 46.

47. (II) Two moles of an ideal gas are carried around the thermodynamic cycle shown in Fig. 18–29. The cycle consists of (1) an isothermal expansion $A \rightarrow B$ at a temperature of 700K, with the pressure at A given by $p_A = 8.0$ atm; (2) an isobaric compression $B \rightarrow C$ at 3.0 atm; and (3) an isochoric pressure increase $C \rightarrow A$. What work is done by the gas per cycle?

48. (III) An external force compresses 0.10 mol of an ideal gas in thermal isolation. The curve of this transformation on a p–V diagram is $pV^{1.4} =$ a constant. The gas initially has a volume $V_i = 1.6$ L and a temperature of 275K. When the compression is finished, the temperature has increased to 380K (Fig. 18–30). (a) What are the final volume and final pressure? (b) How much work was done on the gas to compress it?

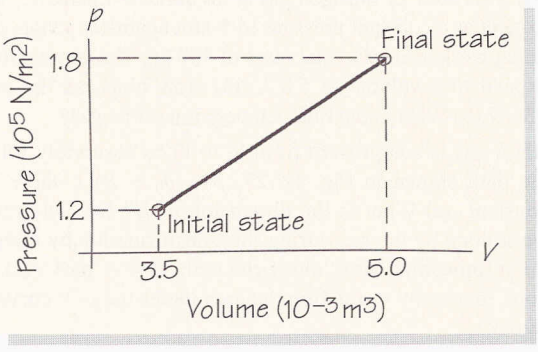
▲ **FIGURE 18–29** Problem 47.

▲ **FIGURE 18–30** Problem 48.



18–6 The First Law of Thermodynamics

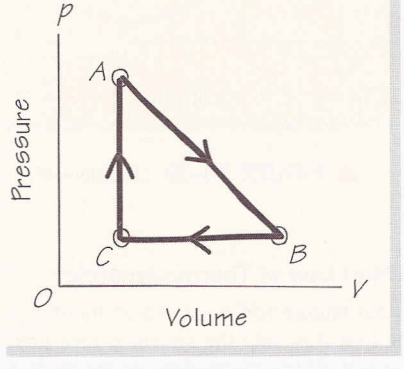
49. (I) A certain engine follows a closed thermodynamic cycle in which the heat flow into the system is measured to be 633 cal. Assuming that all transformations of the cycle can be approximated as reversible ones, what is the net work done, in joules, by the engine in one cycle?



50. (I) An ideal gas undergoes a reversible transformation from an initial state ($p_i = 1.0$ atm, $V_i = 350\ \text{cm}^3$) to a final state ($p_f = 2.0$ atm, $V_f = 175\ \text{cm}^3$). The transformation is carried out in two steps: The gas is compressed at constant pressure, and when the final volume is achieved, the pressure is increased while the volume is held fixed. Use the first law of thermodynamics to calculate the heat flow into the gas during this transformation. Assume (as is shown in Section 18–7) that, for an ideal gas, the internal energy U is a function of T only.

51. (II) Consider the p–V diagram shown in Fig. 18–31. If the system is taken from point A to point B via path $A \rightarrow C \rightarrow B$, 40,000 cal of heat flows into the system, and the system does 20,000 cal of work. (a) How much heat flows into the system along path $A \rightarrow D \rightarrow B$ if the work done is 7000 cal? (b) When the system returns from point B to point A along the curved path, the work done is 15,000 cal. Does the system absorb or liberate heat, and how much?

52. (II) The latent heat of vaporization for water at 1 atm and 100°C is 540 cal/g. How much of that heat is converted into the mechanical work needed to change the volume of 1 g of water into 1 g of steam? [*Hint*: Calculate the volume of 1 g of steam.]



▲ FIGURE 18–31 Problem 51.

▲ FIGURE 18–33 Problem 55.

18–7 Internal Energy of Ideal Gases

53. (I) A thermal system consisting of 1 mol of an ideal gas forms a cycle that contains a leg *AB* in which pressure decreases linearly as the volume increases, a leg *BC* in which the gas is compressed at constant pressure until the initial volume is attained, and a leg *CA* in which the volume is held fixed as the pressure increases to its initial value (Fig. 18–32). (a) Express the internal energy at *A*, *B*, and *C* in terms of p_A, p_B, V_A, and V_B. (b) How much work does the gas do over the cycle?

▲ FIGURE 18–32 Problem 53.

54. (II) An ideal monatomic gas, with $c'_V = 3R/2$, undergoes a change of state. On a plot of pressure versus volume, it follows straight lines from an initial point (p_0, V_0) to $(p_0, 2.5V_0)$ to $(1.5p_0, 2.5V_0)$. (a) Draw the *p*–*V* plot. (b) By how much does the internal energy change? (c) How much work is done by the gas on its surroundings? (d) How much heat is added to the gas?

55. (II) Five grams of N_2 gas (molecular weight 28 g/mol) are allowed to expand from an initial state $(p_i, V_i) = (1.2 \times 10^5\ \text{N/m}^2, 3.5 \times 10^{-3}\ \text{m}^3)$ to a final state $(p_f, V_f) = (1.8 \times 10^5\ \text{N/m}^2, 5.0 \times 10^{-3}\ \text{m}^3)$ along a path that forms a straight line on a *p*–*V* plot (Fig. 18–33). (a) What are the initial and final temperatures? (b) What is the change in the internal energy of the gas? (c) What is the work done by the gas? (d) What is the heat flow into or out of the gas during the process?

56. (II) One mole of an ideal gas in contact with a thermal reservoir at 350K is under 10 atm of pressure. The pressure is slowly increased to 25 atm. (a) What are the initial and final volumes of the gas? (b) How much work is done *on* the gas? (c) What is the change in internal energy of the gas? (d) What is the heat flow into the gas?

57. (II) According to a calorimeter in contact with 0.20 mol of an ideal gas, the gas does 8.0 J of work while 5.0 J of heat is added to it. If the molar specific heat of the gas, c'_V, is 20.8 J/mol · K, independent of temperature, by how much is the temperature of the gas changed in the process described? Is it warmed or cooled?

58. (II) One mole of an ideal gas, $\gamma = 5/3$, is at STP (0°C, 1 atm), and 350 J of heat is added at constant pressure. (a) What are the initial and final internal energies of the gas? (b) What is the work done by the gas? (c) Repeat parts (a) and (b) for the same amount of heat added at constant volume.

18–8 More Applications for Ideal Gases

59. (I) How much work does it take to compress 30 mol of an ideal gas at a fixed temperature of 15°C to half its volume?

60. (I) One mole of ideal gas undergoes an adiabatic transformation in which its temperature changes by 25K. How much work is required to bring about this transformation, given that the constant-volume molar heat capacity of the gas is $c'_V = 30.00$ cal/mol · K?

61. (I) Equation (18–42) is an equation for pressure as a function of height for the atmosphere, which is treated as an ideal gas. Show that, if *T* is independent of height, this equation has the solution $p(h) = p_0 e^{-Mg(h-h_0)/RT}$, where p_0 is the pressure at some reference height $h = h_0$.

62. (I) A monatomic ideal gas with $\gamma = 1.67$ undergoes an adiabatic compression starting from an initial temperature of 248K and an initial volume of 3.01 L. The final volume is 2.22 L. What is the final temperature?

63. (II) The temperature of the (dry) air at the bottom of a mountain valley is 26°C. The air moves as a brisk wind to the ridge 600 m above the valley floor. What is the temperature of the air on the ridge?

64. (II) The wildfires of the California coast are often fed by desert winds, which heat up to about 100°F in the desert at an altitude of 500 m, then rush down to sea level. What is the temperature of the air in these winds at sea level?

65. (II) Consider two thermal states of an ideal gas, *A* and *B*, together with the possible reversible paths that connect them. Is there an adiabatic path that connects these states when (a) $V_A = V_B$? (b) $p_A = p_B$? (c) $T_A = T_B$?

66. (II) An ideal gas is contained in a cylinder with a movable piston of cross sectional area 300 cm^2. The external pressure is held constant at 1.01×10^5 Pa. An external force lifts the piston from a height of 30 cm to a height of 60 cm. What is the work done by the applied force on the gas if the process takes place isothermally?

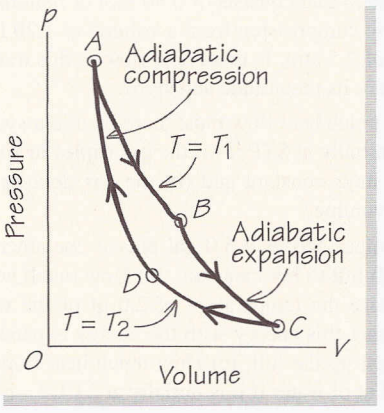
67. (II) An ideal gas expands adiabatically from an initial state p_0, V_0 to a final state p_f, V_f. Such an expansion is characterized by the p–V curve $pV^\gamma =$ constant, where $\gamma > 1$ is a constant. Show that the work done by the gas is $W = (\gamma - 1)^{-1}(p_0V_0 - p_fV_f)$.

68. (II) A diatomic ideal gas such as air, for which $\gamma = 1.4$, expands adiabatically to 40 times its original volume. (a) By what factor does the temperature change? (b) By what factor does the pressure change?

69. (II) One liter of gas characterized by $\gamma = 1.4$ is allowed to expand adiabatically to twice its volume. How does this pressure change compare with the pressure change that would occur for an isothermal expansion?

70. (II) How much work is done by 1.00 L of helium when it expands adiabatically from sea-level pressure (1.00 atm) to the point where the pressure is 0.10 atm? Helium is monatomic, with $c'_V = 3R/2$.

71. (II) A particular adiabatic transformation of an ideal gas occurs as the pressure increases by a factor of 5 while the volume decreases by a factor of 3. What is the ratio of C_V to C_p? How much work is done on the gas during the compression, in terms of the initial pressure and volume? By how much does the internal energy of the gas change?



72. (II) Use the result of Problem 61 to find the pressure at the height of Mt. Everest, which is about 10 km. Find also the temperature at this height. How much volume does 1.0 mol of air occupy? Calculate the density of air at this altitude and compare it with the density of air at sea level. The molecular weight of air is 29.2 g/mol.

73. (II) A gasoline engine of volume 25 cm^3 intakes air at 25°C and 1.0 atm. The engine compresses the air adiabatically to 30% of the original volume. Find the final pressure and temperature and how much work is performed on the gas. You can assume that the air is ideal.

74. (II) The compression ratio (the ratio of the maximum volume to the minimum volume) of the cylinder of a diesel engine is 15 : 1. The working gas is air (for which $\gamma = 1.4$), which enters the cylinder at room temperature, approximately 300K. The compression is so rapid that there is no heat flow through the cylinder walls, and the compression can be said to be adiabatic. To what temperature is the air heated?

75. (II) In Problem 17–57 the operation of a bicycle pump was studied on the assumption that the air in the pump is in thermal equilibrium with the environment. Repeat the analysis for the case when the pump is pushed down so quickly that no heat exchange occurs and the process is adiabatic. Assume that the temperature of the environment is 22°C. (The real process actually lies between the very slow isothermal and the very rapid adiabatic case).

76. (III) Consider the *Carnot cycle* shown in Fig. 18–34. One mole of an ideal gas with volume V_A at temperature T_1 undergoes an isothermal expansion to a volume V_B. This is followed by an adiabatic expansion to a volume V_C and then an isothermal compression at temperature T_2 to volume V_D; the cycle is closed by an adiabatic compression ending with volume V_A at temperature T_1. You will need to know the form of the transformation curve followed on each leg, and the heat flow to the gas for each leg. For the adiabatic legs, you know the heat flows, but for the isothermal legs, you may want to find the work done directly and use your knowledge of the energy change of an ideal gas when the temperature is constant. You also need to know the starting and ending points of the curves. What is the net heat, expressed in terms of the given variables, supplied to the gas during the cycle?

▲ **FIGURE 18–34** Problem 76.

77. (III) In Eq. (18–43) we state that by following an adiabatic curve, the temperature of Earth's atmosphere drops linearly with height h from the surface, and give the coefficient of h. Here this result is derived. The starting points are Eq. (18–41), which expresses the relation between T and p in an adiabatic transformation of an ideal gas, as well as Eq. (18–42), which expresses the pressure of the atmosphere as a function of height. (a) Take the derivative with respect to height of Eq. (18–41), using the chain rule of differentiation (see Appendix IV–7) for the right-hand side, to show that

$$\frac{dT}{dh} = \text{a constant}\left(\frac{\gamma - 1}{\gamma}\right)p^{[(\gamma-1)/\gamma]-1}\frac{dp}{dh}.$$

(b) Show that this result can be rewritten as

$$\frac{dT}{dh} = \left(\frac{\gamma - 1}{\gamma}\right)Tp^{-1}\frac{dp}{dh}.$$

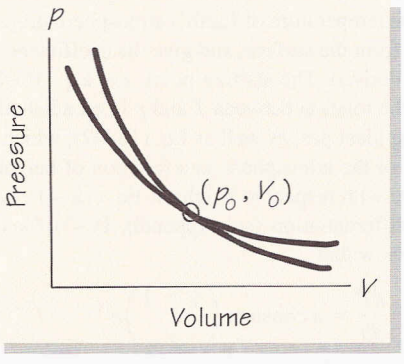
(c) Substitute Eq. (18–42) for dp/dh into the result derived in part (b) to find that

$$\frac{dT}{dh} = -\left(\frac{Mg}{R}\right)\left(\frac{\gamma - 1}{\gamma}\right).$$

(d) Show that Eq. (18–43) is the solution of the differential equation derived in part (c).

78. (III) An experiment shows that the amount of work done is 88.9 J when a certain ideal gas is compressed adiabatically from an initial pressure of 1.00 atm and an initial volume of 1.00 L to a final volume of 0.50 L. In a second experiment, the same amount of gas is again compressed from 1.00 L to 0.50 L, but this time it is in thermal contact with a thermal reservoir at $T = 20$°C, and 189 J of work is required for the compression. (In the second experiment, the initial pressure is not necessarily 1 atm.) (a) How many moles of gas are there? (b) What is γ for the gas? [*Hint*: Calculate the work done in the adiabatic compression for several values of γ between 1.2 and 2.] (c) What is C_V for the gas?

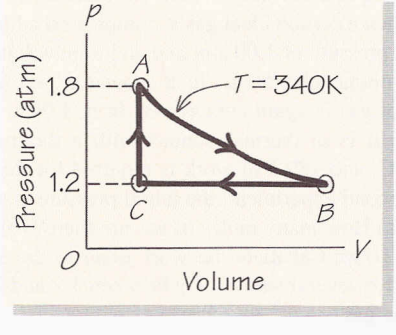
General Problems



79. (I) Five liters of oxygen at one-half atmospheric pressure and 273K is heated at constant pressure until its volume has tripled. It is then compressed isothermally back to 5 L. (a) Draw the process on a p–V diagram. (b) What is the final pressure of the gas? (c) How much work is done by the gas during the entire process?

80. (II) A system that consists of 0.40 mol of helium gas undergoes an isobaric compression from a volume of 1.20 L to 0.70 L at a pressure of 2.5 atm. Is there heat flow in this transformation? If so, what are its magnitude and sign?

81. (II) How much heat flow must there be into a system of 10 L of oxygen initially at STP if (a) the gas triples in volume while the pressure stays constant and (b) the gas doubles in pressure at constant volume?



82. (II) A camper carries a 5.0 gal plastic container of water up a 40-m-high hill to her campsite. (a) How much heat flow does it take to raise the temperature of 2.0 qt of the water by 65°C? (b) Compare this energy with the energy expended to carry the entire 5 gal up the hill. (c) How much heat flow will it take to boil the 2 qt of water if it is initially at 23°C?

83. (II) Consider the adiabatic and isothermal processes that each pass through the point (p_0, V_0) on a p–V diagram (Fig. 18–35). Which of the processes has the greater slope at this point? Compute the ratio of the slopes at this point.

▲ FIGURE 18–35 Problem 83.

84. (II) A 1-mol sample of an ideal gas for which $c'_V = 3R/2$ follows the closed thermodynamic cycle shown in Fig. 18–36. There are three legs in the cycle: an isothermal expansion, $A \rightarrow B$; an isobaric compression, $B \rightarrow C$; and a constant-volume increase in pressure, $C \rightarrow A$. The temperature during the isothermal leg is $T = 340\text{K}$, $p_A = 1.8$ atm, and $p_B = p_C = 1.2$ atm. What are (a) V_A? (b) V_B? (c) The work done by the system during leg $A \rightarrow B$? (d) Q for leg $A \rightarrow B$? (e) T_C? (f) the net work done by the system over the complete cycle?

▲ FIGURE 18–36 Problem 84.

85. (II) The energy in the form of solar radiation that falls on Earth, after reflection is taken into account, is 956 J/m^2 s. The effective area that faces the Sun is that of a disk whose radius is the same as that of Earth. In equilibrium Earth radiates at a rate of σT^4 where σ is given in Section 17–5. T is the temperature of Earth. Under equilibrium conditions, what is T?

86. (II) Consider a van der Waals gas (Section 17–4). Find the work done by such a gas in an isothermal expansion from V_0 to V_f. Is this more or less than the work done by an ideal gas in an isothermal transformation from V_0 to V_f at the same temperature? (The signs of the constants a and b for the van der Waals gas are discussed in Section 17–4.)

87. (II) A 100-g piece of copper is heated from 0°C to 100°C at atmospheric pressure. What is the change in its internal energy?

88. (II) A pan contains 300 g of water at 23°C. (a) What heat flow does it require to raise the temperature of the water to 100°C and vaporize it at 1 atm? (b) How much work is done by the water as it changes to the gaseous phase? (c) What is the total change in internal energy of the water?

89. (II) A nuclear power plant requires 1000 MW (megawatts) of cooling. If environmental concerns limit the temperature rise of the water to 12°C, how much water flow is required to cool the plant?

90. (II) Heat flow is transferred to 0.30 mol of an ideal gas at a temperature of 500K and pressure of 2.5 atm, resulting in an isothermal expansion of the volume by a factor of 5. How many calories are involved in the heat flow?

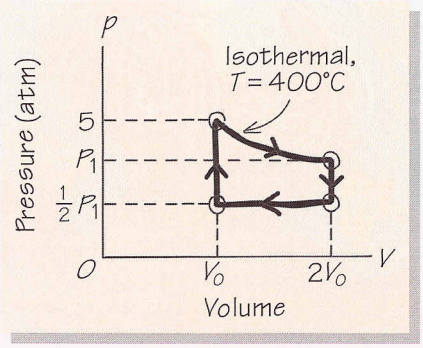
91. (II) One mole of N_2 gas initially at a temperature of 300K and pressure of 1 atm is compressed isothermally until its volume is reduced by a factor of 10. (a) What is the final pressure of the gas? (b) What is the work done by the gas? (c) How much heat flow is transferred?

92. (II) An electric immersion heater is placed in a coffee cup to heat the water to boiling. The cup initially contains 0.18 L of water at 72°F. The heater is rated for 400 W. Neglect heat loss from the water and the cup. How long does it take to heat the water up to boiling? How long after this does it take to boil the water away completely?

93. (II) The internal energy of a van der Waals gas (Section 17–4) is

$$U = \frac{3}{2}nRT + \frac{an^2}{V} + \text{constant}.$$

(a) Find C_p as a function of V and T. (b) Find C_V as a function of V and T. (c) What is the value of the parameter $\gamma \equiv C_p/C_V$ for this gas? Check that your result reduces properly in the low-density limit.



94. (II) A thermally isolated container contains 1.0 L of water at 20°C. A 100-g block of aluminum at 80°C is placed into the container. (a) What is the final temperature of the water? Next 500 g of ice at −20°C is placed in the container. (b) What is the final temperature of the water, iron, and ice (if any)? $c_{\text{ice}} = 0.467$ cal/g · K.

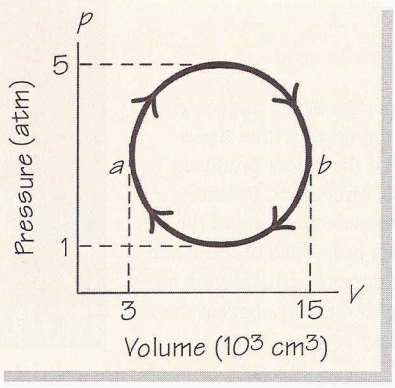
95. (II) A glass contains 150 cm^3 of water at 70°F. Four ice cubes of 25 g each of temperature 10°F are dropped into the water. Neglecting heat-flow loss, what is the final temperature of the water? The specific heat of ice in this temperature range is 2.04 J/g · K.

96. (II) The temperature of espresso coffee (mostly water) can be increased by blowing 100°C steam into it. How much steam (in grams) is needed to heat up a 20-cm^3 cup of espresso from 50°C to 80°C? What is the volume of this quantity of steam, assuming that the steam is an ideal gas?

97. (II) One mole of an ideal gas is carried around the thermodynamic cycle shown in Fig. 18–37. The cycle consists of an isothermal expansion at a temperature of 400°C with an initial pressure of 5 atm, leading to a doubling of the initial volume. This is followed by a pressure drop of a factor of 2 at constant volume, and then by an isobaric compression until the initial volume is restored. The cycle

is completed by a constant-volume pressure increase to the initial value of 5 atm. Calculate the values of p, T, and V not given, and the work done by the gas during one cycle.

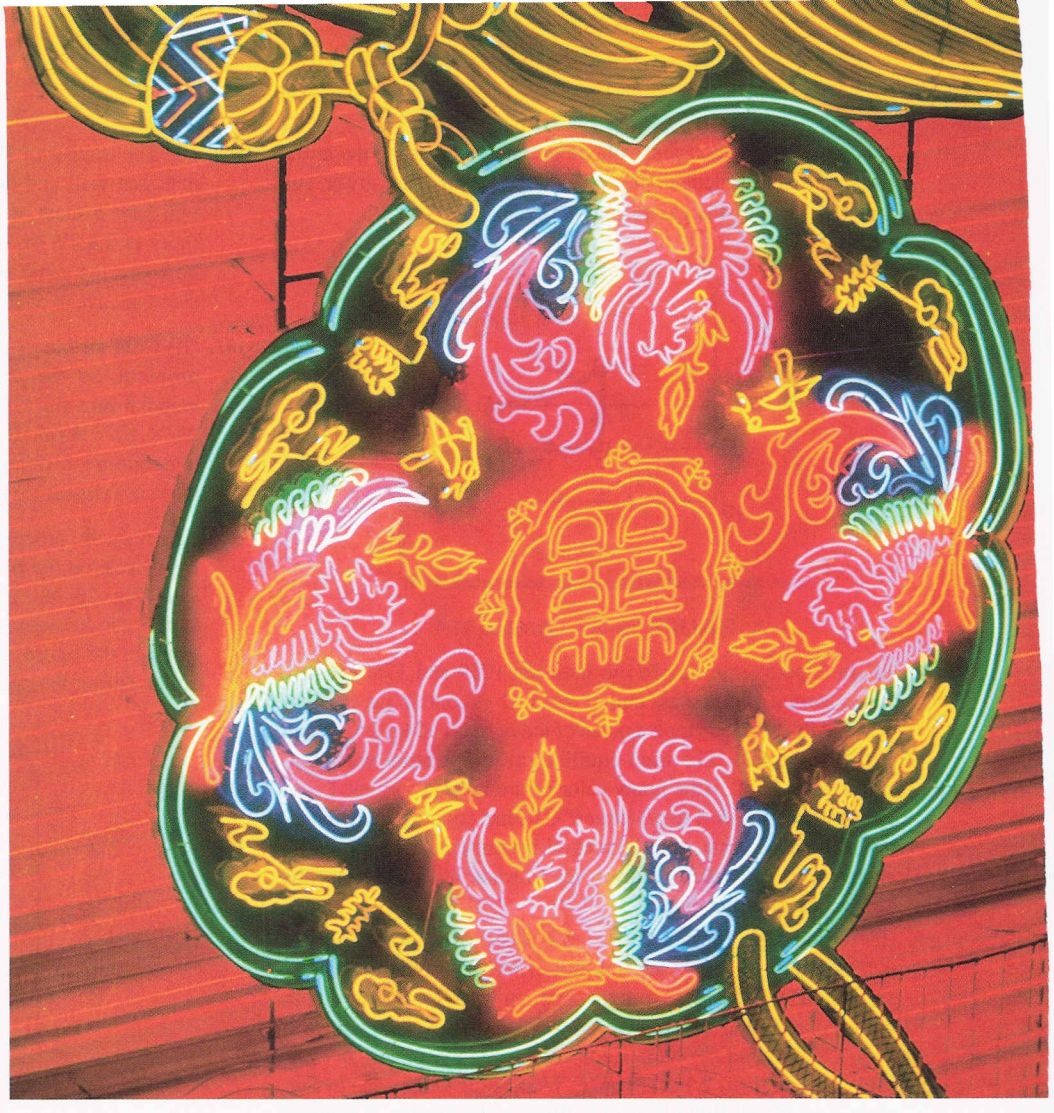
▲ **FIGURE 18–37** Problem 97.



98. (II) In experiments carried out between 1759 and 1762, Joseph Black started with a glass cup of mass 32 g, containing 467 g of water at 88°C. Black took a piece of ice of mass 404 g at 0°C and put it in the cup. The final equilibrium temperature was measured to be 12°C. How many calories are needed to melt 1 g of ice; that is, convert it to water at 0°C? That quantity is the latent heat of fusion. What would the equilibrium temperature be if no energy were required to convert ice to water at 0°C? Ignore the heat capacity of the glass.

99. (II) An ideal gas for which $c'_V = 5R/2$ is carried around a cycle $a \rightarrow b \rightarrow c \rightarrow a$. There are 2.4 mol of the gas in the cycle. The expansion $a \rightarrow b$ is a straight line on a p–V diagram with $T_b = T_a = 540\text{K}$, $b \rightarrow c$ is a constant-pressure segment with $p = 1.8$ atm, and $c \rightarrow a$ is a constant-volume segment at 15 L. (a) What is p_a? (b) What is V_b? (c) What is the work done in segment $a \rightarrow b$? (d) What is T_c? (e) What is the change in internal energy in segment $c \rightarrow a$? (f) What is the net work done during the entire cycle?

100. (II) The trapper of Problem 18–26 tires of looking at the blank entrance wall and decides to cut a window in it. The window will have a sheet of mica 1.0 mm thick with a thermal conductivity of 0.85 W/m · K. How large a window can he construct if he keeps the same stove and plans to keep the temperature inside the cave at 5°C?



101. (II) Cold air blows through a crack in the wall of the previous problem, so the trapper covers the crack with a piece of wood 5 mm thick. The thermal conductivity of the wood is 25×10^{-2} W/m · K. If the area of the crack is 6 cm^2 and the temperature difference between outside and inside is 30°C, what is the heat loss through the covered crack?

102. (III) A cyclic process with 0.40 mol of ideal gas is represented by a circle on the p–V diagram (if the appropriate scale is chosen) (Fig. 18–38). Calculate (a) the amount of heat transferred to the gas between the minimum and maximum volumes, as given in the figure; and (b) the largest and smallest internal energies during the cycle, given that $c'_V = 5R/2$.

▲ **FIGURE 18–38** Problem 102.

Chapter 19

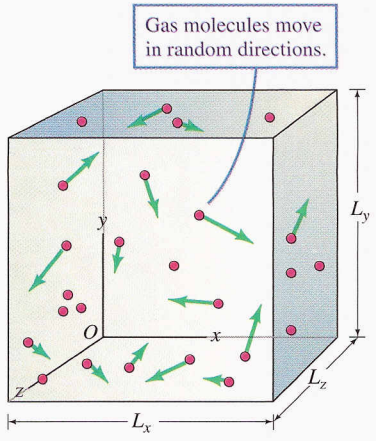
▶ The properties of the molecules that make up the gases within these lights determine the colors produced when electrical effects act. Indeed, a more complete understanding of the thermodynamic properties of these and other systems depends critically on an understanding of these systems at the molecular level.

The Molecular Basis of Thermal Physics

If we could watch a film of the molecular motion of a dilute gas, we would see the molecules rushing around at different velocities, spaced widely compared to their sizes, and bouncing elastically off each other and off the walls of the container in a gigantic three-dimensional game of billiards. Huge numbers of molecules make up even the smallest measurable quantity of a gas. The behavior of such a vast number of molecules can be expressed only in terms of averages. The **kinetic theory** of ideal gases, which is a statistical treatment of the large ensemble of molecules that make up a gas, is the focus of this chapter. We will use kinetic theory to understand the behavior of ideal and nonideal gases. Along the way, we will learn about the velocities of molecules and their statistical distributions, and about how such quantities as energy and momentum can move through a gas—transport phenomena. The kinetic theory of gases is remarkable because it explains so much of the thermodynamics we have already studied with the simplest of assumptions.

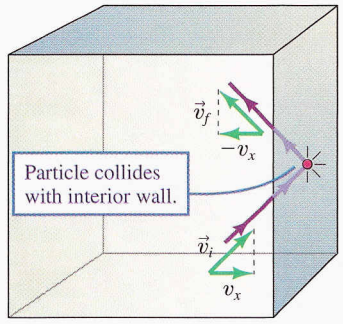
Statistical techniques for the study of large collections of particles have been the subject of intensive work in physics, chemistry, astronomy, and other fields of physical science. Early work was done by James Clerk Maxwell in the 1850s and by Ludwig Boltzmann and Josiah Willard Gibbs in the latter half of the 19th century. Research in this area falls under the general heading of **statistical physics**, a vast field that also includes

many aspects of the physics of liquids and solids. Statistical techniques allow us to explain a great many of the physical properties observed in bulk matter. Statistical physics has been used to explain new and often unexpected phenomena: phase changes, superconductivity, complex crystalline structure, and chaotic behavior, to name just a few.



19–1 A Microscopic View of Gases

A volume of air the size of a birthday balloon contains some 10^{23} molecules. This is an easy number to calculate, given that the air around you is at least approximated by an ideal gas, so that the number of molecules of a volume V of a gas at standard temperature and pressure is $N = pV/kT$, where k is Boltzmann's constant. Equivalently, the number of moles is pV/RT, where R is the universal gas constant. As we know from Chapter 17, the ratio R/k gives us Avogadro's number N_A, some 6.02×10^{23} molecules, the number of molecules in 1 mol of any gas. The properties of individual molecules throw additional light on this number. Atoms and molecules consist of electrons bound to nuclei by electrical forces. Nuclei consist of protons and neutrons. These have almost equal masses, about 1.67×10^{-27} kg $= 1.67 \times 10^{-24}$ g. The atomic weight A of a type of molecule is the total number of protons and neutrons, so that the mass of a single molecule, in grams, is $A \times (1.67 \times 10^{-24}\ \text{g})$. Now one mole of a substance of atomic weight A has, by definition, a mass of A grams, so to find the number of molecules N_A in one mole, we divide the mass A g of a mole by the mass of one molecule: $N_A = (A\ \text{g})/(A \times 1.67 \times 10^{-24}\ \text{g}) = 6.02 \times 10^{23}$ molecules.



Avogadro's number is incomprehensibly large. But just how crowded are the molecules? It follows from the ideal gas law that, at standard temperature and pressure, the volume of 1 mol of gas is $22.4\ \text{L} = 22.4 \times 10^{-3}\ \text{m}^3$. This means that, on average, each molecule occupies a volume of $(22.4 \times 10^{-3}\ \text{m}^3)/(6 \times 10^{23}) \cong 4 \times 10^{-26}\ \text{m}^3$. Using a radius r of 10^{-10} m for a typical molecule, we calculate the molecular volume to be $(4/3)\pi r^3 \cong 4 \times 10^{-30}\ \text{m}^3$. A molecule therefore takes up only $(4 \times 10^{-30}\ \text{m}^3)/(4 \times 10^{-26}\ \text{m}^3) = 10^{-4}$ of the volume available to it! The cube root of this number, namely about $1/20$, gives the ratio of the typical molecular radius to the mean spacing between molecules. If we were to scale molecules to the size of, say, sheep, with a radius of 0.5 m, the molecules would be spaced some 10 m, or 30 ft, apart.

As a gas becomes more dilute, molecular collisions occur less frequently. A dilute (or ideal) gas is a collection of independent molecules that move about with differing velocities and relatively rare collisions. However rare, collisions play an important role. They are the means by which gases come to thermal equilibrium. When a hot gas (consisting of rapidly moving molecules) is mixed with a cold gas (composed of more slowly moving molecules), elastic collisions between fast molecules and slow molecules slow down the fast molecules and speed up the slow ones (see Chapter 8). The entire system comes to equilibrium at an intermediate temperature.

Our treatment of gases will be based on a statistical picture, in which averages of quantities such as speed appear rather than their values for individual molecules. Why do averages tell us anything at all about a gas? After all, if we toss 10 coins ("a set of tosses") many times, the average number of heads in each set of tosses is 5, but we have very little confidence that we will actually get heads 5 times in just 10 tosses. (Try it!) It is only because the number of molecules we deal with is so large that we can be confident that average quantities really do represent the behavior of gases. Suppose that the number of coin tosses (N) is very large. The average number of heads is $0.5N$. But more important, in any given trial (a set of N tosses), the probability that we will get heads more than the average number of times depends on N. For example, the probability that we will get heads more than 51% of the time is about 38 in 100 for $N = 100$. This probability drops to about 2 in 100 for $N = 10^4$, and is on the order of 1 in 10^{88} for a million tosses! It is generally true that for systems with a large number of independent components (for example, the number of tosses in a trial), large deviations from the average value of a variable are unlikely. The molecules in a gas can be viewed as moving independently, and when a gas that contains 10^{24} or so molecules in thermal equilibrium is sampled, the chances that the measured value of any randomly varying quantity will differ from its average value are tiny indeed.

(a)

(b)

▲ **FIGURE 19–1** (a) The dimensions and orientation of a box that contains a gas. (b) A typical molecule, whose x-component of velocity is v_x, has an elastic collision with the right-hand wall. The x-component of the velocity changes its sign in the collision, but the y- and z-components are unchanged.

19–2 Pressure and Molecular Motion

Consider a container of dilute gas that consists of N independently moving molecules each of mass m. In kinetic theory these molecules move with a variety of speeds in a variety of directions, and pressure is due to molecular collisions with the walls of the container. Each time a molecule hits and rebounds from the wall, there is a momentum transfer to the wall, and since a rate of momentum transfer is a force, there is accordingly a force on the wall. To calculate the pressure we need to calculate the *average* rate of momentum transfer.

Some Average Values in a Gas

Suppose that the dilute gas in the container above is in thermal equilibrium at temperature T. The container has volume V and is oriented in a Cartesian coordinate system, as shown in Fig. 19–1a. The molecules in the box are moving in random directions and *the average velocity of the molecules is zero* because as many move in one direction as move in any other. In other words, the average x-, y-, or z-components of the velocity are zero. We will use angular brackets, $\langle\ \rangle$, to indicate the average value, so

$$\langle v_x \rangle = \langle v_y \rangle = \langle v_z \rangle \quad \text{so that} \quad \langle \vec{v} \rangle = 0. \tag{19–1}$$

While the average velocity may be zero, the same is not true for the average *speed*. The speed is by definition positive, and its average value is likewise positive. We will concentrate on the average value of the velocity squared $\langle v^2 \rangle$, or more precisely on $\sqrt{\langle v^2 \rangle}$, a quantity we call the **root-mean-square (rms) speed**. Note that $\langle v^2 \rangle$ is *not* the same as the square of the average value of the velocity: $\langle v^2 \rangle \neq \langle \vec{v} \rangle^2$; in fact, the latter quantity is zero because $\langle \vec{v} \rangle$ is zero.

We can relate $\langle v^2 \rangle$ to the internal energy of a dilute gas by kinetic theory. Forces between molecules are important only when the molecules are close together, and this happens relatively rarely in dilute gases. Thus the internal energy, U, consists mainly of the kinetic energies of the molecules. In other words, U is given by

$$U = N\langle K \rangle = N\left(\frac{1}{2}m\langle v^2 \rangle\right), \tag{19–2}$$

where $\langle K \rangle$ is the average kinetic energy per molecule and N is the total number of molecules. This equation provides us with a link to the temperature of the gas, because, as we learned in Chapter 18, the internal energy of an ideal gas is a function of temperature only.

The average of a sum of terms is the sum of the average of those terms, so

$$\langle v^2 \rangle = \langle v_x^2 + v_y^2 + v_z^2 \rangle = \langle v_x^2 \rangle + \langle v_y^2 \rangle + \langle v_z^2 \rangle. \tag{19–3}$$

The gas as a whole is not moving, so there must be an equivalence among the three directions. The average value of the x-component of the velocity squared must be the same as that of the y-component and that of the z-component. Thus

$$\langle v_x^2 \rangle = \langle v_y^2 \rangle = \langle v_z^2 \rangle. \tag{19–4}$$

Using this relation in Eqs. (19–3) and (19–2), it is possible to relate the average of the components of the velocity squared to the thermal energy of the gas:

$$\langle v^2 \rangle = 3\langle v_x^2 \rangle;$$

$$\langle v_x^2 \rangle = \frac{1}{3}\langle v^2 \rangle = \frac{2}{3}\frac{U}{mN}. \tag{19–5}$$

Next we will relate $\langle v_x^2 \rangle$ to the pressure of the gas.

The Origin of Pressure

Pressure arises from the multiple collisions the molecules of a gas have with the walls that contain the gas. For a quantitative calculation, we compute the momentum transfer to a wall due to a single collision, and then find the number of molecules that strike the wall per unit time. We use this to find the average momentum transfer to the wall per unit time, which is the force on the wall. Pressure is then the force per unit area. Figure 19–1b shows a molecule colliding elastically with the right-hand wall of the box

of Fig. 19–1a. The wall is oriented parallel to the yz-plane, so only the x-component of the velocity changes. If the velocity before the collision is

$$\vec{v}_i = v_x\hat{i} + v_y\hat{j} + v_z\hat{k},$$

then the velocity after the collision is

$$\vec{v}_f = -v_x\hat{i} + v_y\hat{j} + v_z\hat{k}.$$

The momentum change of the molecule, $\Delta\vec{P}_{\text{mol}}$, is

$$\Delta\vec{P}_{\text{mol}} = m\vec{v}_f - m\vec{v}_i = -2mv_x\hat{i};$$

the momentum transfer to the wall, $\Delta\vec{P}$, is the negative of this:

$$\Delta\vec{P} = 2mv_x\hat{i}. \tag{19–6}$$

This sign is reasonable: The wall is pushed to the right by the collision.

We have found the momentum transfer from a single molecule. As we continue, we think of this molecule as an "average" molecule; it has the average x-component of velocity, which we continue to write as v_x for now. The next question is: How many collisions with the wall occur per unit time? Consider Fig. 19–2a: The number of molecules with an x-component of velocity of magnitude v_x that strike an area A in a time interval dt is the number of molecules contained in an imaginary cylindrical volume whose base, which is against the wall, is the area A and whose length is $v_x\,dt$. Molecules that travel toward this area but are farther away than the cylinder height will not reach the wall in the infinitesimal time interval dt. Note also that by making the time interval short enough, we can safely assume that the molecules do not collide with each other before they reach the wall. If the number of molecules per unit volume, the number density, is N/V, then the total number of molecules in our cylindrical volume is $(N/V)(v_x\,dt)(A)$. Thus the number of collisions with the wall in time dt is

$$\#\text{ of collisions} = N_{\text{coll}} = \frac{1}{2}\frac{N}{V}(v_x\,dt)A. \tag{19–7}$$

The factor $1/2$ is present because only half of the molecules are moving to the right; the other half are moving to the left. Only the ones that move to the right contribute to the pressure in this case. The number of collisions must be multiplied by the individual collision momentum transfer ΔP_x, the x-component of Eq. (19–6), to find the total momentum dP_x transferred in the time interval dt:

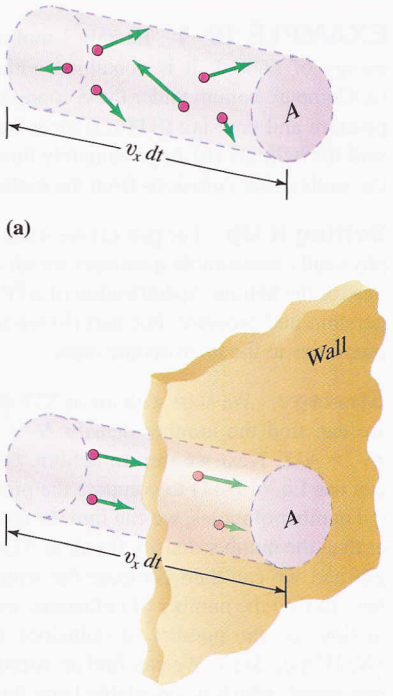
$$dP_x = (2mv_x)\left(\frac{N}{2V}\right)(v_x\,dt)A = mv_x^2\frac{N}{V}A\,dt.$$

In turn, the total momentum transfer per unit time—the force exerted on area A—is

$$\frac{dP_x}{dt} = F_x = mv_x^2\frac{N}{V}A. \tag{19–8}$$

The pressure on the wall, p, is the force per unit area:

$$p = \frac{F_x}{A} = mv_x^2\frac{N}{V}. \tag{19–9}$$



Finally, recall that we have employed the average x-component of velocity squared for each molecule. We make this explicit by employing the notation $\langle v_x^2\rangle$ rather than v_x^2. Then using Eq. (19–5), we find

$$p = m\langle v_x^2\rangle\frac{N}{V} = m\left(\frac{2}{3}\frac{U}{mN}\right)\frac{N}{V} = \frac{2}{3}\frac{U}{V}; \tag{19–10}$$

$$pV = \frac{2}{3}U. \tag{19–11}$$

PRESSURE IN TERMS OF ENERGY

This derivation is an important one. We have used the microscopic properties of a gas to find a relation between macroscopic thermodynamic variables.

▲ **FIGURE 19–2** (a) All the molecules that will collide with an area A of a wall in a time interval dt are contained in a cylinder of area A and length $v_x\,dt$. (b) Only the molecules in the cylinder whose x-component of the velocity is directed towards the wall will contribute to the pressure. The figure only shows the x-component of the velocity.

EXAMPLE 19–1 Exactly 1 mol of helium gas has an internal energy of 3600 J. It is contained within a cube of sides 0.50 m. (a) Compare helium under these conditions with air at standard temperature and pressure (STP). If air is ideal at STP, can the same be said for helium? (b) Approximately how many times per second do the walls suffer collisions from the molecules of the helium gas?

Setting It Up For part (a) we want a "comparison"; we find the physically measurable quantities for air at STP and the same quantities for the helium. Specification of STP means specification of temperature and pressure. For part (b) we must pass from macroscopic properties to the microscopic ones.

Strategy We start with air at STP (0°C; 1 atm). Given p and T, we can find the number density N/V from the ideal gas relation $pV = NkT$. Next we turn to helium. Given the internal energy, we can use Eq. (19–11) to compute the pressure; given the volume and the number of moles, we can find the number density. If this is smaller than the number density for air at STP, the helium will be an ideal gas and we can then compute the temperature using the ideal gas law. To find the number of collisions, we know from Eq. (19–7) that in time Δt the number of collisions with one wall of area A is $(N/2V)(v_x\,\Delta t)A$. We can find an appropriate value for v_x from the rms speed, which is calculable from the total energy. We must take into account the fact that there are six sides to the box.

Working It Out (a) We start with the number density of air. Rearranging the ideal gas law,

$$\text{air: } \frac{N}{V} = \frac{p}{kT} = \frac{1.01 \times 10^5\ \text{Pa}}{(1.38 \times 10^{-23}\ \text{J/K})(273\text{K})} = 2.68 \times 10^{25}\ \text{m}^{-3}.$$

We can find the number density of helium from the fact that there are 6.02×10^{23} molecules (1 mol) in the given volume of $(0.5\ \text{m})^3$:

$$\text{helium: } \frac{N}{V} = \frac{6.02 \times 10^{23}}{(0.50\ \text{m})^3} = 4.8 \times 10^{24}\ \text{m}^{-3}.$$

This is about one sixth that of air at STP, so we can treat the helium as ideal.

We use Eq. (19–11) for the helium pressure: $p = \frac{2}{3}\frac{U}{V} = \frac{2}{3}\frac{3600\ \text{J}}{(0.50\ \text{m})^3} = 1.9 \times 10^4\ \text{Pa}$, which is about 0.2 atm. The temperature can be computed from the ideal gas law:

$$T = \frac{pV}{nR} = \frac{(1.9 \times 10^4\ \text{N/m}^2)(0.50\ \text{m})^3}{(1\ \text{mol})(8.31\ \text{J/mol})} = 2.9 \times 10^2\text{K}.$$

This is in the range of room temperature. Our container of helium has a temperature close to that of the air at STP, is about six times less dense, and has a pressure one fifth that of air.

(b) The collision rate (# of collisions per second) with a wall of area A perpendicular to the x-axis is $N_{\text{coll}} = (N/2V)v_xA$; for v_x we take $\langle v_x^2\rangle^{1/2}$, and we can use (symmetry) $\langle v_x^2\rangle = \langle v^2\rangle/3$. Finally, we can find $\langle v^2\rangle$ from $U = N\left(\frac{1}{2}m\langle v^2\rangle\right)$. Pulling this all together, we have

$$\frac{N_{\text{coll}}}{\Delta t} = 6\frac{N}{2V}A\sqrt{\langle v^2\rangle/3} = 6\frac{N}{2V}A\sqrt{\frac{2U}{3mN}}.$$

The factor 6 takes into account the number of walls. The quantity mN, the mass of one molecule times the number of molecules, is the total mass of a gas, M. There is 1 mol of helium, so the mass is $4.0\ \text{g} = 4.0 \times 10^{-3}\ \text{kg}$. Thus

$$\frac{N_{\text{coll}}}{\Delta t} = \frac{6(6.02 \times 10^{23})}{2(0.50\ \text{m})^3}(0.50\ \text{m})^2\sqrt{\frac{2(3600\ \text{J})}{3(4.0 \times 10^{-3}\ \text{kg})}}$$

$$= 2.8 \times 10^{27}\ \text{collisions/s}.$$

What Do You Think? If the internal energy is doubled, how will the wall collision rate change? *Answers to **What Do You Think?** questions are given in the back of the book.*

19–3 The Meaning of Temperature

The microscopic picture of a gas provides us with a simple and enlightening interpretation of temperature. The fact that the energy is the sum of the kinetic energy of all the molecules, $U = \frac{1}{2}Nm\langle v^2\rangle$ [Eq. (19–2)], on the one hand, and that the energy is related to the pressure, $U = (3/2)pV$ [Eq. (19–11)], on the other, provides a link to temperature. From the ideal gas law $pV = nRT = NkT$, where here n is the number of moles of the gas, R is the universal gas constant, and k is Boltzmann's constant. Thus

$$U = \frac{3}{2}nRT = \frac{3}{2}NkT. \tag{19–12}$$

Equations (19–2) and (19–12) together give a microscopic interpretation of temperature:

$$kT = \frac{2}{3}\frac{U}{N} = \frac{2}{3}\langle K\rangle. \tag{19–13}$$

TEMPERATURE AS ENERGY

The temperature of an ideal gas is a measure of the average kinetic energy of the constituents. The number of molecules has canceled from this expression, so T is (correctly) independent of the amount of gas.

Figure 19–3 gives another view of the close ties between energy and molecular motion, showing at the microscopic level how the change in energy of a system is associated with the work done by the system.

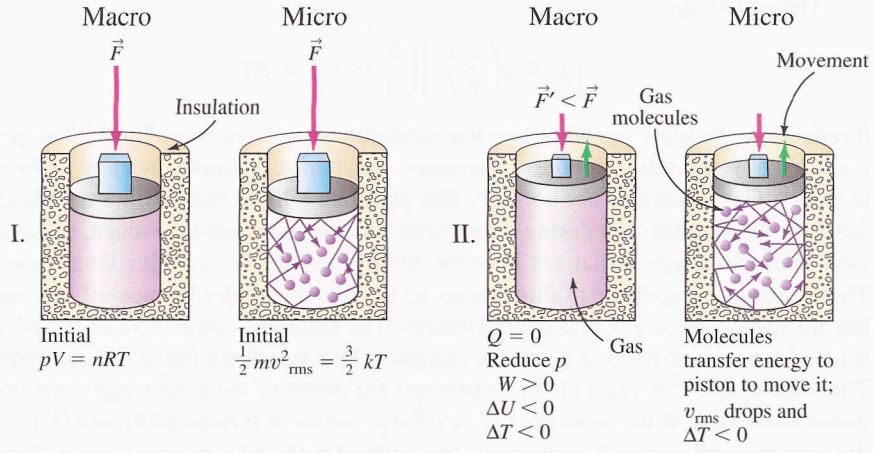


FIGURE 19–3 Macroscopic and microscopic views of the work done by an insulated gas. Molecules colliding with the recoiling piston lose energy. Thus the temperature drops.

CONCEPTUAL EXAMPLE 19–2 You have two identical bottles, one containing neon gas and the other containing the same number of atoms of argon, each in thermal equilibrium with the same thermal reservoir. Both gases can be regarded as ideal. Atoms of argon have twice the mass of atoms of neon. How does the average kinetic energy of the neon atoms differ from that of the argon atoms? How do the measurable thermodynamic variables T, p, and V compare?

Answer Both bottles of gas are at the same temperature (this is what equilibrium with the same thermal reservoir means). We can conclude from this that since the kinetic energy per atom is precisely a measure of temperature [Eq. (19–13)], it is the same for the two gases. The volumes of the two gases are the same, since the bottles containing them are identical. It follows from the ideal gas law, rewritten as $p = NkT/V$, that with N, T, and V the same for the two gases, the pressure will be the same.

EXAMPLE 19–3 1.00 mol of helium gas is contained in a large volume at 31.5K. What is the internal energy of the gas? What is the average value of the x-component of molecular velocity squared, $\langle v_x^2 \rangle$?

Strategy Because the gas is in a large volume, it is dilute and behaves as an ideal gas. We may therefore use Eq. (19–12) in the form $U = (3/2)nRT$ to find the internal energy. Every quantity on the right-hand side of the equation is known. As for $\langle v_x^2 \rangle$, that is dependent on the temperature but independent of the number of molecules: We can use $m\langle v^2 \rangle/2 = 3kT/2$, then $\langle v_x^2 \rangle = \langle v^2 \rangle/3$. Finally, the mass m of a helium atom is obtained by noting that 1 mole $= N_A$ atoms have a mass of 4.00 g, that is, $m = (4.00 \times 10^{-3}\,\text{kg})/N_A$.

Working It Out For the internal energy we have

$$U = (3/2)nRT = (3/2)(8.31\,\text{J/K})(31.5\text{K}) = 393\,\text{J}.$$

For the square of the x-component of the velocity we have

$$\langle v_x^2 \rangle = (1/3)(3kT/m) = (kT)[N_A/(4.00 \times 10^3\,\text{kg})].$$

We can calculate this or alternatively recognize that $N_A k = R = 8.31\,\text{J/mol} \cdot \text{K}$ to get

$$\begin{aligned}\langle v_x^2 \rangle &= RT/(4.00 \times 10^{-3}\,\text{kg}) \\ &= (8.31\,\text{J/mol} \cdot \text{K})(31.5\text{K})/(4.00 \times 10^{-3}\,\text{kg}) \\ &= 6.5 \times 10^4\,\text{m}^2/\text{s}^2.\end{aligned}$$

The square root of this quantity is about 250 m/s. Even at temperatures as low as 31.5K, the helium atoms are moving quite rapidly.

What Do You Think? A few argon atoms are added to your gas. After a little while, will they, on average, move (a) faster than, (b) slower than, or (c) at the same speed as the helium atoms?

THINK ABOUT THIS . . .

WHAT DOES ABSOLUTE ZERO MEAN AT THE MOLECULAR LEVEL?

Absolute zero, the zero of the Kelvin temperature scale, is the point at which the pressure drops to zero. In the microscopic view of an ideal gas, the temperature is zero when the average kinetic energy of the ideal gas is zero. Pressure vanishes because the molecules no longer move around and bounce against the walls.

Interpretation of the van der Waals Gas

Knowing how the microscopic properties of an ideal gas relate to its macroscopic behavior enables us to understand the origin of the van der Waals equation of state, which we encountered in Section 17–4, Eq. (17–15). This equation describes gases away from the dilute gas limit more precisely than does the ideal gas equation of state. As you may recall, the van der Waals equation takes into account the fact that the gas molecules are not point particles and also provides a correction for intermolecular forces—neither of these effects are included in the ideal gas law. Here we can see in more detail how these corrections are made.

The equation is

$$\left[p + a\left(\frac{n}{V}\right)^2\right]\left(\frac{V}{n} - b\right) = RT. \tag{17–15}$$

It reduces to the ideal gas law when the constants a and b are zero. Table 19–1 gives us a sample of some values for these constants, which have a simple meaning in the kinetic theory. Gas molecules are not truly like pointlike billiard balls. Billiard balls exert a force on one another only during a very brief time period when they touch, whereas real molecules have forces that act between them over distances larger than their radii. These forces are repulsive at short range, so that the molecules bounce off one another, but are slightly attractive at longer distances. The attractive component of the intermolecular force acts to make a gas more compact. This translates into a reduced pressure: The term $a(n/V)^2$ in Eq. (17–15) represents the effect of the long-range attraction between molecules. If we solve Eq. (17–15) for p, we see it is reduced by $a(n/V)^2$. As for the term proportional to b, molecules, like billiard balls, take up some space. This term is present because of the strong repulsion between molecules at a characteristic radius. By appearing as a term subtracted from V, the constant b measures the volume unavailable for the motion of molecules because it is space already occupied by other molecules—it is the volume taken up by one mole of molecules. Example 19–4 illustrates how we can use our interpretation of b to estimate the size of molecules.

TABLE 19–1 • Some a and b Coefficients that Appear in the van der Waals Equation of State

	a (Pa • m^3)	b (m^3/mol)
Helium	3.46×10^{-3}	23.71×10^{-6}
Neon	2.12×10^{-2}	17.10×10^{-6}
Hydrogen	2.45×10^{-2}	26.61×10^{-6}
CO_2	3.96×10^{-1}	42.69×10^{-6}
Water vapor	5.47×10^{-1}	30.52×10^{-6}

EXAMPLE 19–4 Measurements show that nitrogen gas obeys the van der Waals equation of state with the constant $b = 3.94 \times 10^{-5}$ m^3/mol. What is the size of a nitrogen molecule?

Strategy We argued above that the parameter b represents the volume occupied by one mole of molecules. We can therefore find the volume of a single molecule by dividing b by Avogadro's number N_A. Setting the result equal to $4\pi R^3/3$ allows us to calculate the radius R of the molecule. (The problem statement gives no indication of the shape of the molecule, so we will assume it is spherical.)

Working It Out The volume of a single molecule is

$$V = \frac{b}{N_A} = \frac{3.94 \times 10^{-5}\ \text{m}^3/\text{mol}}{6.02 \times 10^{23}\ \text{molecules/mol}} = 0.654 \times 10^{-28}\ \text{m}^3/\text{molecule}.$$

We now set this equal to $4\pi R^3/3$, and solve for R:

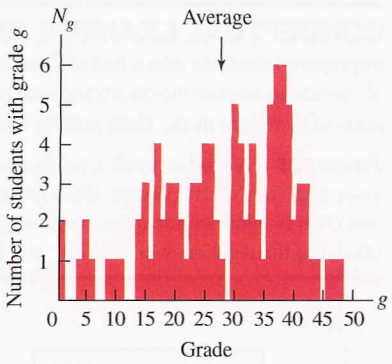
$$R = \left(\frac{3V}{4\pi}\right)^{1/3} = \left(\frac{3 \times 65.4 \times 10^{-30}\ \text{m}^3}{4 \times 3.14}\right)^{1/3} = 2.50 \times 10^{-10}\ \text{m}.$$

This radius is in fair agreement with more direct atomic measurements.

What Do You Think? Table 19–1 shows that all of the b values are within a factor of two of each other. What does this tell you about molecules? Why are the a values all positive?

19–4 Probability Distributions

Just as every student in a class does not receive the average grade on a given test, the molecules in a gas do not each have the average velocity or the average position. Instead, each molecule has its own velocity and position. Two functions describe the probability that a molecule has a particular velocity or a particular position. The **velocity distribution function** describes how many molecules have one velocity, how many have another, and so forth. The **position distribution function** similarly describes how the molecules are distributed in space. We need to know something about these distributions to further develop our understanding of the thermal properties of gases.



We all have a certain familiarity with the notions of probability and averages. Perhaps you have seen films or even played games of chance such as roulette. In this

section, we will sharpen these notions so that we can use them in the analysis of gases and other thermal systems.

A Case Study: The Distribution of a Set of Test Grades

Consider a quiz taken by a class of 100 students. The grades can run from 0 to a maximum score of 50. The number of students who receive each grade is shown in Fig. 19–4, where the number of students with grade g, N_g, is plotted as a function of the grade g. The total number of students here is $N = 100$, and if we add up all the N_g values, we get all of the students taking the quiz:

$$\sum_g N_g = N. \tag{19–14}$$

▲ **FIGURE 19–4** Bar graph of quiz grades in a class.

Given such a distribution of grades, we can find the average grade. We take the number of people with a given grade, multiply it by the grade, add these products for each grade, and divide by the total number of students. We denote the average grade by $\langle g \rangle$. According to the above technique, we find

$$\langle g \rangle = \frac{1}{N}\left(\sum_g g N_g\right). \tag{19–15}$$

In the case illustrated, $\langle g \rangle$ is 28. We could also ask for the average of the *square* of the grade $\langle g^2 \rangle$ given by

$$\langle g^2 \rangle = \frac{1}{N}\left(\sum_g g^2 N_g\right). \tag{19–16}$$

In the case illustrated, $\langle g^2 \rangle = 908.6 = (30.1)^2$. Note that $\langle g^2 \rangle \neq \langle g \rangle^2$, analogous to the remark we made about molecular velocities in Section 19–2. The quantity $\langle g^2 \rangle$ contains different information than does $\langle g \rangle$.

What is the probability that any one student, chosen at random, has a grade of 38 points? This probability is the number of students with a grade of 38 divided by the total number of students—in this case, 6/100. More generally, the probability of finding a student who received a grade g is

$$P_g = \frac{1}{N} N_g; \tag{19–17}$$

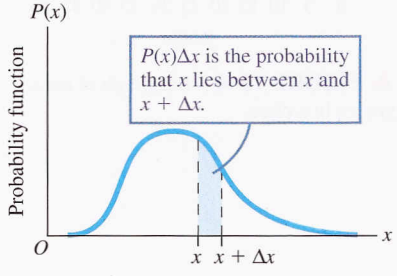
we refer to P_g as the **probability distribution** for the grades. It can run from a minimum of 0 to a maximum of 1, with 1 being the proverbial "sure thing." As a consequence of Eq. (19–14), the probability distribution is such that

$$\sum_g P_g = 1. \tag{19–18}$$

That the sum of probabilities is 1 is known as a **normalization condition**. It expresses the fact that it is a "sure thing" that *something* will happen, in this case that the student will get some grade. As we see from Eqs. (19–15) and (19–16), averages are obtained from weighted sums over P_g:

$$\langle g \rangle = \sum_g g P_g, \tag{19–19}$$

$$\langle g^2 \rangle = \sum_g g^2 P_g. \tag{19–20}$$



We can ask one more type of question: If we pick one student at random, what are the odds that his or her grade lies between 15 and 19? The probability of finding that the student has a grade between 15 and 19 is the number of students with grades in that range divided by the total number of students. We write this as follows:

$$P(15 \leq g \leq 19) = \frac{1}{N}\sum_{g=15}^{19} N_g = \sum_{g=15}^{19} P_g.$$

For our example, this is equal to $13/100 = 0.13$. We will see that this type of question is especially relevant to quantities that vary continuously.

CONCEPTUAL EXAMPLE 19–5 A group of 100 totally unprepared students take a test of 20 true-or-false questions, and they all decide to answer the questions with random guesses. What are the odds of a student in the class getting a perfect score?

Answer A student with a perfect score has chosen the right answer with each of 20 guesses. Each guess is independent of a previous one (this is what we mean by random guesses), and thus the odds of choosing the right answer is $(1/2) \times (1/2) \times (1/2) \times \ldots$ with 20 factors. We know that $2^{10} = 1024$, so that this number is $(1/1024)^2$, or approximately 10^{-6}. One in a million students would have a perfect score; equivalently, the odds that any one student has a perfect score are one in a million. To find out the probability that there is one perfect score in the class, we remark that if a perfect score were to appear, it could be student 1, or student 2, or any of the students. As you likely know, in "or" situations, probabilities add, so the odds that there will be a perfect score at all is $100 \times 10^{-6} = 10^{-4}$.

▲ **FIGURE 19–5** The probability $P(x)\ \Delta x$ associated with a continuous distribution is the area beneath the curve between x and $x + \Delta x$.

Continuous Distributions

Some distributions do not involve discrete quantities, such as the grades on an exam, but instead involve continuous quantities, such as the heights of students. Much of the analysis of this case follows the discussion above of the discrete case, with one exception: We must recognize that the probability that any student will have a *particular* height x—say, $x = 1.73000055\ldots$ m, with an infinite number of digits—is zero. Instead, we must measure the probability $P(x)\ \Delta x$ that the outcome lies within some small interval Δx around the value x (Fig. 19–5). In our example, this could be the probability that a student has a height within an interval $\Delta x = 0.01$ m around $x = 1.73$ m. The normalization condition now expresses the fact that all students must have some height, so that the sum of all probabilities adds to 1:

$$\Sigma P(x)\ \Delta x = 1. \tag{19–21}$$

A sum appears here because—even if x takes on a continuous range of values—the intervals Δx have divided the region into a *finite* number of segments.

The concept we have described can be refined by making the interval smaller and smaller, thereby finding the probability that an outcome near a particular x-value occurs with more and more accuracy. Calculus notation is appropriate in this limit. The quantity Δx is written as dx, and the sum becomes an integral whose upper and lower limits are the upper and lower values of the variable in question, x_2 and x_1:

$$\int_{x_1}^{x_2} P(x)\ dx = 1. \tag{19–22}$$

This is the normalization condition in the case of continuous variables.

The averages of functions of x are found from formulas similar to those of the discrete case. For example,

$$\langle x^n \rangle = \int_{x_1}^{x_2} x^n P(x)\ dx. \tag{19–23}$$

EXAMPLE 19–6 Suppose that all heights between 1.5 m and 1.8 m are equally likely among a group of students and that no students are outside this height range. Find the probability distribution and use it to calculate the average height.

Strategy Since sizes form a continuum, we must take the distribution to be continuous. The first step is to determine $P(x)$. where we use x to denote the height, within the distribution. The data tells us that $P(x) = 0$ for $x < 1.5$ m and for $x > 1.8$ m. In between, the probability of finding any given height is denoted by the constant P. Its value will be found using the normalization condition Eq. (19–22). The calculation of $\langle x \rangle$, the average height, is then a simple matter of working out an integral like that of Eq. (19–23).

Working It Out The normalization condition reads

$$1 = \int P(x)\ dx = P \int_{1.5\text{ m}}^{1.8\text{ m}} dx$$
$$= P \times (1.8\text{ m} - 1.5\text{ m}) = (0.3\text{ m})P.$$

We can solve this for P, $P = 3.33\text{ m}^{-1}$. The average height is then

$$\langle x \rangle = \int xP(x)\ dx = P \int_{1.5\text{ m}}^{1.8\text{ m}} x\ dx = P\left[\frac{x^2}{2}\right]_{1.5\text{ m}}^{1.8\text{ m}}$$
$$= (3.33\text{ m}^{-1})(0.5)((1.8\text{ m})^2 - (1.5\text{ m})^2) = 1.65\text{ m}.$$

As all heights are equally likely, this is a uniform distribution, so it is not surprising that the average lies right in the middle of the interval between 1.5 m and 1.8 m.

What Do You Think? Suppose the probability distribution $P(x)$ were still 0 for $x < 1.5$ m or > 1.8 m, but otherwise symmetrically U shaped, with the bottom (the least likely height) at 1.65 m. What would you expect the average to be in this case?

19–5 The Velocity Distribution of Gases

In this section, we extend our ideas about probability distributions to molecules in a gas. The velocity distribution function $F(\vec{v})$ is a probability distribution for the velocities of the gas molecules. Velocities form a continuum, so we use a probability function appropriate for continuous variables. The velocity distribution function for ideal gases was first described by James Clerk Maxwell in 1859, a time when the molecular model of matter was by no means universally accepted. As was true of the height distribution of Section 19–4, the probability of finding any particular velocity $\vec{v}$ is zero. Therefore we start with a number distribution $N(\vec{v})$ such that

$N(\vec{v})\, d^3v$ = number of gas molecules with a velocity between $\vec{v}$ *and* $\vec{v} + d\vec{v}$.

What this means is that we describe the probability that a velocity will be somewhere in the neighborhood of $\vec{v}$. This "neighborhood" is a box of volume

$$d^3v = dv_x\, dv_y\, dv_z, \tag{19–24}$$

centered about the tip of the vector $\vec{v}$ (Fig. 19–6). The total number of molecules is N, so that

$$\int N(\vec{v})\, d^3v = N. \tag{19–25}$$

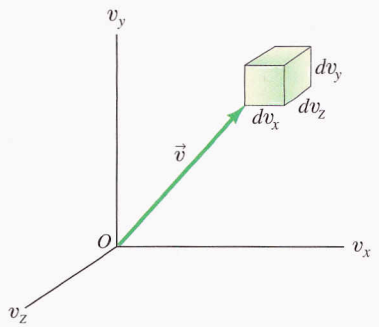
The distribution $N(\vec{v})$ leads directly to a *probability* distribution $F(\vec{v})$:

$$F(\vec{v}) = \frac{1}{N} N(\vec{v}). \tag{19–26}$$

The meaning of this function is that

$F(\vec{v})\, d^3v$ = probability that a gas molecule velocity is between $\vec{v}$ and $\vec{v} + d\vec{v}$.

From $F(\vec{v})$ we can calculate the averages for continuously varying quantities. For example, the average of the velocity squared, which is relevant to the internal energy and the temperature, is



$$\langle v^2 \rangle = \int v^2 F(\vec{v})\, d^3v. \tag{19–27}$$

To determine the probability distribution $F(\vec{v})$, we must make some *physical* assumptions. The model of molecules darting about and occasionally colliding with other molecules suggests that a given molecule may have any velocity. This leads to a fundamental physical postulate: *Any way in which a gas's total energy and total momentum (which is zero) can be shared among the molecules is equally likely*. Once this postulate is accepted, we are in the same position as someone asking for the probability of getting any particular number between 100 and 600 when throwing 100 dice. What counts is the *number of ways* of getting that number. There is only one way of getting 100 or 600 (throwing 100 ones, or 100 sixes, respectively), but there are many ways of getting 400; thus the probability of getting 400 is much greater than the probability of getting 100 or 600. When this analysis is done for molecules whose individual kinetic energy is $\frac{1}{2}mv^2$ and whose average kinetic energy is $\frac{1}{2}m\langle v^2 \rangle = 3/2\, kT$, the distribution function is found to be

$$F(\vec{v}) = \left(\frac{m}{2\pi kT}\right)^{3/2} e^{-mv^2/2kT}. \tag{19–28}$$

IDEAL GAS VELOCITY DISTRIBUTION

The prefactor in this equation ensures that this velocity distribution function is properly normalized, $\int F(\vec{v})\, d^3v = 1$, meaning that the sum over all probabilities is 1. $F(\vec{v})$ is a function only of the magnitude of the velocity (that is, the speed), not the direction. This expresses the physically reasonable fact that there is no preferred direction in a container of gas in which the gas as a whole is not moving—that is, all directions are

▲ **FIGURE 19–6** A molecule has a certain probability of having a velocity $\vec{v}$ within the "volume" $d\vec{v} = d^3v = dv_x\, dv_y\, dv_z$. Here we show the small box d^3v within which the velocity vector is located.

equally likely. It is possible to make a direct experimental verification of Eq. (19–28) by cutting a tiny hole in a container of gas and measuring the different speeds of the molecules that leak out.

The Average of the Velocity Squared

Here we look at an important concrete example of how F is used: Given F, we calculate $\langle v^2 \rangle$. We have

$$\langle v^2 \rangle = \int v^2 F(\vec{v})\, d^3v = \left(\frac{m}{2\pi kT}\right)^{3/2} \int v^2 e^{-mv^2/2kT} d^3v. \tag{19–29}$$

This integral appears to be a very tough one. It is multidimensional, and moreover it has some parameters in it that at first glance look hard to deal with. But we can extract the essential from this integral with very little work by using a technique known as **scaling**. This very useful technique allows us to extract the dependence of the integral on physical parameters of the problem. The idea is to change the integration variable to a dimensionless one, removing the dimensional dependence to a factor. In particular when there is an exponential function (or any transcendental function), the argument of the function is dimensionless. Accordingly, we change the integration variable in Eq. (19–29) from $\vec{v}$ to the dimensionless vector $\vec{u}$ by the definition

$$\vec{v} \equiv \vec{u}\sqrt{\frac{2kT}{m}}. \tag{19–30}$$

This definition means that each component of the vector $\vec{v}$ is transformed; Eq. (19–30) stands for three equations. With this change the argument of the exponential function is simply $-u^2$, and u itself is dimensionless. This can be seen in another way: The integration variable v is not dimensionless. Both kT and mv^2 have the dimensions of energy, so v^2 has the dimensions of kT/m and v those of $(kT/m)^{1/2}$. By comparing this fact with Eq. (19–30), we see right away that u is indeed dimensionless.

In terms of our new variable, the volume element d^3v is

$$d^3v = \left(\frac{2kT}{m}\right)^{3/2} d^3u.$$

The factor $\sqrt{2kT/m}$ is cubed because d^3v stands for $dv_x\, dv_y\, dv_z$, and there is a factor for each variable. We also replace the factor v^2 in the integration of Eq. (19–29) with $u^2(2kT/m)$. Pulling everything together, we have

$$\langle v^2 \rangle = \left(\frac{m}{2\pi kT}\right)^{3/2}\left(\frac{2kT}{m}\right)^{5/2} \int u^2 e^{-u^2} d^3u = \frac{2kT}{m}\frac{1}{\pi\sqrt{\pi}} \int u^2 e^{-u^2} d^3u. \tag{19–31}$$

The remaining integral on the right contains no quantities with dimension; it is a pure number. But even without knowing this number (which is indeed a hard integral), Eq. (19–31) shows that $\langle v^2 \rangle$ is a dimensionless constant times $2kT/m$. We anticipated that in our discussion of Eqs. (19–11) and (19–13) which combined with the ideal gas law led to

$$\langle v^2 \rangle = \frac{2U}{Nm} = \frac{3kT}{m}. \tag{19–32}$$

Thus Eq. (19–31) is in accord with Eq. (19–32)—at least in terms of dimensions. To finish the evaluation, we note with the help of a table of integrals that:

$$\int u^2 e^{-u^2} d^3u = \frac{3}{2}\pi\sqrt{\pi}.$$

When this is inserted into the right side of Eq. (19–31), we find that the result of Eq. (19–32) is confirmed.

With Eq. (19–32) in hand, we can get a feel for molecular speeds from the rms speed v_{rms}:

$$v_{\text{rms}} = \sqrt{\langle v^2 \rangle} = \sqrt{\frac{3kT}{m}}. \tag{19–33}$$

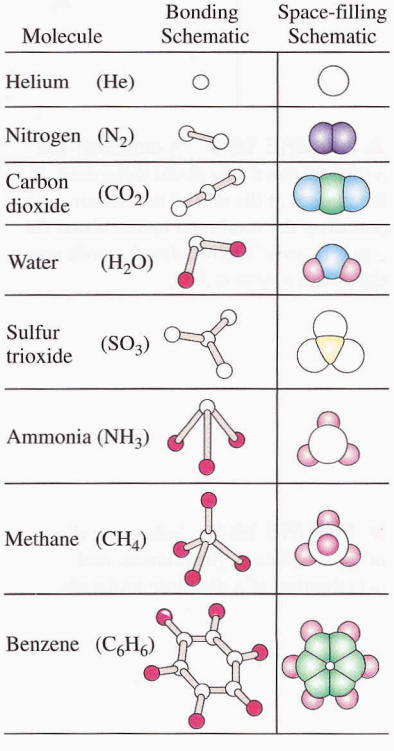
For helium gas, which has an atomic mass $m = 6.7 \times 10^{-27}$ kg, the rms speed is 556 m/s, 1362 m/s, and 2486 m/s for $T = 50$K, $T = 300$K, and $T = 1000$K, respectively. Contrast this with argon gas, which has a molecular mass 10 times greater than helium. The corresponding rms speeds are $\sqrt{10}$ times smaller: 176 m/s, 431 m/s, and 786 m/s.

One can also use the distribution F [Eq. (19–28)] to calculate the mean *speed* of the molecules. The expression will be similar to the rms speed, since dimensional analysis shows that it has to be of the form $[\text{energy/mass}]^{1/2}$, which must be $(\text{constant})(kT/m)^{1/2}$. The fact that the speed is inversely proportional to the square root of the mass implies that lighter molecules (faster ones) escape in greater quantity through a tiny hole than heavier ones (slower ones). This is the practical basis for the separation of uranium isotopes.† The uranium isotope ^{238}U is more common, but the relatively rare isotope ^{235}U is more useful for nuclear reactors such as those used for generating electric power—it is more fissionable, and therefore more useful for the creation of chain reactions. These isotopes cannot be separated by chemical means because they have the same chemical properties. However, the fact that ^{238}U is a bit heavier than ^{235}U means that when they are mixed in a gas—uranium hexafluoride, UF_6, is used—the ^{238}U component moves, on average, at a lower speed. The UF_6 gas is allowed to escape through many tiny holes from one container at a given temperature into another container that is initially empty. The percentage of ^{235}U in the gas that has escaped is slightly higher than that in the original container. Thousands of repetitions of this process of isotope separation lead to significantly increased percentages of ^{235}U. This method was used during World War II in the Manhattan Project.

THINK ABOUT THIS . . .

WHY IS THERE SO LITTLE HYDROGEN IN EARTH'S ATMOSPHERE?

The most common element in the universe is hydrogen, yet there are virtually no H_2 molecules in Earth's atmosphere. It would seem reasonable that the material out of which the planets condensed contained a lot of hydrogen. Jupiter, for example, consists largely of hydrogen, as does the Sun. The explanation lies in the escape speed, 11.2 km/s for objects on Earth (see Section 12–3). This number can be compared to the rms speed of molecules in a gas at temperature T, $v_{\text{rms}} = \sqrt{3kT/m}$, where m is the molecular mass. With a T value of 290K, we get for air ($m = 29.2 \times 1.67 \times 10^{-27}$ kg, an average coming mainly from oxygen and nitrogen molecules) a value of $v_{\text{rms}} = 0.5$ km/s. For H_2 m is a factor of 14.6 smaller, so that $v_{\text{rms}} = 1.9$ km/s. Both numbers are small compared with 11.2 km/s, but since the number of molecules with some speed v is proportional to $e^{-v^2/2kT} = e^{-3/2(v/v_{\text{rms}})^2}$, there are many more hydrogen molecules at speeds >11.2 km/s than there are molecules of the other components of air moving with this speed. Thus the upper layers of the atmosphere will lose their faster (H_2) molecules much more rapidly than they lose their slower (O_2 or N_2) air molecules. It is a slow process, but ultimately all the hydrogen molecules get "filtered out."



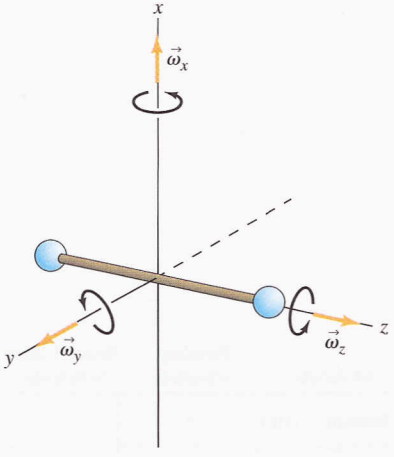
19–6 The Maxwell–Boltzmann Distribution

An ideal gas may consist of molecules that have just one atom (monatomic) such as helium (He) or argon (Ar), or it may consist of molecules with two (diatomic) or more atoms, such as nitrogen (N_2), oxygen (O_2), or water (H_2O) (Fig. 19–7). Is there a difference between these types of ideal gases? The answer came in the last part of the 19th century from the work of Ludwig Boltzmann.

The velocity distribution of a monatomic ideal gas [Eq. (19–28)] has the general form

$$F(\vec{v}) = \frac{1}{Z} e^{-mv^2/2kT} = \frac{1}{Z} e^{-K/kT}, \tag{19–34}$$

†Elements are characterized by their chemical properties, which depend on the number of electrons they carry, and hence on the number of (positively charged) protons in their nuclei. *Isotopes* of an element differ in the number of (electrically neutral) neutrons in the nucleus of the element, and thus differ in atomic weight. For uranium, the atomic weights 235 and 238 refer to the total number of protons plus neutrons.



▲ **FIGURE 19–7** Molecules come in different shapes, as shown here in two schematic representations.

where K is the kinetic energy ($K = mv^2/2$); the factor $1/Z$ takes into account the normalization. Boltzmann generalized the velocity distribution to a distribution that describes the probability that any one molecule has a given energy E. He discovered that in the original velocity distribution, Eq. (19–34), *the total energy of the molecule, E, should replace the kinetic energy of a point mass, K*:

$$F = \frac{1}{Z}e^{-E/kT}. \tag{19–35}$$

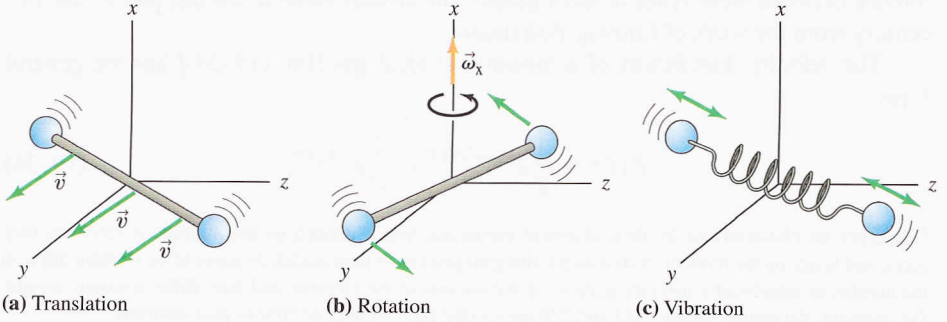
MAXWELL–BOLTZMANN DISTRIBUTION

This result was obtained under the assumption that *all* the variables describing molecular motion, such as velocity and angular velocity, have equal probability of taking on *any* value, subject to the constraint that energy must be conserved, very much in line with the assumptions that led to Eq. (19–28). This distribution function is known as the **Maxwell–Boltzmann distribution**. Equation (19–35) is one of the most frequently used formulas in the physics of the behavior of matter. This distribution function depends on all the dynamical variables that enter into the energy of a molecule. It is only for free, pointlike molecules that the energy depends on speed alone. The energy of a rotating molecule with rotational inertia also depends on the angular velocities of rotation about the various axes. Later in this section we will see how this affects the specific heat of gases.

▲ **FIGURE 19–8** A dumbbell-like molecule can rotate about three axes. If the masses at the end of the rod are pointlike, the rotational inertia about the z-axis is zero. The rotational inertia about the x- and y-axes is I.

The Energy Distribution for Diatomic Molecules

To see the effect of molecular structure on the thermal properties of a gas, let's consider a gas composed of diatomic molecules. To describe a symmetric diatomic molecule, such as O_2, we use a classical model in which the two atoms act as though they are connected by a rigid rod. The rotational inertia has the same value, I, about each of the two axes that pass through the center of the rod and are perpendicular to it (Fig. 19–8). (We can assume that the rotational inertia about the molecular axis is so small that we can ignore it.) The energy of the molecule is a sum of the overall translational kinetic energy from linear motion, or translation (Fig. 19–9a), and of the rotational motion of the atoms about the center of mass (Fig. 19–9b; see Chapters 9 and 10). The rotational energy is



$$E_{\text{rot}} = \frac{1}{2}I\omega_x^2 + \frac{1}{2}I\omega_y^2, \tag{19–36}$$

where ω_x and ω_y are the components of the angular velocity along the x- and y-axes, respectively (Fig. 19–8). The ω_z term is missing from Eq. (19–36) because the rotational inertia about the z-axis is zero. The probability distribution F now refers to the probability that the velocity of a molecule lies in a region d^3v about the velocity vector $\vec{v}$ *and* that the molecule's angular velocity lies in a region $d^2\omega = d\omega_x\, d\omega_y$ about the angular velocity vector ω whose components are ω_x and ω_y. The total energy of a molecule is now $E = K + E_{\text{rot}}$, and, from Eq. (19–35), the Maxwell–Boltzmann distribution is

$$F = \frac{1}{Z}e^{-(mv^2/2kT)-(I\omega_x^2/2kT)-(I\omega_y^2/2kT)}. \tag{19–37}$$

Since not only the molecular velocity but also the rotation speed can vary, the average energy $\langle E\rangle$ takes the form

$$\langle E\rangle = \tfrac{1}{2}m\langle v_x^2\rangle + \tfrac{1}{2}m\langle v_y^2\rangle + \tfrac{1}{2}m\langle v_z^2\rangle + \tfrac{1}{2}I\langle\omega_x^2\rangle + \tfrac{1}{2}I\langle\omega_y^2\rangle. \tag{19–38}$$

▶ **FIGURE 19–9** Schematic diagram of (a) translation, (b) rotation, and (c) vibration of a diatomic molecule.

The average is found by taking the integral of $E \times F$, and that integration is over d^3v, $d\omega_x$, and $d\omega_y$. The integrals are all of the form that lead to Eq. (19–31), and evaluation of each of the five terms in Eq. (19–38) is precisely $kT/2$. Thus for our rigid-rod diatomic molecule,

$$\langle E \rangle = \frac{5}{2}kT. \tag{19–39}$$

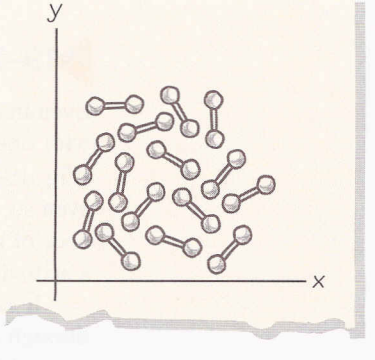
The total internal energy of the gas is then $U = N\langle E \rangle$, where N is the number of molecules. This result should be compared to the monatomic case, in which there are only the three terms of the kinetic energy of linear motion and $\langle E \rangle = \frac{3}{2}kT$ [Eq. (19–12)].

There is yet another aspect to diatomic molecules that we have not yet mentioned. If the diatomic molecules are not rigidly attached to each other, the bond between them acts like a spring with spring constant k (Fig. 19–9c). There are then two additional vibrational contributions to the energy, of the form $E_{\text{vib}} = (mV^2/2) + (kx^2/2)$. Here, V is the speed of the atoms of the molecule relative to the molecule's center of mass and x is the displacement of the vibrating atoms from an equilibrium position. Each of these terms also contributes $kT/2$ to the average energy and, for these molecules, $\langle E \rangle = \frac{7}{2}kT$.

We mention here in passing that the different average energies for molecules of different structure will be reflected in different values for the heat capacity. Thus these effects are directly translated to the macroscopic scale. We'll explore this in more detail below.

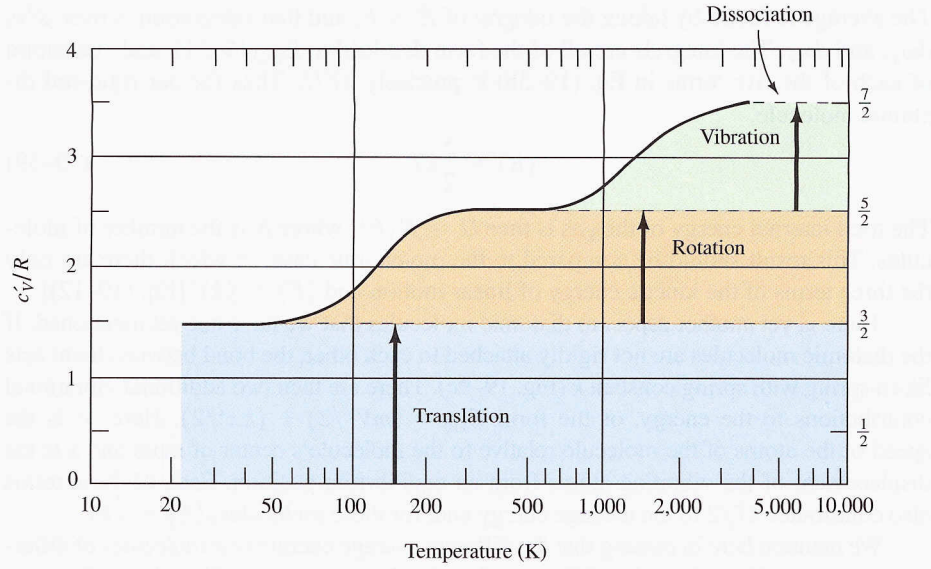
Equipartition

The discussion above shows that the total average energy per molecule depends on how many independent motions a molecule can have. If a molecule acts like a point mass, all it can do is move in the x-, y-, and z-directions. In this case, the energy has the three terms, proportional to v_x^2, v_y^2, and v_z^2, corresponding to linear motion in the x-, y-, and z-directions, respectively. If, in addition, the molecule is diatomic with a rotational inertia about axes x and y, we have two new terms in the energy—this time proportional to ω_x^2 and ω_y^2—making five terms in all. If vibration is possible, then there are two more terms, this time proportional to the squares of the relative speed of the atomic constituents and to their separation; thus there are in total seven such terms. Every term in the energy expression that is quadratic in an independent dynamical variable designates a **degree of freedom**. Generally, *the contribution of each degree of freedom to the average energy of a molecule is* $kT/2$. This result is called the **equipartition theorem**. If s is the number of degrees of freedom, then



$$\langle E \rangle = \frac{s}{2}kT. \tag{19–40}$$

EQUIPARTITION



Remember, $\langle E \rangle$ may contain contributions associated with translation, rotation, and vibration.

CONCEPTUAL EXAMPLE 19–7 Suppose you have a gas of rigid diatomic molecules constrained to move in just two spatial dimensions, for example between two plates spaced a molecular diameter apart. What would you expect the value of $\langle E \rangle$ to be?

Answer We may visualize this by thinking of the molecules as a collection of matches on a table forming the xy-plane, as in Fig. 19–10. The velocity of the center of mass can have only x- and y-components, and the integration that gives the average value of energy is over only two rather than the usual three translational degrees of freedom. Rotations can only occur when the nuclei rotate about their centers of mass in the xy-plane, that is, there are rotations only about a z-axis. This means there is only one rotational degree of freedom. The total number of degrees of freedom is three, just as for a monatomic gas. Therefore the average energy $\langle E \rangle$ is $3 \times kT/2$, the same result as for a three-dimensional monatomic gas.

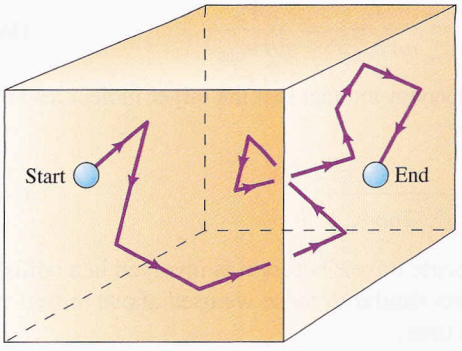
▲ **FIGURE 19–10** Diatomic molecules move in xy-plane.

▶ **FIGURE 19–11** The constant-volume molar heat capacity divided by the gas constant, c_V'/R, for H_2 as a function of temperature.

A dilute gas—even one whose molecules have a complicated structure—continues to obey the ideal gas law. The internal energy is

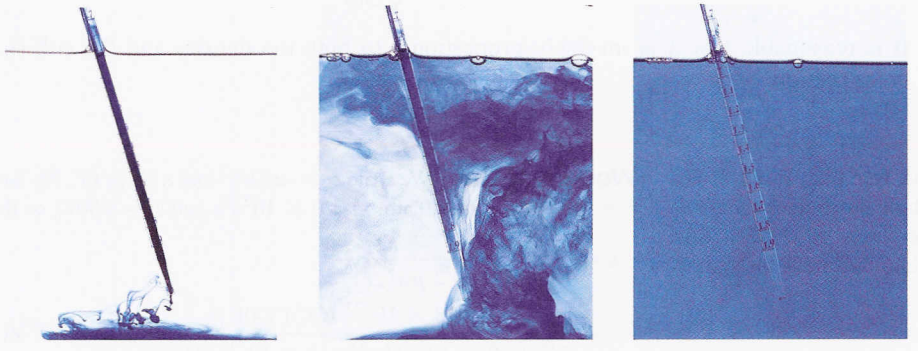
$$U = N\langle E\rangle = \frac{s}{2}NkT. \tag{19–41}$$

The internal energy continues to be linearly dependent on temperature, as for any ideal gas. The term by which the temperature is multiplied in Eq. (19–41) is the constant-volume heat capacity of the gas, C_V. The heat capacity therefore depends on the number of degrees of freedom of the molecules through the relation



$$C_V = \frac{s}{2}nR. \tag{19–42}$$

Molecular hydrogen (H_2), for example, should have a *molar heat capacity*, c' or heat capacity per mole $(n = 1)$, of $(7/2)R$ at constant volume: $(3/2)R$ is from the overall motion of the center of mass, $(2/2)R$ is from rotations about two axes, and $(2/2)R$ is from the kinetic and potential energies of the springlike bond that connects the two hydrogen atoms. How does this compare with experimental results? Figure 19–11 plots c_V'/R where c_V' is the constant-volume molar heat capacity, as a function of temperature. At lower temperatures, hydrogen gas behaves like a monatomic system, with a molar heat capacity of $(3/2)R$, which explains why we can treat H_2 at room temperature as a monatomic gas. The full factor of $(7/2)R$ comes in only at high temperatures. The steplike nature of the curve suggests that, somehow, the effects enter one at a time. The reason for this cannot be found in the realm of classical physics, but instead requires quantum mechanics. Quantum physics sets certain minimum temperatures for the excitation of the different degrees of freedom.

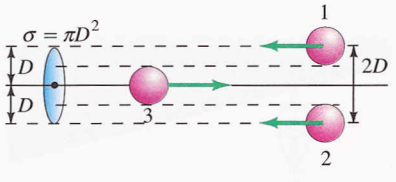


*19–7 Collisions and Transport Phenomena

Even in a dilute ideal gas, molecules follow a tortuous path in their container, colliding with one another and the walls, changing in direction and speed with each collision (Fig. 19–12). At STP an air molecule undergoes billions of collisions per second, but even so, the collisions are brief, and most of the time the molecule is free of the influence of other molecules. The *average* distance a molecule travels between collisions is a statistical quantity that can be calculated just as the average speed can be calculated.

It is by means of these collisions that molecules can carry physical properties through a gas. If there is local heating, that extra thermal energy can be carried to other parts of the gas through successive collisions. If some molecules with a particular odor or color are introduced in one location, they will spread through the gas through colli-

◀ **FIGURE 19–12** A molecule follows a tortuous zigzag path because of its multiple collisions with other molecules.



◀ **FIGURE 19–13** (a) Dye is placed with the help of a pipette at the bottom of a flask of water. (b) A combination of convection and diffusion has moved the dye into other regions of the flask. (c) Dye has diffused throughout the flask of water to make a uniform distribution. While stirring can speed the process, diffusion will make this happen if given enough time.

sions, even without wind currents (convection). The movement of such properties is called **transport** (of thermal energy, odor, and so forth), and, more particularly, the movement of molecules by random collisions is called **diffusion**. Figure 19–13 illustrates transport in a liquid. Ordinary thermodynamics has nothing to say about transport phenomena, but kinetic theory can explain them.

Collisions and Molecular Movement in a Gas

For a given gas density, the distance that a molecule travels before it has a collision depends on the size of the molecules. If molecules were infinitely small, they would never encounter each other; if they were very large, they would always be colliding. Molecules of diameter D collide when the path of the center of one molecule lies within an area πD^2 presented by the second molecule (Fig. 19–14). This area is the **collision cross section**, σ.

$$\sigma = \pi D^2. \tag{19–43}$$

▲ **FIGURE 19–14** If the projected centers of two molecules of diameter D that move together are less than or equal to a distance D apart, the molecules will collide. An area $\sigma = \pi D^2$ of one molecule, shown in blue, is available for collisions with another molecule.

Even if the molecules interact differently than billiard balls, there is some effective distance D that characterizes the collision, and the collision cross section still has the form of Eq. (19–43).

Consider now a molecule that moves with speed v and sweeps out an area σ. If no other molecules are present, then in time t the molecule travels a distance $d = vt$, sweeping out a volume $V = \sigma d = \sigma vt$. However, our molecule is not alone: Within the volume V, there are $N = nV$ target molecules, where n is the number density of molecules (not the number of moles). The traveling molecule therefore suffers N collisions. Even though the path is bent with each collision, the volume V remains unchanged if the speed is not changed by the effect of multiple collisions, and, on average, it is not. Because the number of collisions in time t is N, there is on average a collision every t/N seconds. This is the **mean collision time**, τ. Since we are averaging over

many molecules, we replace v with some average value. It is reasonable to replace it with v_{rms} so that

$$\tau = \frac{t}{N} = \frac{t}{nV} = \frac{t}{n\sigma v_{\text{rms}} t} = \frac{1}{n\sigma v_{\text{rms}}}. \tag{19–44}$$

A more precise calculation takes into account the fact that the target molecules are also moving, and Eq. (19–44) is modified to

$$\tau = \frac{1}{\sqrt{2}n\sigma v_{\text{rms}}}. \tag{19–45}$$

The average distance a given molecule travels before it is involved in a collision is the **mean free path**, λ. Using arguments similar to those we used above to find τ, λ is the rms speed times the mean collision time:

$$\lambda = \tau v_{\text{rms}} = \frac{1}{\sqrt{2}n\sigma}. \tag{19–46}$$

It is reasonable that λ is inversely proportional to both the density and the collision cross section.

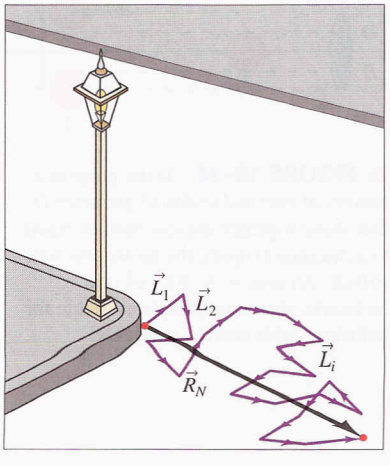
EXAMPLE 19–8 What is the mean free path in air at sea level when the temperature is 300K? By how much does the mean free path change when the temperature drops to 275K? Take $r \cong 10^{-10}$ m as a typical molecular radius, and treat the atmosphere as ideal.

Strategy To find the mean free path we need to assemble all the quantities that enter into the expression for it, Eq. (19–46). The collision cross section σ can be found with the given molecular radius using Eq. (19–43). The number density is obtained from the ideal gas law written in the form $pV = NkT$, from which we get the number of molecules per unit volume as $n = N/V = p/kT$. All that remains is to put in the numbers. For the second part of the problem, we notice that since $n \propto 1/T$, the mean free path $\lambda \propto T$. We can then get the mean free path at 275K by taking ratios.

Working It Out We write $\sigma = \pi(2r)^2$ and $n = p/kT$. We have $r = 10^{-10}$ m, $p = 1.0$ atm $= 1.0 \times 10^5$ Pa and $T = 300$K, so that

$$\lambda = \frac{1}{\sqrt{2}n\sigma} = \frac{1}{\sqrt{2}}\frac{kT}{p\pi(2r)^2}$$

$$= \frac{1}{\sqrt{2}}\frac{(1.38 \times 10^{-23}\ \text{J/K})(300\text{K})}{(1.0 \times 10^5\ \text{N/m}^2)\pi(2 \times 10^{-10}\ \text{m})^2} = 2.3 \times 10^{-7}\ \text{m}.$$



For the second part of the problem (the mean free path at 275K), the linear dependence tells us that it is 90% of that at 300K:

$$\frac{\lambda(275\text{K})}{\lambda(300\text{K})} = \frac{275}{300} = 0.9.$$

What Do You Think? If you slowly increase the pressure by slowly moving a piston into a cylinder containing the gas, will the mean free path of the molecules increase or decrease?

The Random Walk and Diffusion

Molecules move through a gas by diffusion. How far does a molecule move, *on average*, from its initial position in a given amount of time? This problem is similar to a classic problem in mathematics called the **random walk**, known historically as the drunkard's walk. In this problem, a drunkard starts at a lamppost and takes steps that are equal in length but random in direction (Fig. 19–15). Compare Fig. 19–15 to Fig. 19–12, a typical molecular path in a gas. If the length of the drunkard's step is replaced by the mean free path, and if the time between steps is replaced by the mean collision time, then—aside from the fact that the molecule moves in three dimensions rather than two—the problems are very similar.

▲ **FIGURE 19–15** The random walk (a drunkard's walk around a lamppost).

We can find the average displacement of a molecule after N steps as follows. Let the successive displacements of the molecules be $\vec{L}_1, \vec{L}_2, \ldots \vec{L}_N$. These have random directions, but their magnitudes are all the same value, L. After N steps the net displacement of a molecule is $\vec{R}_N = \vec{L}_1 + \vec{L}_2 + \cdots + \vec{L}_N$. Squaring this quantity, we find that

$$R_N^2 = L_1^2 + L_2^2 + \cdots + L_N^2 + 2\vec{L}_1 \cdot \vec{L}_2 + 2\vec{L}_1 \cdot \vec{L}_3 + \cdots + 2\vec{L}_{N-1} \cdot \vec{L}_N.$$

We want the average value of this quantity. The directions of the vectors $\vec{L}_i$ are random, so all the dot products, such as $\vec{L}_1 \cdot \vec{L}_2$, have an average over time of zero, whereas the terms L_i^2 all equal L^2. We are left with

$$\langle R_N^2 \rangle = NL^2. \tag{19–47}$$

To connect this result to the properties of the gas, we replace L^2 by the mean free path squared. The time interval between steps is the mean collision time, τ, so after N steps, a time $t = N\tau$ has elapsed. N can thus be replaced by t/τ. Therefore, Eq. (19–47) states that after time t, a molecule will have moved on average a distance squared given by

$$\langle r^2 \rangle = \frac{t}{\tau}\lambda^2. \tag{19–48}$$

It is typical of random-walk problems that the displacement *squared* is linear in time, or equivalently that the displacement is proportional to the square root of the time.

This result (or the slightly modified result of a more detailed calculation) as it applies to molecules can be verified experimentally. Molecules that have been marked in one way or another (for example, by using some radioactive molecules) can be traced as they move. Even better, the actual motion of this random walk is observable when particles larger than molecules, such as smoke particles, are added to a gas. This motion is called **Brownian motion**. The observation of Brownian motion and its explanation in kinetic theory was a "smoking gun" that established once and for all the atomic picture of atoms.

THINK ABOUT THIS . . .

HOW DOES THE MOLECULAR PICTURE EXPLAIN THERMAL ENERGY CONDUCTION IN MATERIALS?

In Section 17–1 we discussed the various methods of thermal contact, which we subsequently learned involves the flow of thermal energy. We have learned here that thermal energy is the energy of motion of the constituents of matter and so we can now look at thermal conductivity in materials from a molecular point of view. It is useful to think about gases and solids separately.

Gases

In gases, thermal energy movement by conduction is a transport phenomenon of the type discussed in this section. Molecules that move more rapidly because they are in a region of higher temperature collide with molecules in a neighboring region, giving the adjacent molecules more kinetic energy and consequently more thermal energy. This model accounts satisfactorily for such quantities as the thermal conductivity κ (see Chapter 18).

Table 18–3 shows that air, like all gases, has a small thermal conductivity. So why is a house built of double walls with air between them poorly insulated? The reason is that convection, which involves large-scale movement ("wind currents"), is the main form of heat transport in fluids. Thermal energy is transported efficiently by convection. Fiberglass insulation is placed in walls so that air is trapped, unable to flow, or convect, easily.

Solids

It is a fact that metals conduct thermal energy better than nonmetals do. This is because in some sense metals contain a gas of electrons, and the thermal conduction mechanism available to gases is also available to metals. Within the atoms of metals, the outermost electrons that orbit the nucleus are attached very loosely (they are *weakly bound*) to the nucleus, and it takes very little energy to make them move almost freely through the material. The practically free electrons of metals are efficient in transferring energy from one end of a piece of metal to the other. The same electrons also transfer electric charge (Chapter 26), and thermal and electrical conductivity in metals are closely related. (The analogy between metals and gases only goes so far, and there is no analog to convection in metals.)

Nonmetals also conduct thermal energy, but less well than metals do. The outermost electrons of the atoms of nonmetals are attached tightly to their nucleus or to other atoms, and are therefore not readily available to conduct thermal energy. Both metals and nonmetals can move energy in the form of waves (Chapters 14 and 15), but purely elastic waves traverse a material without depositing energy along the way. Thus thermal energy cannot be distributed through material this way. What is required to do so is a set of impurities or defects in the medium, because when an elastic wave meets such obstacles it can indeed transfer some of its energy to them.

Summary

Molecules are sparse in gases under normal conditions. The kinetic theory of ideal gases is a statistical description in which molecules bounce randomly and relatively infrequently off each other and off the walls of their container. This theory accurately predicts many thermodynamic properties.

The internal energy, U, is given in this model by the number of molecules, N, times the average energy of a molecule:

$$U = N\langle K\rangle = N\left(\frac{1}{2}m\langle v^2\rangle\right), \tag{19–2}$$

where $\langle v^2\rangle$ is the average of the velocity squared. The pressure of a gas arises from multiple elastic collisions between the walls and the molecules. Pressure is related to internal energy by

$$pV = \frac{2}{3}U, \tag{19–11}$$

where V is the volume of gas. In the ideal gas law, pV is proportional to temperature, so temperature can be interpreted as a measure of the internal energy, or of the average energy of molecules:

$$kT = \frac{2}{3}\frac{U}{N} = \frac{2}{3}\langle K\rangle. \tag{19–13}$$

Probability distributions describe the probability that various outcomes will be represented in a large statistical sample. For gases, $F(\vec{v})\,d^3v$ describes the probability that a given molecule will have a velocity $\vec{v}$ in the range from $\vec{v}$ to $\vec{v} + d\vec{v}$. Averages are computed from the probability distribution by integration. For example, the average of v^2 is

$$\langle v^2\rangle = \int v^2 F(\vec{v})\,d^3v. \tag{19–27}$$

The probability distribution $F(\vec{v})$ for the velocity of the molecules of a gas is

$$F(\vec{v}) = \left(\frac{m}{2\pi kT}\right)^{3/2} e^{-mv^2/2kT}. \tag{19–28}$$

Boltzmann generalized the velocity distribution to the cases in which molecules have internal energy as well as a center-of-mass kinetic energy, or in which the molecules are subject to external forces. The Maxwell–Boltzmann distribution is given by

$$F = \frac{1}{Z}e^{-E/kT}, \tag{19–35}$$

where E is the total energy of a molecule. Every variable that appears quadratically in the expression for the energy of a single molecule—such variables are called degrees of freedom—contributes $\frac{1}{2}kT$ to the average energy. If the number of degrees of freedom is labeled s, then the average energy of a molecule is

$$\langle E\rangle = \frac{s}{2}kT. \tag{19–40}$$

This result is the equipartition theorem. The internal energy is then $U = N\langle E\rangle$; in addition to the energy itself, the heat capacity, which is related to how fast U changes with temperature, is also determined, completing the link to thermodynamics.

Transport phenomena describe the motion of molecules, momentum, energy, and so forth through a gas as a result of multiple molecular collisions. Molecules have a collision cross section, σ, which describes the area available for collisions with another molecule. If the number of molecules per unit volume is n, then the mean time τ between collisions, called the mean collision time, is

$$\tau = \frac{1}{\sqrt{2}n\sigma v_{\text{rms}}}. \tag{19–45}$$

The average distance a given molecule travels before it suffers a collision is the mean free path, λ:

$$\lambda = \tau v_{\text{rms}} = \frac{1}{\sqrt{2}n\sigma}. \tag{19–46}$$

As a result of multiple collisions with other molecules, an individual molecule within a gas will undergo a random walk. In a time t, the molecule moves—diffuses—a distance that is proportional to the square root of t.

Understanding the Concepts

1. Consider an ideal gas in an insulated cylinder outfitted with a piston. The piston is moved slowly, so that the volume of the gas is decreased. What happens to the temperature of the gas? How do you explain your answer in terms of the motion of molecules?
2. On average, which will travel faster: the oxygen molecules or the nitrogen molecules in your room?
3. In Example 19–6 the calculated quantity P is 3.3 m^{-1}. Is this a probability? If so, how can it be greater than one?
4. In our discussion of pressure, we used the fact that the collisions of molecules with the walls are elastic. If there are diatomic molecules, they could be set into rotation by the collision, and thus their translational kinetic energy after the collision could be smaller than before the collision. How can these statements be reconciled? What is the effect on the pressure?
5. We made the connection between temperature and the average kinetic energy of a molecule without taking into account the large number of intermolecular collisions estimated in Section 19–1. Why do you think this approximation holds?
6. Why would more massive molecules in a gas at a given temperature have smaller average speeds?
7. In an extremely dilute gas, the rate of interatomic collisions is very small. As the gas becomes less dense, the rate of interatomic collisions becomes much less than the collision rate with the container's walls. Can we still make a connection between temperature and the average kinetic energy of a molecule? What are the possible problems in making the connection in this limit?
8. Very few hydrogen molecules are present in Earth's atmosphere today. Is this fact in conflict with the possibility of their abundance a long time ago? In explaining your answer, ignore the possibility that hydrogen is removed by chemical reactions.
9. Can we assign a temperature to a single molecule? Explain.
10. Why, from the point of view of kinetic theory, does the air near a hot stove become heated?
11. In Section 19–1 we stated that the typical distance a molecule travels before it suffers a collision in 1 mol of a gas at standard temperature and pressure is roughly 3×10^{-7} m. This will be much less than the size of a container of gas. How is it that the approximation that each molecule in the cylinder collides freely with the wall, without worrying about intermediate collisions between molecules, leads to a satisfactory result for the pressure, Eq. (19–11)?
12. Suppose you place a thin chip of paint of dimensions 1 cm by 1 cm in a gas. Do the collisions knock it to one side? Which side?
13. At standard temperature and pressure, a molecule of one mole of an ideal gas has a mean free path of about 3×10^{-7} m, some 100 times greater than the average intermolecular spacing. How is it possible for the mean free path to be greater than the average spacing?
14. You have a container of a dilute gas at a certain temperature and inject a small quantity of a different type of molecule into that container. What processes determine how long it takes the new molecules to come to thermal equilibrium with the original molecules?
15. If you were to consider helium gas and air at the same temperature, which gas would have a higher root-mean-square *momentum*?
16. Gravity keeps the atmosphere of Earth close to the surface. Why, then, is there no atmosphere on the Moon, which also exerts a gravitational force?
17. In Newtonian mechanics, energy is added to a system when work is done on it. In the language of classical mechanics, how is energy added to a gas in a container when a piston is pushed in and the container's volume is changed?
18. We have a container of helium gas and another of nitrogen gas. Both have molecules with the same average speed. What is the ratio of their temperatures?
19. Given our explanation of the origin of pressure, why is there no net force on a pane of glass placed in a container of gas, even though there may be a net force on a wall of the container?
20. Will the air just above the surface of hot water in a bowl be at the same temperature as the water? If so, what molecular mechanism is responsible for the equality of the two temperatures?
21. Why will a cup of hot water cool off much more rapidly when air is blown across its surface than when the air above the cup is stationary?
22. The smoke from the burning end of a cigarette rises; the flame of a candle points upward. Why?
23. In our discussion of the distribution of heights we claimed that in a group of persons all heights are equally likely. How would you check this premise? Can you know this with certainty, given that the number of people in the world is finite?
24. When a candle burns, carbon combines with the oxygen in air to form carbon dioxide, a compound used in fire extinguishers to put out fires. Why does the candle not snuff itself out? Could you burn a candle in a satellite in orbit?
25. Does temperature depend on the rotational kinetic energy of molecules?

Problems

19–1 A Microscopic View of Gases

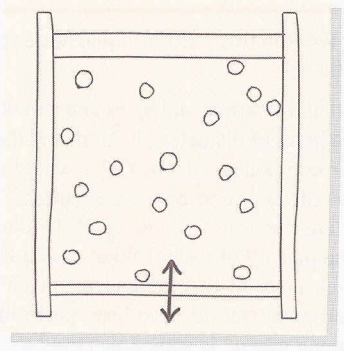
1. (I) We can define a volume ratio R_V of a gas to be the ratio of the volume taken up by the molecules to the total volume of the container; similarly, we can define a spacing ratio R_L to be the ratio of the linear size of a molecule to the mean spacing between molecules. Compute R_V and R_L for a gas with molecules of diameter 2×10^{-10} m. Assume that the gas obeys the ideal gas law for the following values of temperature and pressure: (a) $T = 300$K, $p = 1.0$ atm; (b) $T = 5$K, $p = 1.0$ atm; (c) $T = 300$K, $p = 10^{-8}$ atm; (d) $T = 5$K, $p = 10^{-8}$ atm.
2. (I) For an ideal gas at 0°C and 1.0 atm, the ratio of the typical molecular radius $(10^{-10}\ \text{m})$ to the intermolecular spacing is about 1/20. What is this ratio in liquid water (H_2O, molecular weight 18 g/mol)?
3. (II) Assume that the carbon and hydrogen atoms that make up oil behave like spheres of diameter 10^{-8} cm, and that the fundamental molecular component of oil, CH_2, would take up a corresponding area of 10^{-15} cm^2 on a water surface. How many such components are there in 0.1 L of oil if the density of oil is 90 percent of the density of water? What would the area of a one-molecule-thick layer of this amount of oil on water be? (This type of experiment, said to have been performed by Benjamin Franklin, among others, is sometimes used to compute the size of molecules.)

19–2 Pressure and Molecular Motion

4. (I) A rubber ball, confined to move in the x-direction, bounces elastically back and forth between two walls. The ball, which has a mass of 85 g, moves at a speed of 11 m/s, and the spacing of the walls is such that the ball strikes the right-hand wall 20 times in a ten-second period. What is the average force on the right-hand wall due to the ball during that ten-second span?

5. (I) Grains of sand of mass 3×10^{-3} g each, fall from a height of 0.8 m on a sticky surface at a rate of 50 grains per second per cm^2. What pressure does this shower of sand exert on the surface, assuming that air resistance can be neglected?

6. (II) Use dimensional analysis to estimate the number of air molecules that strike the 12-in × 12-in screen of a television set during a 1-h program.



7. (II) One mol of a monatomic ideal gas is placed in a chamber under 5 atm pressure. The volume of the chamber is 5000 cm^3. (a) What is the internal energy of the gas? (b) What is the temperature of the gas? (c) Assuming that the mass of a molecule of the gas is 3.36×10^{-26} kg, what is the value of $\langle v^2 \rangle$ of a gas molecule? (d) What is the root-mean-square (rms) velocity?

8. (II) A cubic box of volume 0.080 m^3 contains helium gas at 0.85 atm pressure and 22°C. (a) How many total collisions do the molecules make with the walls per second? (b) What is the total internal energy of the gas? (c) If the temperature is doubled, what happens to the rate of collisions?

9. (II) Consider a gas constrained to move in a plane of area A rather than a volume in three dimensions. The pressure in that case is a force/unit length exerted at the edge. What is the relation between pressure and internal energy in this case?

10. (II) Consider a spherical satellite of mass M and radius R, moving with speed v through a dilute gas, the upper atmosphere. We shall take v to be much smaller than v_{rms} so that we can ignore the distribution in velocities of the molecules of the gas. Assuming that the gas molecules are stationary, and that the satellite is slowed down by collisions with the gas molecules, obtain an expression for the change of velocity of the satellite as a function of time in terms of m, the molecular mass, n, the number density of molecules in m^{-3}, and the characteristics of the satellite. [*Hint*: The area presented by the satellite to the stationary molecules is just the same as if the satellite were a disc of radius R, oriented perpendicular to the motion.]

11. (II) The apparatus shown in Fig. 19–16 is designed to demonstrate aspects of the kinetic theory of gases. It consists of a transparent cubical box, 20 cm on each side, containing 100 steel balls of diameter 5 mm. The density of steel is 7.8 g/cm^3. The bottom of the box vibrates so that the steel balls bounce around. The top of the box consists of a movable piston of mass 1 kg. What is the rms speed of the steel balls if the top of the box is in dynamic equilibrium with the "gas" of steel balls? Ignore gravity in your treatment of the motion of the steel balls. Is this approximation justified?

▲ **FIGURE 19–16** Problem 11.

12. (II) When particles of mass 1.3×10^{-17} kg are suspended in a liquid at room temperature, they are observed to have an rms speed of 0.030 m/s. Use this to determine Avogadro's number. (You will need to look up the gas constant R.)

13. (II) The rms speed of galaxies in a large part of the visible universe is roughly 100 km/s. The number density of these galaxies is $3 \times 10^{-20}/ly^3$, and the average mass of a galaxy is 3×10^{41} kg. What is the pressure of a gas of such galaxies?

14. (II) Molecules are confined to move in a plane, for example, by putting them between two glass plates separated by a distance that is small compared to the mean free path. What is the relation between the pressure and the internal energy? What is the relation between internal energy and temperature for an ideal gas?

19–3 The Meaning of Temperature

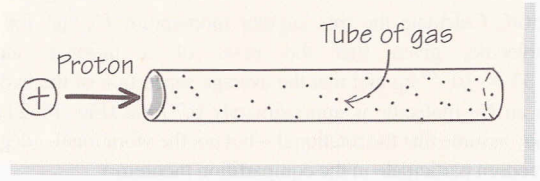
15. (I) Consider the mole of helium gas with an internal energy of 3600 J that we discussed in Example 19–1. (a) What is the temperature of the gas? (b) If 1/1000 of this amount of gas had the same internal energy as the total gas, what would its temperature be? (c) What would the internal energy of 1/1000 of the original sample of gas be, at its original temperature?

16. (I) A gas is heated from 120K to 470K. What is the change in the rms speed?

17. (I) What is the average kinetic energy per molecule of a gas at room temperature, 293K? How fast would a baseball of mass 0.10 kg be moving to have this same kinetic energy?

18. (I) An ideal gas is contained in a vessel of volume 3.0×10^{-4} m^3 that is under a pressure of 1.2 atm. What is the internal energy of the gas?

19. (I) The temperature of hydrogen in a dilute plasma—a state of matter in which atoms are broken apart into electrons and nuclei—inside a nuclear fusion reactor needs to be on the order of 20 million K in order to initiate nuclear fusion. What is the rms speed of the hydrogen nuclei in the plasma?



20. (II) A mixture of nitrogen gas and sulfur dioxide gas is in equilibrium at 27°C. What is the rms speed of the sulfur dioxide molecules (SO_2, molecular weight 64 g/mol), and that of the nitrogen molecules (N_2, molecular weight 28 g/mol)?

21. (II) Calculate the rms speed at 300K of the principal components of air: O_2 molecules (molecular weight 32 g/mol), N_2 (molecular weight 28 g/mol), CO_2 (molecular weight 44 g/mol) and H_2 (molecular weight 2.0 g/mol).

22. (II) The rms speed of 1 mol of argon atoms (atomic weight 40 g/mol) in a box is 680 m/s. (a) What is the temperature inside the box? (b) What is the internal energy? (c) If the box has a volume of 10^{-3} m^3, what is the pressure? Treat the gas as ideal.

23. (II) Estimate v_{rms} for hydrogen atoms (a) on the surface of the Sun, where the temperature is 6000K; (b) on the surface of the Moon, where the temperature at one point is 150K.

24. (II) A proton of kinetic energy 3×10^7 eV comes to a stop because of molecular collisions in a thin tube that contains 1.0×10^{-3} mol of oxygen at STP, as in Fig. 19–17. By how much is the temperature in the tube increased at equilibrium?

▲ **FIGURE 19–17** Problem 24.

25. (II) A "gas" of water droplets 10^{-6} m in diameter is in equilibrium with air molecules at 300K. Given that the density of water is 1.0×10^3 kg/m^3, what is the value of v_{rms} for the droplets?

26. (II) A relativistic gas is one in which a significant fraction of the constituents have speeds that are some finite fraction of the speed of light, $c \cong 3 \times 10^8$ m/s. Suppose that the rms speed of the constituents of a gas of atomic hydrogen is just 1% of c. What is the temperature? The energy that binds the electron and the proton together into a hydrogen atom is 2.18×10^{-18} J. Would this gas break down into a gas of electrons and protons? In the interior of stars, where temperatures comfortably exceed the temperature you have calculated, atoms cannot exist; they are broken into their components.

27. (II) If their kinetic energy greatly exceeds the average gravitational potential energy, galaxies in the sky may be viewed as an ideal gas. Given that the rms speed of galaxies is 100 km/s and the average mass is 3×10^{41} kg, what is the temperature of a gas of galaxies?

19–4 Probability Distributions

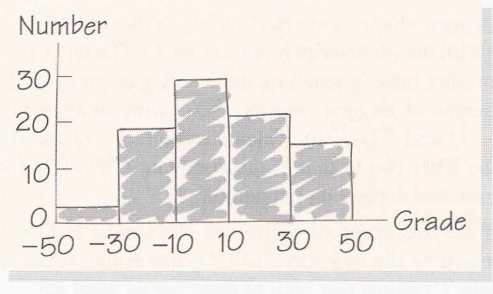
28. (I) A lottery that costs \$1 to play has a jackpot of \$10,000,000. The state that runs the lottery is obligated to tell the players that the probability of winning is one in 50,000,000. Is it a good idea from a financial point of view to play this lottery? Answer this question by calculating the ratio of your outlay to your revenue under the assumption that you play the game an unlimited number of times.

29. (I) Nine cars are measured at a given spot on a highway to have speeds v of 52.3, 54.5, 57.0, 57.2, 57.9, 63.6, 63.6, 68.1, and 82.2 mi/h. Calculate (a) the average speed, and (b) the rms speed.

30. (I) Take a deck of cards. Draw cards from that deck, one by one, without putting any cards back in the deck. What is the probability that the first card is a spade? What is the probability that the second one is also a spade? What is the probability that the third one is also a spade? (You may extend this procedure to calculate the probability that when you draw thirteen cards, they are all spades, by multiplying all the thirteen probabilities together).

31. (I) Four dice are tossed. What are the probabilities of getting (a) four sixes; (b) three sixes and a five?

32. (II) A cage of 50 Ping-Pong balls has air blowing through it to keep the Ping-Pong balls moving. Five Ping-Pong balls have the number 0 painted on them, five have the number 1, and so forth, finishing with five Ping-Pong balls painted with the number 9. The apparatus is used to choose the numbers for a lottery, and the balls are not returned to the cage after they are chosen. (a) The first drawing is for three balls. Your number is 186. Before any balls are drawn, what is the probability that you will win? (b) The first ball drawn is 1. What are your chances now? (c) The second ball drawn is 8. Now what is the probability that you will win?



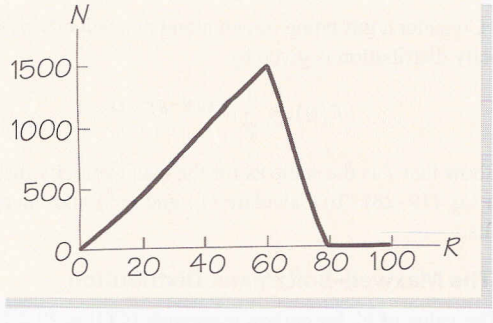
33. (II) Consider the distribution of grades g discussed in Section 19–4. (a) Plot the distribution of the numbers D for the students, where D is defined as the deviation of the grade from the average. (D can be positive or negative.) (b) Calculate the average value of D^2. (c) Show that $\langle D \rangle = 0$ and $\langle D^2 \rangle = \langle g^2 \rangle - \langle g \rangle^2$.

34. (II) Find an expression for the probability of getting 13 spades in a bridge hand. (In bridge, the entire deck of 52 cards is dealt to four players.)

35. (II) In a true-or-false test, a correct answer is awarded +1 point and an incorrect answer is awarded −1 point. In a test involving 87 students, the following grade distribution is found (Fig. 19–18):

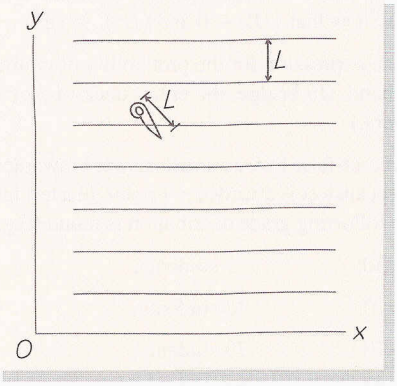
−50 to −30:	3 students;
−30 to −10:	18 students;
−10 to +10:	29 students;
+10 to +30:	22 students;
+30 to +50:	15 students.

(a) Calculate the average grade. (b) Calculate $\langle D^2 \rangle$, where D is defined in Problem 33. (c) Suppose that the distribution was such that every student has a grade between +10 and +30. With this information, what would the average be?



▲ **FIGURE 19–18** Problem 35.

36. (II) Suppose that the distribution of grades (the number of test takers, N, with a grade x) in a national test is approximated by a continuous curve of the form (Fig. 19–19)



$$\begin{aligned} N(x) &= 25x && \text{for } 0 < x < 60 \\ &= 6000 - 75x && \text{for } 60 < x < 80 \\ &= 0 && \text{for } 80 < x < 100. \end{aligned}$$

(a) What is the total number of students who took the test? (b) What is the average grade?

▲ **FIGURE 19–19** Problem 36.

37. (III) A way to find the value of π (*Buffon's method*) is the following: Drop a needle of length L repeatedly onto a grid of parallel lines separated by a distance L (Fig. 19–20). Show that the probability of the needle falling on a line is $2/\pi$. [*Hint*: Take the lines as parallel to the x-axis. Calculate the average value of the component of the needle's length along the y-axis.]

▲ **FIGURE 19–20** Problem 37.

19–5 The Velocity Distribution of Gases

38. (I) What is the rms speed of a helium atom in the vapor above liquid helium at 20K? (The system is enclosed in a perfectly insulating bottle.)

39. (I) Oxygen atoms come in a variety of isotopes: ^{16}O, ^{17}O, and ^{18}O (with the superscript representing A). The latter two isotopes are present only in small quantities. A gas consists of diatomic molecules of oxygen (mostly $^{16}O_2$, with small admixtures of ^{16}O–^{17}O and ^{16}O–^{18}O). Calculate the ratios of the rms speeds for the latter two to that of the dominant (^{16}O–^{16}O) form. Does your answer depend on temperature?

40. (I) If the rms speed of molecules of gaseous H_2O is 200 m/s, what will be the rms speed of CO_2 molecules at the same temperature? Assume that both of these are an ideal gas.

41. (II) Calculate $\langle v \rangle$, the average speed for an ideal gas. In doing this calculation with the help of the velocity distribution $F(\vec{v})$, use the fact that for a spherically symmetric integrand, you may replace d^3v by $4\pi v^2\, dv$. You will need the integral

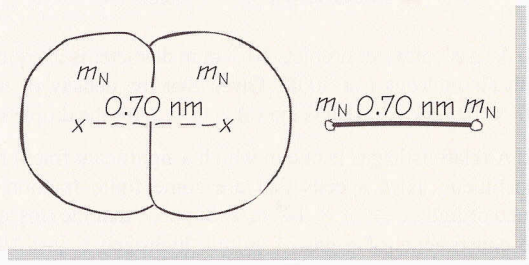
$$\int_0^\infty z^3 e^{-z^2}\, dz = \tfrac{1}{2}.$$

[*Hint*: This problem illustrates the use of dimensional analysis as an intermediate step.]

42. (II) Use the result of Problem 41 to find the numerical value of the average speed for an ideal gas of CO_2 at 550K, and compare it with v_{rms} at that temperature.

43. (III) Consider a gas being blown along at a velocity $\vec{u}$, so that its velocity distribution is given by

$$F(\vec{v}) = \frac{1}{Z} e^{-m(\vec{v}-\vec{u})^2/2kT}.$$



(a) Show that Z is the same as for the usual velocity distribution, as in Eq. (19–28). (b) Calculate $\langle \vec{v} \rangle$ and $\langle v^2 \rangle$ and interpret your results.

19–6 The Maxwell–Boltzmann Distribution

44. (I) The value of c'_p for carbon monoxide (CO) is 29.2 J/mol · K. What value do you expect for c'_V for the diatomic CO molecule?

45. (I) One mole of hydrogen gas is determined to have an internal energy of 1.87×10^4 J at 900K. How many degrees of freedom are there for the hydrogen molecule? Which degrees of freedom are likely to be available?

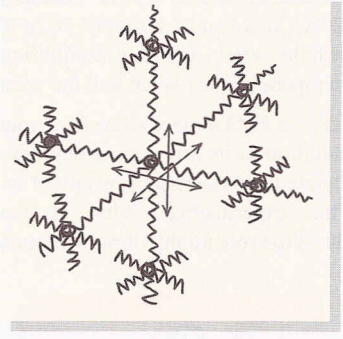
46. (I) A gas of N_2 molecules is in equilibrium at a temperature of 450K. Calculate the rms angular momentum $I\sqrt{\omega^2}$ for an N_2 molecule, given that the mass of a nitrogen atom is 2.33×10^{-26} kg and that the average separation of the two atoms in an N_2 molecule is approximately 0.70 nm (Fig. 19–21). (You may assume that the rotational—but not the vibrational—degrees of freedom participate in the equipartition theorem.)

▲ **FIGURE 19–21** Problem 46.

47. (II) The following data can be found in a table of thermodynamic properties of gases:

Argon (Ar): $c_p = 0.214$ cal/g · K; $c_V = 0.074$ cal/g · K
Oxygen (O_2): $c_p = 0.219$ cal/g · K; $c_V = 0.157$ cal/g · K
Water (H_2O): $c_p = 0.445$ cal/g · K; $c_V = 0.335$ cal/g · K
Carbon dioxide (CO_2): $c_p = 0.201$ cal/g · K;
$c_V = 0.156$ cal/g · K

What can you infer about the shape of the molecules from these data?

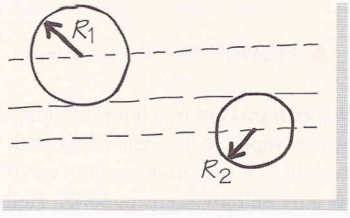


48. (II) Leaving out any contributions due to internal motion, what is the average molecular energy for a dilute gas of methane (see Fig. 19–7) at temperature T according to the Maxwell–Boltzmann distribution?

49. (II) A container has 1.3 mol of argon gas and 2.0 mol of nitrogen gas at room temperature. (a) What is the total internal energy of the gas? (b) What is the constant volume specific heat of the mixture?

50. (II) A gas of diatomic molecules is in equilibrium at a temperature of 350K. Assuming that the rotational inertia of the molecule [as used in Eq. (19–36)] is 2.4×10^{-40} kg · m^2, what is the rms angular speed of the molecules? What is the mean angular momentum of the molecules?

51. (III) Write down an integral for the probability that a molecule is found to have a velocity larger than 90 percent of v_{rms}. Show that the probability is independent of the temperature. Show that this is not the case if we ask for a velocity larger than some fixed number; for example, the escape velocity from a planet.

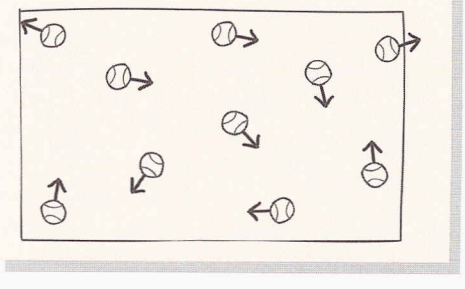


52. (III) A crystal can be thought of as a collection of N atoms arranged in a lattice, with all the atoms connected by springs (Fig. 19–22 see next page). Thus we can think of each atom as a mass at the end of three springs, aligned respectively along the x-, y-, and z-directions. Using this model of the lattice, count the number of degrees of freedom for each atom, then use the equipartition theorem to compute the molar heat capacity of the crystal at temperature T.

▲ FIGURE 19–22 Problem 52.

*19–7 Collisions and Transport Phenomena

53. (I) For a collision between two molecules of radii R_1 and R_2, respectively, show that the collision cross section is $\sigma = \pi(R_1 + R_2)^2$ (Fig. 19–23).



▲ FIGURE 19–23 Problem 53.

54. (I) Compute the pressure of a container of air molecules of diameter 2.5×10^{-10} m if the temperature is 273K and the mean free path is (a) 1 mm, (b) 1 μm. The gas should be treated as ideal.

55. (II) One can treat the flow of gas through a vacuum hose as if the gas were a fluid if the diameter of the hose is much larger than the mean free path. If, however, the mean free path is much larger than the diameter of the hose, the motion of the individual free molecules has to be considered. Consider a hose of diameter 1 cm. At what pressure is the mean free path of air at 300K shorter than 0.01 cm? Longer than 100 cm? Take the diameter of an air molecule to be 3×10^{-10} m.

56. (II) Using a reasonable value for the collision cross section or, more simply, a model of a gas in which the molecules are like tiny billiard balls, make an estimate of the density at which the mean free path becomes equal to the mean spacing between molecules.

57. (II) Ten tennis balls are rolling around randomly on a tennis court (Fig. 19–24). Estimate the mean free path for collisions.

▲ FIGURE 19–24 Problem 57.

58. (II) A student walks across a field that is 60 m $\times$ 40 m. Estimate the student's mean free path if there are (a) 10, (b) 100, (c) 300 other students on the field.

59. (II) A cubic box of sides 10 cm, contains helium atoms (diameter $\cong 1.0 \times 10^{-10}$ m) at a pressure of 3×10^4 Pa. If the mean free path in the box is 4×10^{-4} m, how many helium atoms are in the box? How many are there if the mean free path is 40 cm? What will the pressure be if the temperature is held fixed?

60. (III) According to one theory, planets are formed as a consequence of near collisions between stars. The number density of stars in our part of the galaxy is 10^{-51} m^{-3}. The velocity of the Sun relative to these stars can be taken to be 25 km/s, and the size of the stars is roughly 10^9 m. If we assume that a passage of two stars at a distance of 100 radii is close enough to set off the tidal forces that give rise to planet formation, what is the probability that the Sun would have acquired a planetary system in 10 billion yr?

General Problems

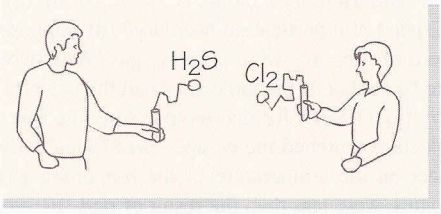
61. (I) Argon and methane (CH_4) gas are mixed together at 400K. What is the ratio of the rms speeds of the argon and methane atoms? What happens to this ratio if the temperature is halved?

62. (II) The density as well as the temperature of material in intergalactic space is rather uncertain. Suppose that the density and temperature were one hydrogen atom per cubic meter and 3K, respectively. (a) What is the pressure? (b) What is the mean free path if the diameter of a hydrogen atom is 10^{-10} m?

63. (II) The acceleration due to gravity on the surface of Mercury is 3.5 m/s^2, and Mercury's radius is 2.4×10^6 m. (a) What is the escape speed of a particle on Mercury? (b) Suppose that the atmosphere of Mercury were pure H_2 gas. What would the temperature be so that, if the molecules had the velocity distribution given by Eq. (19–28) for that temperature, the rms speed of the H_2 molecules matched the escape speed? Qualitatively, what is the effect on the temperature of the remaining gas? (c) If the temperature were less than the result of part (b), would there be a similar effect, and why or why not? (d) Suppose that Mercury's atmosphere has two or more molecular components. What happens to the composition of the atmosphere over time as a result of the effects discussed here?

64. (II) Some molecules (magnetic dipoles) carry a (vector) property $\vec{\mu}$ called the magnetic dipole moment. When such a dipole is placed in a magnetic field $\vec{B}$ it has an energy $-\vec{\mu} \cdot \vec{B}$. When a collection of N molecules with this property are placed in a box within which there is a magnetic field (meaning that at every point in the box the magnetic field has the magnitude and direction of the given $\vec{B}$), they each have an energy $-\vec{\mu} \cdot \vec{B}$. If the collection of molecules are at temperature T, what is the most likely orientation of $\vec{\mu}$? What is $P(30°)/P(60°)$, where $P(\theta)$ is the probability of finding one of them making an angle θ with the given magnetic field?

65. (II) In the quantum mechanical description of nature, electromagnetic radiation is carried in units called photons. These come with different frequencies. The equilibrium distribution of electromagnetic radiation in a cavity can be thought of as a collection of photons of different frequencies, appearing and disappearing as they are emitted or absorbed by the walls. For a given cavity volume and temperature, the probability of finding n photons of a given frequency f is $P_f(n) = x^n(1 - x)$, where $0 < x < 1$. (a) Is $P_f(n)$ normalized correctly? (b) What is $\langle n \rangle$, the average number of photons of frequency f? (c) What is the fractional spread $\dfrac{\sqrt{\langle n^2 - \langle n \rangle^2 \rangle}}{\langle n \rangle}$? Does this ever go to zero?



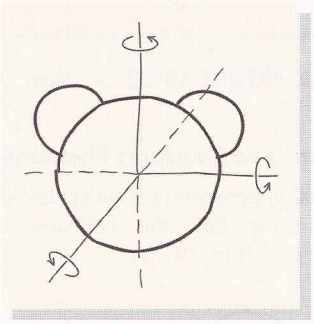
66. (II) The surface of the Sun contains both hydrogen and helium atoms at 6000K. (a) What is the average kinetic energy of each type of atom? (b) What is the rms speed of each? (c) Which is most likely to escape from the Sun?

67. (II) The regions in which the beams of accelerated particles circulate in accelerators have high vacuums (10^{-9} torr) to allow the particles to circulate freely. (a) What are the mean free paths of air molecules inside the accelerator at room temperature? (b) By how much does the mean free path decrease if the pressure inside increases to 10^{-6} torr?

68. (II) Suppose that molecules were confined to move in a plane. Calculate the velocity distribution $F(\vec{v})$, assuming that it is of the general form $(1/Z)e^{-mv^2/2kT}$. In other words, calculate Z so that $\int_{\text{surface}} F(v)\, d^2v = 1$.

69. (II) Brownian motion is the random walk followed by individual molecules as well as by larger objects such as smoke particles. The Brownian motion of smoke particles in a room can be observed with the aid of a microscope. If the mass of the smoke particles is typically 3×10^{-15} kg, what is the rms speed of the particles at room temperature?

70. (II) Peter and Paul are standing in opposite corners of a large room, 14 m apart. The air in the room is still. Peter holds a small vial full of H_2S while Paul holds a vial containing Cl_2. They open their vials at the same time (Fig. 19–25). Paul smells H_2S after 3.5 min. When will Peter smell the Cl_2?



▲ **FIGURE 19–25** Problem 70.

71. (II) Calculate an expression for the pressure of a gas of massless particles, using the following facts: Massless particles always move with the speed of light, so that $v = c$; the energy of a massless particle, E, is related to its momentum magnitude P by $E = Pc$. Use this expression to show that for a gas of massless particles, $pV = U/3$. This result is applicable to the blackbody radiation discussed in Chapter 17.

72. (II) The relation $pV = 2U/3$ is correct only for a monatomic gas. Show that the more general relation is $pV = (\gamma - 1)U$, where $\gamma = c'_p/c'_V$.

73. (II) Consider a tank of volume 0.30 m^3 containing 2.5 mol of helium gas at 20°C. If we add 1.0 mol of O_2 at 0°C to the helium and let the whole system come to equilibrium, what will the equilibrium temperature be? What will the pressure be?

74. (II) Assume that an H_2O molecule has three rotational degrees of freedom in addition to its three linear degrees of freedom (Fig. 19–26). Calculate the molar heat capacity of its vapor. Compare this with the experimental value at low pressures of 0.48 cal/g · K. What role might vibrational motion play?

▲ **FIGURE 19–26** Problem 74.

75. (II) A vessel is pumped out to a high vacuum and then heated to get rid of water vapor. It is then filled with dry helium and pumped out again to a very high vacuum of 10^{-11} torr, so that it now contains only helium atoms at 300K. Helium atoms have a diameter of about 10^{-10} m. (a) What is the density of helium atoms? (b) the mean collision time? (c) the mean free path?

76. (II) The *law of partial pressures* states that the total pressure of a mixture of gases is the sum of the pressures that each gas would exert if it were present alone in the same amount as in the mixture. Use the kinetic theory to demonstrate this fact. Could this law be true if the gases were not ideal?

77. (III) The escape speed of a particle from Earth is 11 km/s. Assuming that the oxygen molecules at Earth's surface are at a temperature of 300K, how would you use the velocity distribution to calculate the probability that a particular molecule at the surface would escape Earth's gravitational attraction if the molecule were to suffer no further molecular collisions? Express this probability in the form of an integral, and manipulate the integral into a form that involves the ratio $v_{\text{rms}}/v_{\text{escape}}$, but do not attempt to perform the integration. [*Hint*: This problem is analogous to finding the probability that a given student in a class has a grade of 35 or more on a test.]

Chapter 20

The engines that power racing cars such as these are highly sophisticated, a world away from the first steam engines of the industrial revolution. Yet both types of engines are subject to fundamental limitations on their possible efficiency.

The Second Law of Thermodynamics

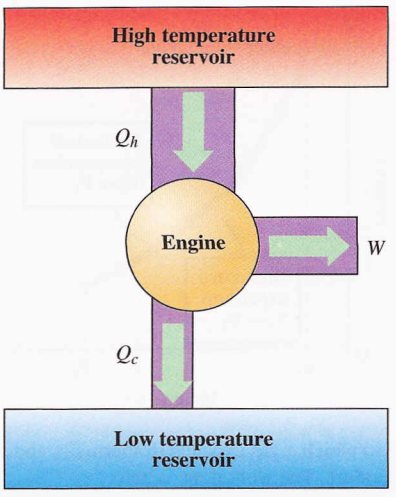
The first law of thermodynamics does not specify the direction of thermal-energy transfer. Nevertheless, we know from experience that the spontaneous transfer of thermal energy always proceeds from a hotter system to a cooler one. For example, if you put ice cubes in hot water, the ice cubes melt and the water cools off—nothing would be more surprising than to see the water becoming hotter and the ice cubes colder. This directionality in nature is enshrined in the second law of thermodynamics. The directionality of the spontaneous transfer of thermal energy can be understood from a molecular point of view by using the notions of probability developed in Chapter 19. These notions will allow us to develop the idea of order in a thermal system and to see that a spontaneous process proceeds from a more ordered to a less ordered state.

The second law has an important practical consequence: An engine, which is a device that takes thermal energy and uses it to do work, has a limit to how much of the thermal energy can be used in this way. (This limit is one that goes beyond the limits imposed by the first law of thermodynamics, which states that energy is conserved.) In this chapter we'll explore the meaning of the limit of how much thermal energy can be used to do work. What does this limit have to do with the direction of spontaneous processes? The answer to this question is provided by the concept of entropy, a new state variable for thermal systems, which quantifies the degree of order in thermal systems in thermodynamic terms.

20–1 Beyond Energy Conservation

The first law of thermodynamics extends the conservation of energy to thermal systems. We saw in Chapter 18 that we can construct engines, which are cyclic systems that do work on their surroundings—they may lift weights, or make vehicles go forward—by using thermal energy from thermal reservoirs. (These reservoirs may quite literally be heat baths, or they come in the form of hot gases that have been brought to high temperatures by burning fuel.) However, the first law cannot explain certain facts about thermal systems. For example, it is a fact that it is impossible to devise an engine that extracts all the thermal energy from a thermal reservoir and turns that energy into work. If we had such an engine, we could use it to power New York City—run its subway, light all its buildings, and provide heat in winter—while doing nothing more than cooling the Atlantic Ocean a little. Yet the existence of such an engine is completely consistent with the first law of thermodynamics.

There is a second set of facts about thermal systems that looks superficially different and that is also not explained by the first law. An example is the fact that when ice cubes are put into hot tea, the ice cubes melt and the tea cools. The first law of thermodynamics requires only that the heat flow into the ice cubes match the heat flow out of the hot tea, and heat flow could proceed in either direction. Nevertheless, lukewarm tea never *spontaneously* turns into hot tea with a couple of ice cubes floating in it. Another example is the observation that gas released into an evacuated chamber through a small opening spontaneously spreads throughout the available space—free expansion (Sections 18–1 and 18–7). We never see the gas spontaneously concentrating in a corner of the chamber, leaving most of the chamber evacuated.



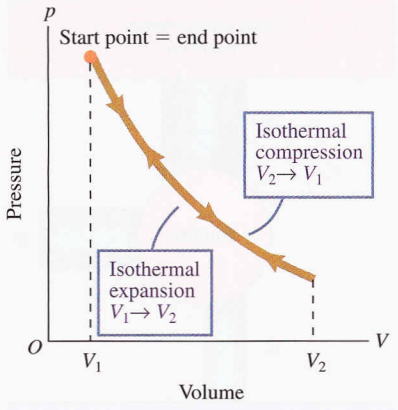
These experimental phenomena can be summarized as follows:

1. *Not all the thermal energy in a thermal system is available to do work.*
2. *Thermal systems spontaneously change only in certain ways, and in particular, spontaneous heat flow always goes from a body at higher temperature to a body at lower temperature.*

These facts are expressions of the **second law of thermodynamics**. We will look in more detail at the second law and how it applies to point 1 in the next section, and how it applies to point 2 in Section 20–5. We can nevertheless make a few pertinent remarks that lean on the microscopic picture of thermal behavior, in which molecules undergo random motion. It is this chaos that lies behind the second law. The only way to get all the thermal energy out of a gas in a cylinder would be to get all the molecules moving in the same direction such that they can collide with and lift a weight together. But this is a very unlikely occurrence in a thermal system made of so many constituents. Similarly, the directionality of spontaneous processes has to do with probability—as we shall see, the directionality is determined by what configuration of molecules is the most probable one. Keep this very rough set of ideas in the back of your mind as you go through this chapter.

Engines and Refrigerators

In Sections 18–5 and 18–6 we described engines in terms of a set of thermal transformations that form a cycle. We emphasized that even though over one cycle the thermal system ends up where it starts, net work is done on the surroundings. To do this work, the engine has to get energy from someplace, and this comes in the form of thermal energy extracted from the equivalent of thermal reservoirs. An engine is thus a device that cyclically transforms thermal energy into mechanical energy. For example, in an automobile engine the thermal energy of burning fuel is converted into the energy of the automobile's motion. So is an automobile engine really like the abstract-sounding set of transformations we described in Chapter 18? The answer is yes. You can trace a set of transformations that describe the operation of an automobile engine on a p–V diagram—the engine does consist of cylinders in which gases expand against pistons and so forth. There is one difference between a real automobile engine and the systems



▲ **FIGURE 20–1** Abstract representation of an engine, which takes energy—here represented by a system at high temperature—to perform work. We shall learn in this chapter that it is not possible to convert thermal energy entirely into work, so there is some thermal energy left over, which is "dumped" at cooler temperatures.

we described: The automobile engine, even though it is well lubricated, has friction in it, and there is some irreversibility in its operation—some energy is lost this way. The engines we'll deal with here, at least to start, are idealized in that they are described by a set of reversible transformations, but below we will certainly address the issue of friction.

There is one feature of the cycles that we dealt with in Chapter 18 that we did not emphasize very much: There are parts of the cycle where there is positive heat flow *into* the system, and other parts of the cycle where there is positive heat flow *out of* the system. In every engine the conversion of thermal energy into mechanical energy is accompanied by the emission of exhaust gases, which carry off some thermal energy. This means that only part of the thermal energy of the burning fuel is converted into mechanical energy (Fig. 20–1).

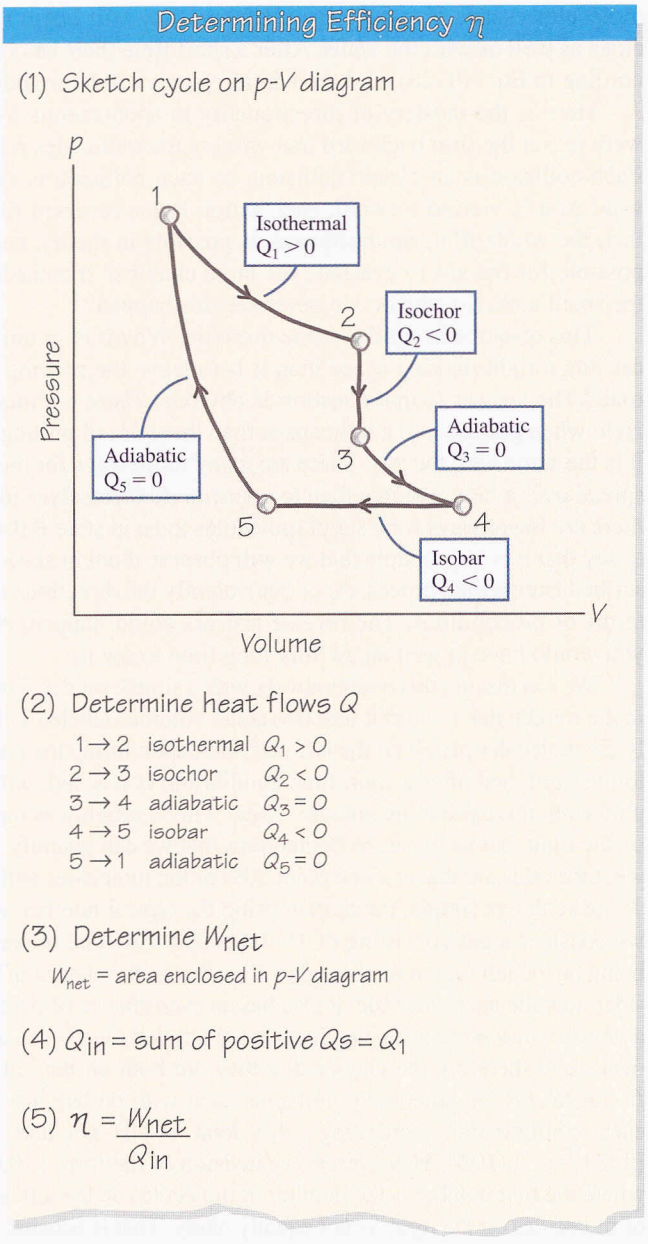
We can restate the points above by recognizing that a useful engine exhibits two key features:

1. *An engine must work in cycles if it is to be useful.* We can understand this best by considering why a *noncyclic* operation is less useful. Consider an ideal gas confined to a cylinder with a movable piston that undergoes isothermal expansion. It is held at constant temperature through contact with a thermal reservoir; for example, it could literally be sitting in a large container of hot water. If there is a mass on top of the upward-oriented piston, the gas does work as it expands. To satisfy the first law, there must be a heat flow from the reservoir to the gas, and this means that thermal energy from the reservoir is converted into mechanical energy. But is this system an engine? It is not, because the process is not cyclic. The volume of the cylinder cannot increase indefinitely, because the pressure, which is inversely proportional to the volume, will decrease until at some point the expanding gas will no longer be able to push the piston. You will have an ineffectual container of gas that takes up a lot of room! To have a functioning engine, *the gas must be recompressed and the piston restored to its original position, ready to do work again.*
2. *A cyclic engine must include more than one thermal reservoir.* To understand this, consider the cylinder and piston again. If the piston were returned to its original position while the cylinder remained in thermal contact with the original thermal reservoir, then all the work that the gas did while it expanded would be needed to recompress the gas. In this scenario the original expansion is reversed, and nothing has been gained. In Chapter 18 we learned that the area enclosed by a closed path on a p–V diagram is the work done during the cycle. In this case the area enclosed is

▲ **FIGURE 20–2** A cycle in which a gas expands isothermally and is then compressed isothermally at the same temperature. The work done is zero.

zero, so the net work done by the system is also zero (Fig. 20–2). For finite work to be done over a cycle, thermal contact with the original thermal reservoir must be broken, and *temperatures other than the temperature of the original reservoir must come into play.* Here we would want a second large container of water, this time with cold water, so that the gas is compressed at a temperature that is lower than the temperature at which it expanded. If we do this, the pressure will be lower, and less work will be needed for the compression than was produced in the expansion. You will have done net work, and you will be back where you started, ready to repeat the operation. Note that in the process thermal energy is taken from the hot reservoir and dumped to the colder reservoir. We'll come back to this very important theme later in the chapter.

A young engineer, Sadi Carnot, gave an early but perfectly correct statement of the second law of thermodynamics in 1824. Working during the Industrial Revolution, he was interested in the very practical problem of improving the efficiency of steam engines. He found that there are limits to the possible efficiency of any engine. (It is interesting that his discovery of the second law was made even before the first law was understood!) Accordingly, we now look at engine efficiency.



Efficiency: Engines have an **efficiency**, which is a measure of what fraction of the heat flow from the hotter thermal reservoir (such as a burning fuel) is converted into work (Fig. 20–1). If the work done in one complete cycle is W, then we define the efficiency, η, as the ratio of the work done to the total positive heat flow supplied by the burning fuel, Q_h:

$$\eta \equiv \frac{W}{Q_h}. \qquad (20\text{–}1)$$

DEFINITION OF ENGINE EFFICIENCY

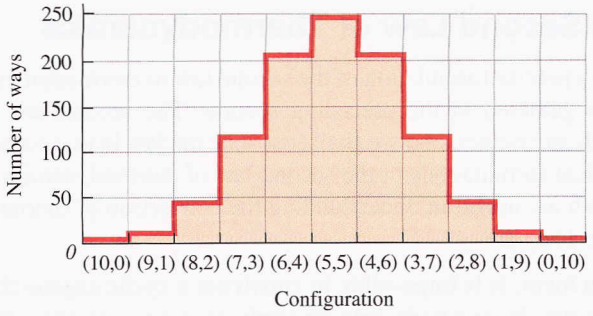
According to the *first* law of thermodynamics, this efficiency can run from 0 to 1. When the efficiency is 1, or 100%, all the thermal energy taken from the thermal reservoir is converted to mechanical work; this is allowed by the conservation of energy (the first law). We will see, however, that an efficiency of 100% is impossible according to the second law. Figure 20–3 illustrates how the efficiency is calculated. This is an important quantity to be able to calculate, and we'll illustrate it by example in several places below.

Finally let us turn to refrigerators, which at first sight might seem to have nothing to do with engines. In fact, they are very closely related: A refrigerator is an engine run in reverse. Since the path on a p–V diagram of an idealized engine is reversible, we can indeed run it in reverse. Work will be done on the system by the surroundings, and thermal energy taken from a colder reservoir and released to a hotter reservoir. The motor in a refrigerator is even called a compressor; it compresses the gas of the idealized version

◀ **FIGURE 20–3** An illustration of the technique for calculating efficiency.

of the refrigerator and thereby does work on the system. The colder reservoir is the ice-box—by removing thermal energy from it, you make it still colder or maintain its temperature when your little brother stands in front of the open door. Where is the hotter reservoir to which thermal energy is added? It is in the coils at the back of the refrigerator, and it ends up warming the air in the room in which the refrigerator sits.

Spontaneous Processes



The directionality of spontaneous processes is illustrated by the two examples we have mentioned—hot tea with ice cubes, and free expansion. Let's concentrate on free expansion, which we can discuss directly in terms of molecules. When a valve is opened and gas escapes from a small tank into a large, empty chamber, the gas spreads and fills the chamber until the density and temperature are uniform throughout that chamber. Now imagine a film of this process made on a scale in which individual molecules can be seen. The molecules move rapidly and collide frequently in the small tank. When the valve is opened, molecules that reach the opening escape. They enter a vast space, empty of molecules, and the first batch of molecules encounter nothing in their way. Their first collisions will be with the walls of the chamber. As more and more

molecules escape into the large chamber, they will begin to collide with other molecules as well as with the walls. After a short time their velocities will be distributed according to Eq. (19–28), and the whole system will be in thermal equilibrium.

Here is the mystery of directionality in spontaneous free expansion. Suppose we were to run the film backward and witness the molecules returning to the smaller tank. Each collision is an elastic collision, so each collision is as convincing viewed backward as it is viewed forward; each action in the reversed film is perfectly possible. In fact, the whole film, run backward, is possible in theory, and so in theory it should be possible for the gas to evacuate the large chamber spontaneously and concentrate into the small tank. So why do we never see this happen?

This question is similar to the question, Why it is so much harder to parallel park a car into a tight parking space than it is to leave the parking space and get back on the road? The answer to that question is obvious: *There are many fewer ways of getting it right* when pulling into a tight space than there are of pulling out into a wide boulevard. It is the same with the gas. There are many more ways for the molecules of the gas to be spread over a large volume than to concentrate themselves into a small one. Saying that there are fewer ways for a set of molecules to be in state B than in state A is another way to say that it is improbable that we will observe them in state B. In this way, we have described irreversible processes, or equivalently the direction of spontaneous processes, in terms of probabilities. The reverse process could happen, but it is so improbable that you would have to wait an awfully long time to see it.

We can discuss this quantitatively with a simple model. Consider a box with a partition in the middle that divides it into two equal volumes labeled L (left) and R (right). If initially the molecules are all on the left side, then upon lifting the partition, molecules can move to the right, and after a short time equilibrium is reached, with the molecules distributed uniformly throughout the volume. There will be roughly as many molecules on the left as on the right, but there can be fluctuations that we can quantify. We could ask, for example, what the odds are that at some point 80% of the molecules will be on one side or the other. To make things simple, rather than using the typical number of order of $N_A = 6 \times 10^{23}$, we consider a gas consisting of 10 molecules. Any one molecule has an equal chance of being on the left (L) or on the right (R)—that is, the chance of being in, say, L is $1/2$. Consider now the next molecule: it also has an even chance of being on the left. We now make a *physical assumption*: The molecules are not tied together in any way—they are independent—and therefore the chance that they are both on the left is $(1/2) \times (1/2)$. In fact *LL,LR,RL,RR* are all equally probable, each with probability $(1/2)^2$. With 10 molecules each configuration, consisting of a total of 10 L's and R's, has a probability of $(1/2)^{10} = 1/1024$. However, every division of the form $(10,0)$, $(9,1)$, $(8,2)$, $(7,3)\ldots$, where the first number is the number of molecules on the left and the second is the number of molecules on the right, is not equally likely. That is because the number of ways of getting them is different. Let us work out the number of ways of getting the configurations $(10,0)$, $(9,1)$, $(8,2)$, and so on. The number of ways in which we can have all 10 molecules on the left and none on the right is just one. It consists of the assignment $LLL\ldots L$ (10 terms). If we ask for the number of ways of having 9 on the left and 1 on the right, we can pick any one of the 10 molecules to go to the right, and therefore there are 10 *different* ways of having the division $(9,1)$. For the division of $(8,2)$ we have 10 ways of picking one molecule to go on the right, and then, since there are only 9 left, 9 ways of picking the second one. That would give us 10×9 ways. However, with this way of figuring things, we have overcounted. We have counted as different possibilities two different orders for choosing the two molecules: M_1 first and M_2 second, and the other way around. This is overcounting because we are interested only in the fact that there are 2 molecules on the right, and not in the order of their arrival. Thus we must divide by 2 for the 2 orders, and the number of ways of getting $(8,2)$ is not (10×9) but rather $(10 \times 9)/2 = 45$. For the order $(7,3)$, we can pick out the three molecules in sequence: there are 10 ways of picking the first, 9 ways of picking the second, and 8 ways of picking the third. Here again we have overcounting. If we label the molecules with 1,2,3, then they are counted as arriving in all the possible 6 sequences: (123), (132), (231), (213), (312), (321). We must therefore divide by 6, and we get $(10 \times 9 \times 8)/6 = 120$ for the $(7,3)$ division. It is not very hard to see what the whole picture yields [Fig. 20–4]:

▲ **FIGURE 20–4** The number of ways, and hence the relative probability, that in a collection of 10 molecules the configuration in a box is (# on left, # on right). For example, there are 120 ways to get 7 on the left and 3 on the right. We are assuming that the "choice" of whether a molecule goes left (or right) is independent of the other molecules.

Division	# of ways	Probability P
(10,0) or (0,10)	1	1/1024
(9,1) or (1,9)	10	10/1024
(8,2) or (2,8)	$(10 \times 9)/(2 \times 1) = 45$	45/1024
(7,3) or (3,7)	$(10 \times 9 \times 8)/(3 \times 2 \times 1) = 120$	120/1024
(6,4) or (4,6)	$(10 \times 9 \times 8 \times 7)/(4 \times 3 \times 2 \times 1) = 210$	210/1024
(5,5)	$(10 \times 9 \times 8 \times 7 \times 6)/(5 \times 4 \times 3 \times 2 \times 1) = 252$	252/1024

The probability results above show that with even as few as 10 molecules, the odds of equal division with a fluctuation of 1 [i.e. (5, 5) + (6, 4) + (4, 6)] compared with the outer extreme with a fluctuation of 1 [i.e. (10, 0) + (9, 1) + (0, 10) + (1, 9)] are in the ratio of (252 + 210 + 210) to (1 + 10 + 10 + 1) = 672/22 = 30.1 to 1. There are many more ways of finding nearly equal numbers on both sides than there are ways of finding almost all the molecules on one side or the other. When we get to numbers as large as 10^{24} molecules, this effect is much bigger. In fact, the ratio of the odds becomes more like 10^{12} than 30.1. This means that once equilibrium is established, there is effectively no going back.

Our simple model suggests that the directionality of spontaneous processes is determined by what takes you to the state with the highest probability. There may be subsequent fluctuations around the most probable state, but they are relatively small when the numbers of molecules is high. The irreversibility of a spontaneous process such as free expansion is not guaranteed but it is an almost sure bet.

EXAMPLE 20–1 Three dice are thrown. Assuming honest dice, what is the probability of getting a total of 3? What is the probability of getting a total of 10?

Strategy When it lands, each die gives 6 possible outcomes, and each outcome is equally likely. Thus the probability of any one given outcome on one of the dice is 1/6. Since the three dice are totally independent, any single outcome has probability $(1/6)^3 = 1/216$. (Equivalently, there are 216 different outcomes for the set of three dice.) The difference between the three dice giving a total of three and a total of 10 lies in the number of ways of getting these totals with three dice. The simplest way of getting at these numbers is straight enumeration.

Working It Out There is only one way of getting a total of 3, and that is by the dice reading (111). This means that the probability of getting a total of 3 is 1/216.

Let's now enumerate ways of getting a total of 10: We list the triplets that can add up to 10 as follows: (136), (145), (226), (235), (244), (334). For an entry in this list in which all three digits differ, there are six different ways to get them. For example, if square brackets mean that we are keeping track of the order, we can get (136) as [136], [163], [316], [361], [613], or [631]. When two of the integers are the same, then there are only three ways of getting them—for example, we can get (226), by the throws [226], [262], or [622]. Thus in the list of the number of ways to get 10 we have 6 + 6 + 3 + 6 + 3 + 3 = 27 different throws. Thus the probability of getting 10 is 27/216, 27 times more probable than the probability of a 3.

What Do You Think? If you deal with the triplet (136), do you really have to list all six possibilities to convince yourself that there are six? *Answers to **What Do You Think?** questions are given in the back of the book.*

20–2 The Second Law of Thermodynamics

Here we'll give a precise formulation of the second law of thermodynamics, using some of the facts we gathered in the preceding section. The second law was discovered through the study of engines, and we shall first state the law in that context. There are in fact two equivalent formulations of the second law of thermodynamics associated with engines, and both are useful in understanding the conversion of thermal energy to mechanical energy. They are:

> **The Kelvin form. It is impossible to construct a cyclic engine that converts thermal energy from a body into an equivalent amount of mechanical work without a further change in its surroundings.**

For example, there is no way to extract thermal energy from the ocean and use that energy to run an electrical generator without further effect on the surroundings of the system, such as a heating of the atmosphere. In the example discussed in Section 20–1 (a gas expanding against a piston without recompression), thermal energy from a thermal reservoir is indeed converted into work, but the engine is not cyclic. In an engine that takes thermal energy from a thermal reservoir cyclically and converts that energy to work, the additional effect is typically a heat flow from the engine into its lower-temperature surroundings, as in point 2 (page 574) of Section 20–1. This brings us to the second formulation of the second law of thermodynamics:

> **The Clausius form.[†] It is impossible to construct a cyclic engine whose only effect is to transfer thermal energy from a colder body to a hotter body.**

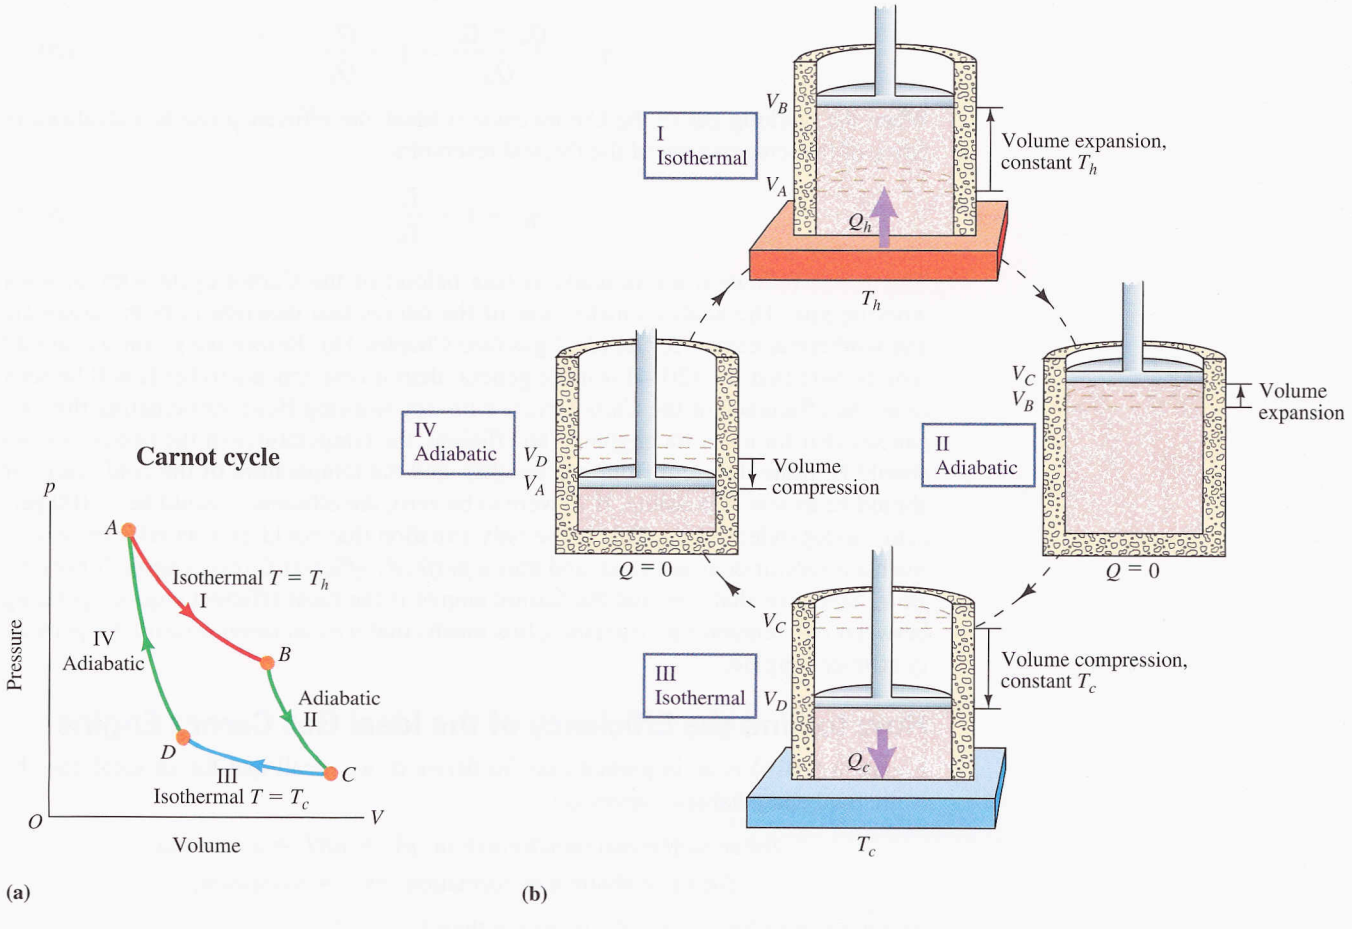
In other words, there is no cyclic engine that can start with a pot of cold water, make it still colder by taking thermal energy from it, and use that energy to warm up a second pot of water *with no further effect*. In this case, the further effect is associated with the fact that the apparatus *must* take some mechanical energy from its surroundings (such as an electric motor could provide).

We will use mainly the Kelvin form, which was first stated by Lord Kelvin around 1850. Detailed analysis, however, shows that the two formulations of the second law of thermodynamics are entirely equivalent.

THINK ABOUT THIS . . .

HOW DO PERPETUAL MOTION MACHINES WORK?

The search for a *perpetual motion machine* has stimulated thought for centuries. The simplest version of such a machine is an engine that does more work than the energy that goes into it. (Analysis of a seemingly attractive example of such a machine can be found in Problem 16–67.) The discovery of the first law of thermodynamics, and the underlying law of conservation of energy, explained why no such machine (a "perpetual motion machine of the first kind") ever worked. Such knowledge has not stopped "inventors" from trying to violate this law, though the U.S. Patent Office no longer even considers granting patents on such contraptions. Inventors also attempt to construct machines that do not violate energy conservation but have the property that they take energy from a reservoir at a lower temperature and transfer it to one at a higher temperature, without requiring further energy input. Such a machine could take in thermal energy from the ocean and, for free, use it to heat a city on the shore. This is a very attractive idea. Unfortunately, it violates the second law of thermodynamics. It is this law that forbids the construction of this type of machine, also known as a "perpetual motion machine of the second kind."



We can construct wind-power generators that extract energy from the wind and convert it to useful power. The second law is followed in this case because not *all* of the energy in the air flux that hits a windmill can be converted to work in the form of the turning blades. In other words, a windmill does not have a 100% efficiency. Effectively the wind that flows in acts as a hot reservoir, and the outgoing air, which has been stirred up by its passage past the blades, acts as a cold reservoir. The role of such reservoirs in the operation of the second law is described in Section 20–3.

[†]Rudolf Clausius is best known for introducing the concept of entropy.

20–3 The Carnot Cycle

We argued earlier that thermal reservoirs at two (or more) different temperatures are necessary for the operation of a reversible thermodynamic cycle that performs work; that is, a reversible engine. A minimal version of such an engine—one that requires exactly two such reservoirs—at temperatures T_h and T_c, respectively, was invented by Sadi Carnot in 1824. The reversible cycle followed by this engine—known as a **Carnot cycle**—is of great importance in thermodynamics because it is the most efficient engine one can construct that operates between any two temperature extremes. While the Carnot cycle is not used for real engines in common use, some real engines at least approximately match it. By learning the efficiency of the Carnot cycle, we learn the best we can hope to accomplish in engine efficiency.

The Carnot cycle, demonstrated in Fig. 20–5 with a gas-filled cylinder and a piston, consists of four reversible steps. Figure 20–5a is a p–V diagram of these four steps, and Fig. 20–5b depicts the cycle schematically. Step I (AB in Fig. 20–5a) is an isothermal expansion: The expansion takes place with gas in the cylinder in thermal contact with a thermal reservoir—say, a kitchen hot plate—at temperature T_h. In step II (BC) the cylinder of gas has been insulated from thermal contact with its surroundings so that there is no heat flow ($\Delta Q = 0$; the transformation is adiabatic). The volume slowly expands further, while the pressure as well as the temperature of the gas decrease. The temperature of the gas is monitored throughout this adiabatic expansion. When the temperature has dropped to T_c (the temperature of a second, colder, thermal reservoir—for example, a bathtub full of cold water), it is placed in thermal contact with this second reservoir (step III). During this stage (CD), an isothermal compression of the gas at T_c

▲ **FIGURE 20–5** (a) The Carnot cycle, which consists of two adiabatic and two isothermal transformations. (b) How the cycle might be realized.

takes place. The final pressure of step III is determined such that when the gas is removed from contact with the bathtub and again placed in thermal isolation, the adiabatic compression of step IV (DA) increases the temperature and pressure of the gas until it returns to the starting point, A.

In Fig. 20–5a the isothermal legs are drawn as hyperbolas, and the adiabatic legs follow the curve $p = (\text{a constant})\ V^{-\gamma}$ for $\gamma > 1$—as is appropriate for an ideal gas (see Chapter 18). However, the working fluid does not have to be an ideal gas.† *Any* gas or other compressible fluid is suitable, as isothermal or adiabatic changes are possible for any substance. The crucial features of the Carnot cycle are independent of whether the working fluid is an ideal gas or not.

The work W done *by* the gas in tracing out a complete Carnot cycle is the area enclosed by the curve in the p–V diagram. The cycle shown is clockwise, so W is positive. There is also heat flow associated with the Carnot cycle, although not during steps II and IV, which are by definition adiabatic. During step I, there is a positive heat flow Q_h from the hotter thermal reservoir into the thermal system. (For an ideal gas, $\Delta U = 0$ during an isothermal process, and then $Q_h = W_{A\to B}$, the positive work done by the gas in that expansion.) Similarly, there is a negative heat flow $-Q_c$ from the colder thermal reservoir to the system during step III. In other words, there is a positive heat flow Q_c from the thermal system to the colder reservoir. Thus the Carnot engine absorbs a heat flow Q_h during step I, gives up a heat flow Q_c during step III, and does a total amount of mechanical work W. (This is shown schematically in Fig. 20–1, without making precise the steps.) The first law of thermodynamics can be applied to the entire cycle. Because the engine returns to its original state, the internal energy is unchanged, a statement we could make even if the working fluid is not an ideal gas. Then, according to the first law,

$$0 = W - Q_h + Q_c. \tag{20–2}$$

Equation (20–2) allows us to find the efficiency of the Carnot cycle, $\eta_C = W/Q_h$:

$$\eta_C = \frac{Q_h - Q_c}{Q_h} = 1 - \frac{Q_c}{Q_h}. \tag{20–3}$$

When the working gas of the Carnot cycle is ideal, the efficiency can be calculated in terms of the temperatures of the thermal reservoirs:

$$\eta_C = 1 - \frac{T_c}{T_h}. \tag{20–4}$$

This result follows from an analysis (see below) of the Carnot cycle with an ideal working gas. The analysis makes use of the curves that describe both the adiabatic and isothermal curves for an ideal gas (see Chapter 18). Before we go on we should remark here that Eq. (20–4) is more general than it first appears to be: It will be seen to be the efficiency of the Carnot cycle with *any* working fluid. Anticipating this, we can say that for a Carnot engine to be efficient, the temperatures of the two reservoirs should be quite different from one another, and the temperature of the cold reservoir should be as low as possible. If T_c were to be zero, the efficiency would be 1 (100 percent), independent of T_h. This is the only situation that could give an efficiency of 1. Such a reservoir does not exist, and thus *a perfectly efficient Carnot engine is not possible*. Since we shall see that the Carnot engine is the most efficient engine operating between two temperature extremes, this means that we can never construct a perfectly efficient engine.

How to Find the Efficiency of the Ideal Gas Carnot Engine

Equation (20–4) is an important one. To derive it, we recall that for an ideal gas, the isothermal and adiabatic curves are

$$\text{for an isothermal transformation: } pV = nRT = \text{a constant},$$
$$\text{for an adiabatic transformation: } pV^\gamma = \text{a constant},$$

where the quantity $\gamma = C_p/C_V$ is greater than 1.

†The "working fluid" is the material that expands and contracts, allowing the engine to do work.

Refer now to Fig. 20–5a. For an ideal gas the thermal energy is a function of temperature only, so the thermal energy, U, is constant during the isothermal steps (I and III). For these steps, $\Delta U = 0$, and the first law of thermodynamics, $\Delta U = Q - W$, implies that

$$\text{for step I: } Q_h = W_{A\to B},$$

and

$$\text{for step III: } Q_c = -W_{C\to D}.$$

There is a minus sign in the second equation because we have defined Q_c as the heat flow *from* the thermal system to the cold reservoir, whereas in the first law of thermodynamics the heat flow is always *to* the thermal system.

The work done by the gas during the isothermal steps is

$$W_{A\to B} = \int_{V_A}^{V_B} p\,dV = \int_{V_A}^{V_B} \frac{nRT_h}{V}\,dV = nRT_h \ln\left(\frac{V_B}{V_A}\right);$$

$$W_{C\to D} = \int_{V_C}^{V_D} p\,dV = \int_{V_C}^{V_D} \frac{nRT_c}{V}\,dV = nRT_c \ln\left(\frac{V_D}{V_C}\right).$$

Using these results, we find the efficiency of the cycle:

$$\eta_C = 1 - \frac{Q_c}{Q_h} = 1 - \frac{-W_{C\to D}}{W_{A\to B}} = 1 + \frac{nRT_c}{nRT_h}\frac{\ln(V_D/V_C)}{\ln(V_B/V_A)}$$

$$= 1 - \frac{T_c}{T_h}\frac{\ln(V_C/V_D)}{\ln(V_B/V_A)}. \tag{20–5}$$

We have not yet used any information about the shape of the adiabatic curves in this expression. This information will relate the various volumes. Points B and C lie on the same adiabatic curve, so $p_B V_B^\gamma = p_C V_C^\gamma$. Similarly, for points A and D, $p_A V_A^\gamma = p_D V_D^\gamma$. The ratio of these two equations gives

$$\frac{p_B V_B^\gamma}{p_A V_A^\gamma} = \frac{p_C V_C^\gamma}{p_D V_D^\gamma}. \tag{20–6}$$

Next, we substitute for the ratio of the pressures on each side of this equation. Because A and B lie on an isotherm, $\dfrac{p_B}{p_A} = \dfrac{nRT_h/V_B}{nRT_h/V_A} = \dfrac{V_A}{V_B}$, and similarly, because C and D also lie on an isotherm, $\dfrac{p_C}{p_D} = \dfrac{nRT_c/V_C}{nRT_c/V_D} = \dfrac{V_D}{V_C}$. We insert these ratios into Eq. (20–6) to find that

$$\frac{V_B^{\gamma-1}}{V_A^{\gamma-1}} = \frac{V_C^{\gamma-1}}{V_D^{\gamma-1}}.$$

The same power, $\gamma - 1$, appears on both sides of this equation, so the arguments must be equal:

$$\frac{V_B}{V_A} = \frac{V_C}{V_D}.$$

This result considerably simplifies the expression for efficiency. The arguments of the logarithms in Eq. (20–5) are the same, so the logarithms cancel and we finish with Eq. (20–4).

EXAMPLE 20–2 In a Carnot engine with an ideal gas, calorimetry reveals that the heat flow Q_h from the hot thermal reservoir in one cycle equals 38 J, and the heat flow Q_c to the cold thermal reservoir is 28 J. The temperature of the cold reservoir is 290K. (a) What is the mechanical work done during one cycle? (b) What is the efficiency of the cycle? (c) What is the temperature of the hot reservoir?

Strategy For part (a) we find the mechanical work done during one cycle by finding the area enclosed by the cycle on a p–V diagram. This evaluation can in principle be done by integration, but only with great difficulty because all the parameters of the cycle are not yet known. A much simpler way to compute the work done is to use the first law of thermodynamics, which, for a closed cycle, states that the work done plus the heat flow out of a thermal system equals the heat flow into the system: $W + Q_c = Q_h$, from Eq. (20–2), so that $W = Q_h - Q_c$.

For part (b) we can use the expression for the efficiency in terms of the heat flows, given in Eq. (20–3). Once we have the efficiency, we can solve part (c): We express the efficiency in terms of the temperatures and solve this for the temperature of the hot reservoir, $T_h = \dfrac{T_c}{1 - \eta}$. Everything on the right hand side of this is known.

Working It Out (a) We have

$$W = Q_h - Q_c = 38\text{ J} - 28\text{ J} = 10\text{ J}.$$

(b) Equation (20–3) expresses the efficiency directly in terms of the given heat flows:

$$\eta = 1 - \frac{Q_c}{Q_h} = 1 - \frac{28\text{ J}}{38\text{ J}} = 0.26.$$

(Remember, this the *most* efficient engine you can have that operates between these two temperature extremes.)

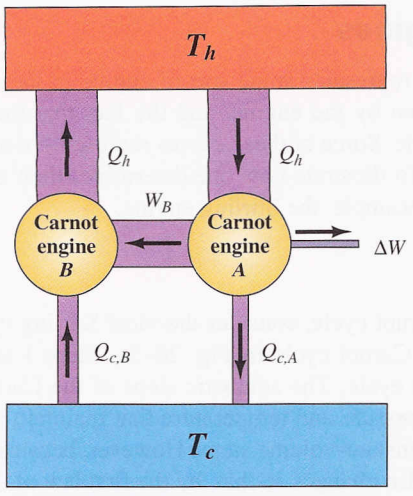
(c) We have

$$T_h = \frac{T_c}{1 - \eta} = \frac{290\text{K}}{1 - 0.26} = 3.9 \times 10^2\,\text{K}.$$

What Do You Think? What single parameter change will increase the efficiency of an ideal Carnot engine? If the efficiency cannot change, how could you make sure to get more work done by the gas in the engine?

CONCEPTUAL EXAMPLE 20–3 Describe the operation of a Carnot cycle run in reverse.

Answer Running a Carnot engine—or any reversible engine—in reverse means that the direction of the transformation in each step is reversed, so that the path runs counterclockwise on the p–V diagram. For example, step I in Figure 20–5a becomes an isothermal compression rather than an isothermal expansion. The work done during one cycle is then negative. Positive work must be supplied to the cycle from the exterior to make it run—while heat flow Q_c is taken from the cold reservoir and heat flow Q_h goes to the hot reservoir. We'll see in the subsection on heat pumps and refrigerators below how an engine run in reverse is useful to us.



The Importance of the Carnot Engine

The second law of thermodynamics implies two important results; the second of these explains why any discussion of engine efficiency must start with discussion of the Carnot engine.

1. *All Carnot cycles that operate between the same two temperatures have the same efficiency*. In particular, the efficiency of a Carnot cycle *does not depend on the use of an ideal gas*. The expression for the efficiency of a Carnot engine with an ideal gas, Eq. (20–4), is the expression for a Carnot engine with any working fluid.
2. *The Carnot engine is the most efficient engine possible that operates between any two given temperatures*. (We will demonstrate this in Section 20–4.) This fact is the reason why the Carnot cycle is so important. In a sense it provides us with a target for the best possible engine.

We can demonstrate the first result with a standard method: we show that we would violate the second law of thermodynamics if it were not true. Suppose that we have two Carnot engines, A and B, that operate between the same two temperatures. Further, suppose that somehow the efficiency $\eta_A = W_A/Q_{hA}$ of cycle A were 75 percent, whereas the efficiency $\eta_B = W_B/Q_{hB}$ of cycle B were 74 percent. Let's adjust the amount of working gas in the cycles so that $Q_{hA} = Q_{hB}$, say, 100 J. This does not change the efficiencies. The work done by the two engines, which is the product of efficiency and heat flows, would then be different; namely, $W_A = (75\%)(100\text{ J}) = 75\text{ J}$, whereas $W_B = (74\%)(100\text{ J}) = 74\text{ J}$. Cycle A does more work than cycle B by an amount $\Delta W = W_A - W_B = 1\text{ J}$. We can now connect these two cycles in a way that violates the second law. Like any Carnot engine, engine B is reversible. We connect it to engine A as in Fig. 20–6 and run it in reverse. (In Conceptual Example 20–3 we described what is meant by running an engine in reverse.)

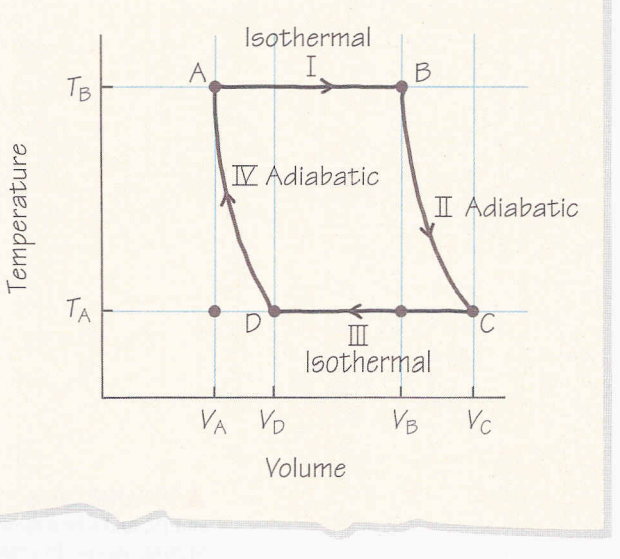
We can divide the 75 J of work done by engine A in Fig. 20–6 into two parts: We use 74 J to run engine B and 1 J is left over. An equivalent amount of heat flow goes into the hot reservoir as is taken out, so this reservoir plays no role. Thus the net effect of this combination engine is to employ only one reservoir to extract 1 J of work with each

◀ **FIGURE 20–6** Carnot engines A and B are connected together, with B run in reverse. If engine A is more efficient than engine B, the net effect of the combination is to circumvent the Kelvin form of the second law of thermodynamics.

cycle. But such an arrangement violates the Kelvin form of the second law of thermodynamics. This result is quite general, and it is a remarkable one because Carnot engines can be constructed with many different working fluids.

We have shown that the efficiency of *any* Carnot cycle that operates between temperatures T_c and T_h is given by Eq. (20–4), whether or not the gas is ideal:

$$\eta_C = 1 - \frac{T_c}{T_h}. \qquad (20\text{–}7)$$



EFFICIENCY OF ANY CARNOT CYCLE

We have found a universal expression for the efficiency of a Carnot cycle in terms of the temperatures of the thermal reservoirs. Note that the temperature scale here is the ideal-gas temperature scale—the Kelvin scale.

What happens if instead of the Carnot engine, with its idealized reversible cycle, we have an engine with some element of irreversibility? For example, there might be friction between the piston and the cylinder walls. We could reasonably expect that such an engine is less efficient than the Carnot engine that operates between the same two temperatures. We can, in fact, prove that this must be the case (see Problem 19).

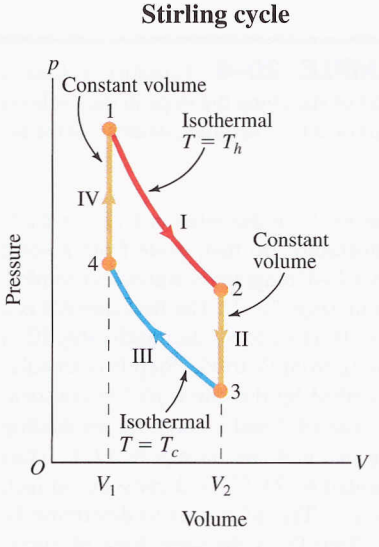
CONCEPTUAL EXAMPLE 20–4 Consider a Carnot cycle with an ideal gas. Instead of sketching the steps in the cycle on a p–V diagram, sketch the steps on a U–V diagram, where U is the internal energy.

Answer For an ideal gas we have the relation $U(T) = C_V T$, with C_V independent of temperature, so that, aside from a scale change, plotting the steps on a U–V diagram is equivalent to plotting the steps on a T–V diagram (Fig. 20–7). The first step AB is a horizontal line at T_h extending from V_A to V_B. Similarly, step III is a horizontal line at T_c extending from V_C to V_D. Step II is an adiabatic expansion. This is described by the curve pV^γ = constant. We are able to express p in terms of T and V since we are dealing with an ideal gas. Assuming one mol, we have $p = RT/V$. Thus the adiabatic curve is represented by $TV^{\gamma-1}$ = a constant. In fact, the constant is given by $T_h V_B^{\gamma-1}$. This allows us to determine V_C when the temperature is T_c. Step IV is the same kind of curve. Here $TV^{\gamma-1} = T_h V_A^{\gamma-1}$. This allows us to determine V_D at the lower temperature.

▲ **FIGURE 20–7** The Carnot cycle plotted on a T–V diagram.

20–4 Other Types of Engines

Any closed curve in the p–V diagram represents some sort of engine in the sense that the enclosed area represents work done by the engine, and the fact that the curve is closed implies that it can work in a cycle. Some of these curves represent, or at least approximate, real, functioning engines. To illustrate how one determines their efficiency, we consider a particularly interesting example, the Stirling engine.



The Stirling Engine

As an example of a reversible non-Carnot cycle, consider the ideal Stirling cycle (Fig. 20–8), and compare this cycle to the Carnot cycle in Fig. 20–5a. Steps I and III are isothermal steps, just as in the Carnot cycle. The adiabatic steps of the Carnot cycle, however, are replaced by changes in pressure and temperature that maintain a constant volume. No work is done during the constant-volume steps. However, because the temperature changes, the internal energy also changes so that, by the first law of thermodynamics, there is a heat flow to or from the working gas of the engine during the constant-volume steps. This heat flow occurs at decreasing temperatures during step II and at increasing temperatures during step IV. It is as though a series of ever colder thermal reservoirs enter into step II and ever hotter thermal reservoirs enter into step IV. Increasingly, hotter fuel must be used throughout step IV. Under these conditions, we note that the efficiency of an engine is really a measure of the work done for the total fuel burned; thus the denominator of the efficiency should be the entire positive heat flow to the thermal system, which we write as Q_{pos}.

In the subsection immediately below we work out the efficiency of the ideal Stirling engine, η_S, when the working fluid is 1 mol of an ideal gas. We find that

$$\eta_S = \frac{W}{Q_{\text{pos}}} = \frac{R(T_h - T_c)\ln(V_2/V_1)}{RT_h \ln(V_2/V_1) + C_V(T_h - T_c)}. \tag{20–8}$$

This result would be the corresponding Carnot efficiency if it were not for the term proportional to C_V in the denominator (due to step IV). Because this extra term is positive, the denominator of η_S is greater than the denominator of η_C, and thus *the efficiency of the Stirling cycle is less than that of the Carnot cycle.*

▲ **FIGURE 20–8** The ideal Stirling cycle. There is a positive heat flow to the engine in steps I and IV, and a heat flow from the engine in steps II and III. This cycle was described by Robert Stirling almost 20 years before Carnot discussed his own ideas. The engine Stirling patented in 1816 may be useful in outer space and under other conditions and has become the subject of active engineering work.

How to Get the Efficiency of the Stirling Engine

We assume that the working gas in a Stirling engine is ideal. We need the total positive heat flow $Q_{\text{pos}} = Q_{\text{I}} + Q_{\text{IV}}$ as well as W, the work done during one cycle (Fig. 20–8). During step I, the temperature is constant and $\Delta U = 0$. Thus, by the first law of thermodynamics, the heat flow to the engine is the work done during the transformation:

$$Q_{\text{I}} = W_{\text{I}} = \int_{V_1}^{V_2} p\,dV = RT_h \int_{V_1}^{V_2} \frac{dV}{V} = RT_h \ln\left(\frac{V_2}{V_1}\right).$$

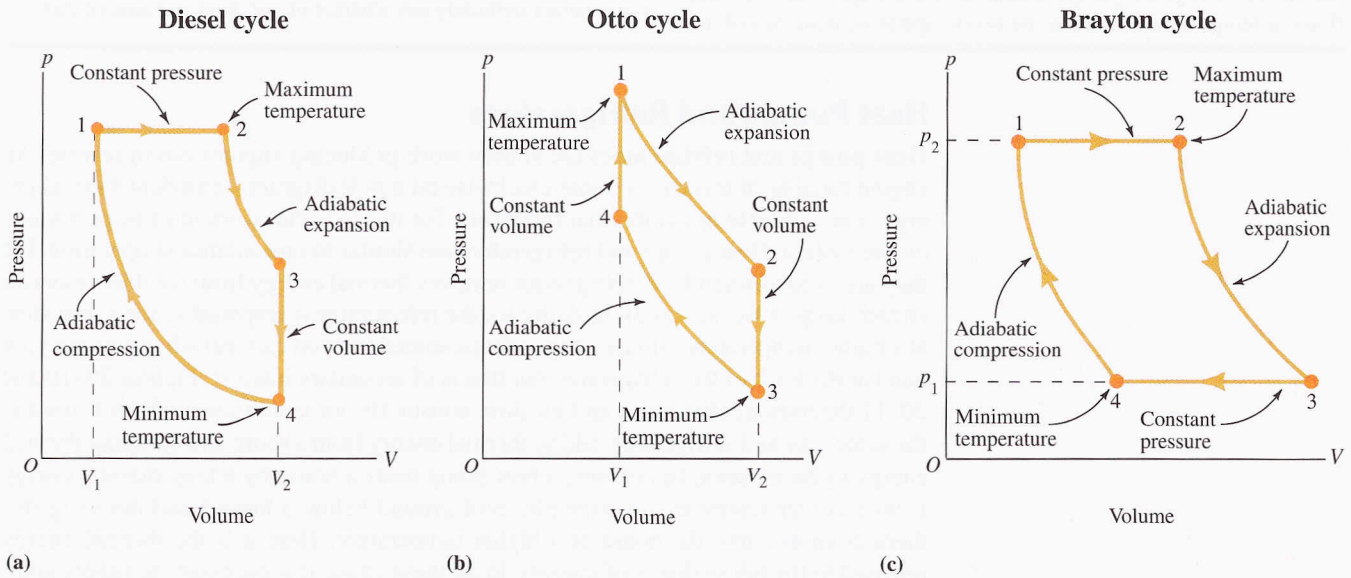
According to the first law, the heat flow to the engine during step IV is the change in internal energy $U(T_h) - U(T_c)$ because no work is done by the engine during this portion of the cycle. Thus

$$Q_{\text{IV}} = U(T_h) - U(T_c) = C_V \times (T_h - T_c).$$

Combining these two equations, we see that the total heat flow to the engine is

$$Q_{\text{pos}} = Q_{\text{I}} + Q_{\text{IV}} = RT_h \ln\left(\frac{V_2}{V_1}\right) + C_V \times (T_h - T_c).$$

The total work done in the cycle is the area enclosed by the cycle on the p–V diagram:



$$W = W_{\text{I}} + W_{\text{III}} = RT_h \ln\left(\frac{V_2}{V_1}\right) + RT_c \ln\left(\frac{V_1}{V_2}\right) = RT_h \ln\left(\frac{V_2}{V_1}\right) - RT_c \ln\left(\frac{V_2}{V_1}\right)$$

$$= R(T_h - T_c) \ln\left(\frac{V_2}{V_1}\right).$$

The efficiency of this cycle, W/Q_{pos}, is then given by Eq. (20–8).

Other Engines and Their Efficiencies

In addition to the Stirling cycle there are other reversible cycles that represent idealized (friction ignored) versions of real engines. A short list would include the Diesel cycle (Fig. 20–9a), which as you know is used in many different settings; the Otto cycle (Fig. 20–9b), which is very close to an automobile engine; and the Brayton cycle (Fig. 20–9c). Even ignoring friction, these cycles are inherently less efficient than the Carnot cycle for given temperature extremes. With friction, which is always present in real engines, the efficiency is reduced still further. A more detailed treatment of these cycles and their efficiency can be found within the end-of-chapter problems.

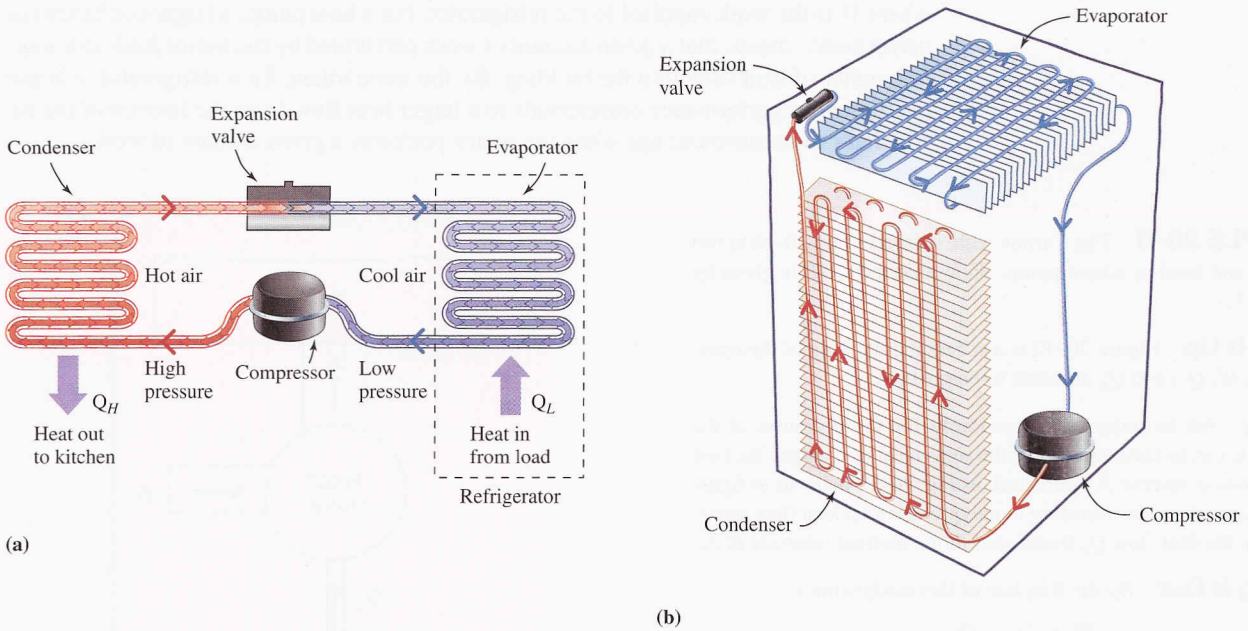
▲ **FIGURE 20–9** (a) The Diesel cycle, for the engine patented by Rudolf Diesel in 1892. (b) The Otto cycle, for the engine designed by Nikolaus Otto in 1876. (c) The Brayton cycle, named for George B. Brayton.

There is a way to decompose an arbitrary reversible cycle into a series of Carnot cycles operating at intermediate temperatures that allows one to prove that any non-Carnot cycle (even if it is reversible) that operates between two temperature extremes T_h and T_c is less efficient than the Carnot cycle that operates between those same temperatures. While we won't work this out in detail, we point out that a Carnot cycle is more efficient if the two temperatures are farther apart. An arbitrary reversible cycle is approximated by Carnot cycles operating at intermediate temperatures and therefore involves a decrease in efficiency.

THINK ABOUT THIS . . .

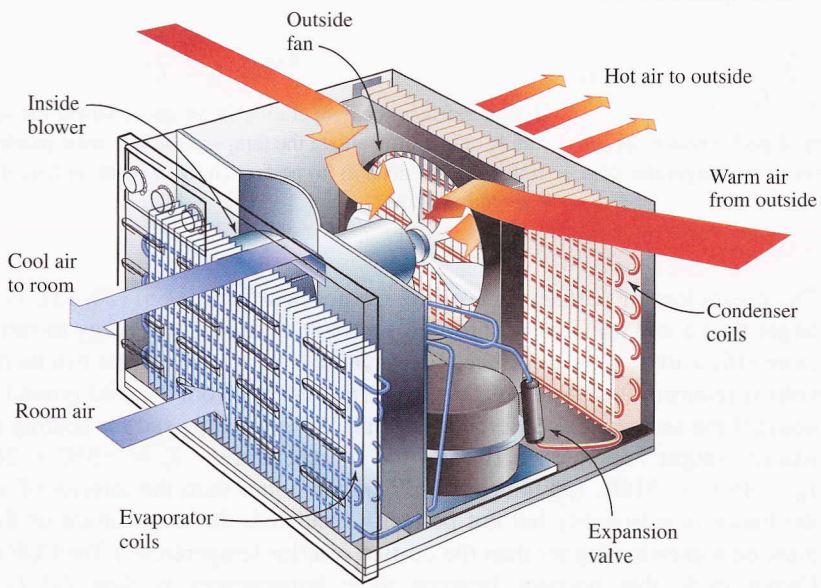
WHY IS IT SO HARD TO MAKE AUTOMOBILE ENGINES THAT DON'T POLLUTE?

From the end of the 1960s the U.S. government has been requesting that the efficiency of internal combustion engines be improved and air pollution reduced. Automobile engines of that period used an excess of fuel and the residue of unburnt hydrocarbons was a significant pollution source. The pollution problem was alleviated by adding air to the products of combustion as they left the engine's cylinder, thereby burning them. But, how is engine efficiency improved? The easiest way to accomplish this is to increase the maximum temperature at which the fuel is burned. But a higher temperature leads to a secondary reaction: the oxidation of the nitrogen in the added air, and the resulting oxides of nitrogen add very significantly to "acid rain" problems. Thus the government-mandated increase in efficiency resulted in a new pollution problem. The solution to this inherent conflict of efficiency and pollution is a complex one, involving recycled gases and catalysts, and it is not yet completely resolved. This area presents problems whose solution involves physics, chemistry and engineering. In the meantime, although we do have more efficient engines than in recent decades, some of us choose to drive oversized vehicles, and we are back in an era of vehicles that consume excessive amounts of fuel.



CONCEPTUAL EXAMPLE 20–5 The efficiency of a certain engine is half that of a Carnot engine operating between the same temperature extremes. Does that mean that there is an element of irreversibility in the working of the engine?

Answer An engine with an efficiency smaller than that of the Carnot cycle can differ from the Carnot cycle in two ways. First, the path traced out in a p–V diagram may not have the form of the Carnot cycle (two isothermal transformations and two adiabatic transformations), even though the path is reversible. These engines involve heat flows at temperatures between the two temperature extremes of the Carnot cycle and are in principle always less efficient than the Carnot cycle. This makes sense if we consider the fact that Carnot cycles themselves are more efficient when the two temperatures between which they work are larger. When one brings in intermediate temperatures, as for these "other" engines, the efficiency drops. Second, real engines generally involve some friction (that is, some irreversibility), and as you might expect this leads to less efficiency. But without knowing more details about the engine we cannot say which of these effects is the reason for the loss of efficiency, so we cannot definitely say whether or not there is irreversibility.



Heat Pumps and Refrigerators

Heat pumps and **refrigerators** are simply work-producing engines run in reverse. An engine running in reverse—counterclockwise on a p–V diagram—transfers thermal energy from colder to hotter thermal reservoirs. For this to occur, work must be performed *on* the system. Heat pumps and refrigerators are similar to one another in operation, but they are used differently. A refrigerator removes thermal energy from a colder reservoir (which keeps a freezer cold). In doing so, the refrigerator is responsible for a heat flow at a higher temperature into its surroundings, something you can feel when you put your hand at the back of the refrigerator, but that is of secondary interest. Figures 20–10 and 20–11 diagram a refrigerator and its close cousin, the air conditioner, which is used in the same way as a refrigerator, taking thermal energy from a room and dumping thermal energy to the exterior. In contrast, a heat pump heats a house by taking thermal energy from a colder reservoir (for example, cool ground below a house) and dumping this thermal energy into the house at a higher temperature. Here it is the thermal energy released to the house that is of interest. In all these cases, it is necessary to supply additional energy through the performance of work on the thermal system.

We can analyze heat pumps or refrigerators by the same method that we used to analyze heat engines. Because of the different ways these devices are used, their

▲ **FIGURE 20–10** (a) Diagram of how a refrigerator operates. A compressor, which is typically operated by electrical energy, does work on the working fluid (freon or an environmentally acceptable substitute) by compressing it, thereby raising its temperature. That thermal energy is released by thermal contact to the exterior of the refrigerator at the coils, and the working fluid is allowed to expand (at the expansion valve) to reduce its temperature. Again thermal contact with the interior of the refrigerator at the evaporator then cools the interior of the refrigerator, and the cycle repeats. (b) The condenser coils are normally on the back of the refrigerator and the compressor coils inside where we want it to be cold.

◀ **FIGURE 20–11** Diagram of a room air conditioner, whose operation follows the steps described for the refrigerator.

efficiencies are defined differently. For a heat pump, where the total positive heat flow rejected from the pump into a building, Q_{rej}, is of interest, we use the *coefficient of performance COP*, which is defined as

$$COP \equiv \frac{Q_{\text{rej}}}{W}, \tag{20–9}$$

where W is the total work that must be supplied in one cycle. For a refrigerator, where we are interested in the total positive heat flow absorbed from the interior of the refrigerator, Q_{abs}, the coefficient of performance K_{ref} is defined by

$$K_{\text{ref}} \equiv \frac{Q_{\text{abs}}}{W}, \tag{20–10}$$

where W is the work supplied to the refrigerator. For a heat pump, a larger coefficient of performance means that a given amount of work performed by the motor leads to a larger transfer of heat flow into the building. By the same token, for a refrigerator, a larger coefficient of performance corresponds to a larger heat flow from the interior of the refrigerator to its surroundings when the motor performs a given amount of work.

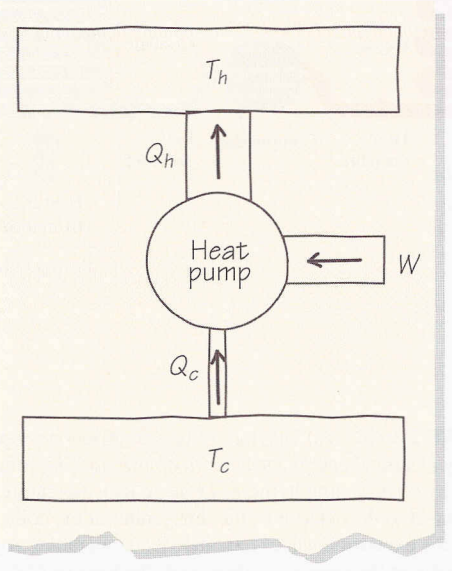
EXAMPLE 20–6 The Carnot cycle shown in Fig. 20–5a is run in reverse and used as a heat pump. Show that the *COP* is given by $T_h/(T_h - T_c)$.

Setting It Up Figure 20–12 is a schematic drawing of the operation, with W, Q_c, and Q_h all taken to be positive.

Strategy All formulas given previously for the operation of the Carnot cycle can be used, except that the signs must be changed because the cycle runs in reverse. A figure such as Fig. 20–12 helps us to figure out these signs. It is also necessary to interpret the total heat flow rejected, Q_{rej}, as the heat flow Q_h transferred to the thermal reservoir at T_h.

Working It Out By the first law of thermodynamics,

$$W = Q_h - Q_c,$$



so *COP* is given by

$$COP = \frac{Q_h}{Q_h - Q_c} = \frac{1}{1 - (Q_c/Q_h)},$$

according to Eq. (20–9). The ratio Q_c/Q_h is, in fact, the ratio of temperatures for any Carnot cycle—see Eq. (20–4) and the accompanying discussion. It is not important that the signs of the heat flows are reversed because we use only the ratio of these quantities. With $Q_c/Q_h = T_c/T_h$, we find

$$COP = \frac{1}{1 - (T_c/T_h)} = \frac{T_h}{T_h - T_c}. \qquad (20\text{–}11)$$

What Do You Think? The coefficient of performance, as defined in Eq. (20–10), for a Carnot cycle run as a refrigerator (see Problem 26) is given by

▲ **FIGURE 20–12** The Carnot cycle operated as a heat pump.

$$K_{\text{ref}} = \frac{T_c}{T_h - T_c}. \qquad (20\text{–}12)$$

If your refrigerator is operating in an igloo, where the air temperature is only a little above the temperature you want inside the refrigerator, do you need to (a) perform a lot of work, or (b) little work for a given heat flow?

The coefficient of performance of the Carnot heat pump, Eq. (20–11), is a number larger than 1 and it increases, or improves (you are using the energy to run the pump more efficiently), if the difference between the temperatures of the two thermal reservoirs is reduced: It is easier to transfer thermal energy from the cold ground to a warm house if the temperature difference is small. A heat pump used for heating a house in winter might operate between the temperatures $T_c = -5°\text{C} = 268\text{K}$ and $T_h = 45°\text{C} = 318\text{K}$. (Although 45°C is much hotter than the interior of a house, if the house is reasonably but not perfectly insulated, the temperature of the exhaust must be somewhat higher than the desired interior temperature.) The COP of an ideal Carnot cycle that operates between these temperatures is then $T_h/(T_h - T_c) = (318\text{K})/(50\text{K}) = 6.36$. In contrast, a commercial heat pump that operates between the temperatures 45°C and −5°C has a COP that is only about half this value.

20–5 Entropy and the Second Law

In Section 20–1 we argued that the direction of spontaneous processes as well as the ability to extract thermal energy and use it to do work had something to do with the random nature of thermal energy and with the relative probability of certain states. Here we will find a way to measure the degree of disorder: the entropy. We will in fact start with a thermodynamic approach and use the Carnot cycle to identify entropy as a new ther-

modynamic variable. This variable is like internal energy in that it is a function of state. On a macroscopic level, we will see that the entropy is a measure of the energy unavailable to do useful work. By understanding entropy on a microscopic level, we will make the connection back to disorder and the role of probability.

Entropy as a Thermodynamic Variable

In a Carnot cycle, the efficiency, defined by $1 - (Q_c/Q_h)$, is given by Eq. (20–7): $\eta_C = 1 - (T_c/T_h)$. Thus Q_c/Q_h must equal T_c/T_h [see Eqs. (20–3) and (20–4)]. This relation can be expressed as

$$\frac{-Q_c}{T_c} + \frac{Q_h}{T_h} = 0. \tag{20–13}$$

Recall that Q_c is the heat flow from the Carnot engine to the cold thermal reservoir. The expression $-Q_c$ in the first term of Eq. (20–13), minus sign and all, is then the heat flow to the engine at the cold temperature, just as Q_h is the heat flow *to* the engine at the high temperature. The implication of all of this is that for the entire Carnot cycle, made of a series of steps on the p–V diagram,

$$\sum_i \frac{Q_i}{T_i} = 0, \tag{20–14}$$

where the index i labels the steps and where we always regard the heat flow as the heat flow *to* the engine. We will now show that this is a more general property of thermal systems going through reversible transformations, not just a particular property of the Carnot cycle. Our demonstration lacks in generality only in that it assumes that we are operating with an ideal gas. Consider the integral $\int_A^B \frac{dQ}{T}$ between any two points A and B on a p–V diagram. Then, working with one mole of gas,

$$\begin{aligned}\int_A^B \frac{dQ}{T} &= \int_A^B \frac{dU + pdV}{T} = \int_A^B \frac{C_V\, dT}{T} + \int_A^B R\frac{dV}{V} \\ &= (C_V \ln T_B + R \ln V_B) - (C_V \ln T_A + R \ln V_A).\end{aligned} \tag{20–15}$$

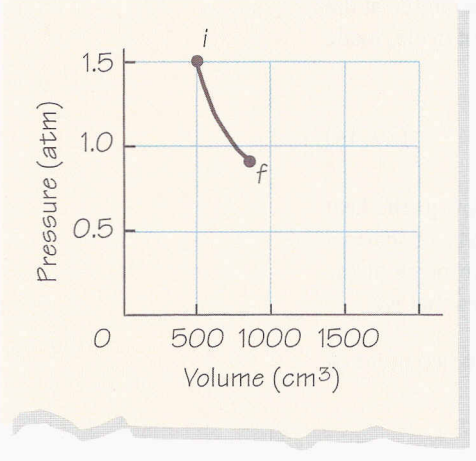
In the first step we have used the first law of thermodynamics; to evaluate the temperature integral we have used the fact that C_V is independent of T. Equation (20–15) implies that the value of the integral depends only on the initial and final values of the variables, and not on the path along which the integral is evaluated. This property of the integral in fact holds even if the working fluid is not an ideal gas. This implies that there is a state function S which, like the internal energy U, depends only on the state of the gas, and not on how it reached that state. This state function is called the **entropy** of the system. It is precisely defined by

$$S(B) - S(A) = \int_A^B \frac{dQ}{T}. \tag{20–16}$$

This immediately leads to the generalization of (20–15),

$$\oint \frac{dQ}{T} = 0, \tag{20–17}$$

CLAUSIUS' THEOREM



for a reversible cycle. The circle placed on the integral is a reminder that the integral is taken over a cycle, i.e. a closed path. This result is known as **Clausius' theorem**. A mathematical way of expressing our result is to say that dS, defined by

$$dS = \frac{dQ}{T}, \tag{20–18}$$

is a perfect differential for any reversible transformation: its integral between two points is the difference of a function of each point, so that the integral over a closed path trip, for which the initial and final points are identical, vanishes. This statement also applies to dU but not to dQ.

EXAMPLE 20–7 Calculate the entropy change of 1.0 mol of an ideal gas that undergoes an isothermal transformation from an initial state of pressure 1.50 atm and volume 500 cm^3 to a final state of pressure 0.90 atm. (Being able to find the entropy change in ideal gases will help us later to understand the connection between entropy and chaos on the microscopic scale.)

Setting It Up Figure 20–13 includes the isothermal curve for this transformation and labels the initial and final points i and f as well.

▲ **FIGURE 20–13** An isothermal change of state.

Strategy The specified path is one of constant temperature, so the integral of dQ/T along the specified path is $(1/T)$ times the integral of dQ along the path. By the first law we can write $dQ = dW + dU$, and since for an ideal gas thermal energy is a function of temperature only (that is, $dU = 0$ along this path), we have $dQ = dW = pdV$. For an ideal gas $pV = nRT$ so that $p = nRT/V$ and therefore $dS = \frac{1}{T}dQ = \frac{1}{T}\left(\frac{nRT}{V}dV\right) = nR\frac{dV}{V}$. This can be integrated between the limits. We are lacking the final volume V_f, but since the temperature is fixed, we can use $p_iV_i = p_fV_f$ to replace V_f with known quantities.

Working It Out The change in the entropy ΔS is

$$\Delta S = nR\int_{V_i}^{V_f}\frac{dV}{V} = nR\ln\frac{V_f}{V_i}.$$

Using $V_f/V_i = p_i/p_f$ this reads

$$\Delta S = nR\ln\frac{p_i}{p_f} = (1.0\text{ mol})(8.3\text{ J/mol}\cdot\text{K})\ln\frac{1.5\text{ atm}}{0.90\text{ atm}} = 4.2\text{ J/K}.$$

Note that we did not need the value of the initial volume of the gas to get the answer.

What Do You Think? What is the entropy change if the transformation from the initial state to the final state is accomplished in two steps: a first step at constant volume as the pressure drops from 1.50 atm to 0.90 atm, followed by an isobaric transformation with the volume increasing from 500 cm^3 to the final volume of the example?

How Entropy Changes for Irreversible or Spontaneous Processes

Irreversible processes (processes with friction, for example) lead to increased inefficiency in any otherwise reversible engine. We'll now see what friction or other irreversibilities imply for heat flows to such a cycle. We start by looking again at efficiency, which for an arbitrary cycle is

$$\eta = \frac{W}{Q_{\text{abs}}} = 1 - \frac{Q_{\text{rej}}}{Q_{\text{abs}}},$$

where Q_{rej} is the total heat flow rejected by the cycle and Q_{abs} is the total heat flow absorbed. We have used the relation $W = Q_{\text{abs}} - Q_{\text{rej}}$ from the first law of thermodynamics. Each of these heat flows is positive.

The efficiency is reduced if $Q_{\text{rej}}/Q_{\text{abs}}$ gets bigger, and this can happen in two ways. First, reduce the denominator Q_{abs}, the heat flow *to* the system. Second, increase the numerator Q_{rej}, the heat flow *out* of the system. But an algebraic increase of Q_{rej} is the same as an algebraic decrease of $-Q_{\text{rej}}$, and $-Q_{\text{rej}}$ can be interpreted as heat flow *to* the system. Both ways of reducing the efficiency boil down to reducing the heat flow *to* the system. In other words, anything that causes the *algebraic sum* of the heat flows into the system to decrease will make the engine less efficient. But this is exactly the effect of irreversibilities that occur anywhere along the cycle. For example, in a real automobile engine, there is heat flow to the exhaust, but there is additional heat flow out (less heat flow in) due to the heating of the pistons and other parts of the engine. Broadly speaking, all irreversibilities

cause the algebraic heat flow to the system to be reduced. More heat flow out is equivalent to less heat flow in. That means less energy to do work, and hence less efficiency.

What is the effect of a reduction in the heat flow to the system on Clausius' theorem, Eq. (20–17)? In that integral, dQ represents the differential flow to the system, so the integral will be be decreased. We can say that *for an irreversible cycle* (one with any element of irreversibility),

$$\oint \frac{dQ}{T} < 0. \tag{20–19}$$

This result is known as **Clausius' inequality**.

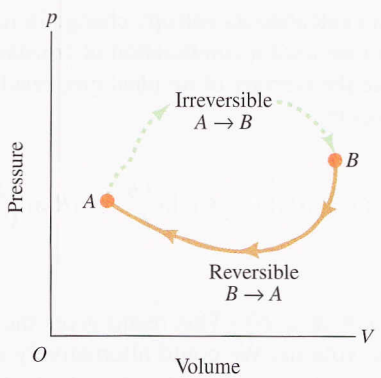
Equations (20–17) and (20–19) can be combined into

$$\oint \frac{dQ}{T} \leq 0. \tag{20–20}$$

CLAUSIUS' THEOREM AND INEQUALITY

The equality, Clausius' theorem [Eq. (20–17)], applies for a reversible path; the inequality applies when the transformations include any irreversibility.

Now we can use Equation (20–20) to learn about entropy changes in irreversible transformations. Consider the cycle shown in Fig. 20–14, in which leg $A \rightarrow B$ is irreversible. From Eq. (20–20),



$$0 > \oint \frac{dQ}{T} = \int_{A}^{B}{}_{\text{irrev}} \frac{dQ}{T} + \int_{B}^{A}{}_{\text{rev}} \frac{dQ}{T}.$$

The second term on the right-hand side of this equation is given by $S(A)$–$S(B)$ because it is taken over a reversible path. When we move this quantity to the left-hand side, we find that

$$S(B) - S(A) > \int_{A}^{B}{}_{\text{irrev}} \frac{dQ}{T}. \tag{20–21}$$

Thus *the difference in entropy between two points is greater than the integral of dQ/T over an irreversible change*.

How do we compute the increase in entropy when there is an irreversible transformation from thermodynamic state A to thermodynamic state B? We have seen that entropy is a function of state, so we can compute the change $S(B)$–$S(A)$ by any means we like; that is, *we can use a reversible path to find the change in entropy as long as that path connects the two given states*. We will illustrate this procedure in Section 20–6.

▲ **FIGURE 20–14** A cycle that contains an irreversible path from A to B and a reversible path from B back to A.

The Entropy of an Isolated System Never Decreases

In any reversible process in which there is no heat flow—an adiabatic process—the change in entropy will be zero. If there is no heat flow, but there are irreversible processes, then the entropy increases. That is because with no heat flow, the right-hand side of Eq. (20–21) is zero, and the equation reads $\Delta S > 0$. As an example, consider the free expansion of a gas from a small container into a bigger one, the entire system enclosed in Styrofoam. There is no heat flow into or out of the system, but the entropy increases. More generally a *spontaneous process in an isolated system increases the system's entropy*. Because the universe—our entire surroundings—is in contact with no other system, we say that irreversible processes increase the entropy of the universe. A consequence of this property of entropy is that the state of maximum entropy is a stable one. Once one has arrived at such a state, no further spontaneous changes can occur. (Or, more precisely, no more macroscopic changes occur—there will always be very small fluctuations about the equilibrium state, ones that are invisible on the macroscopic scale.) In other words, for an isolated thermal system *the state of maximum entropy is the state of stable equilibrium*. This is still another way to state the second law of thermodynamics. Below we are going to connect the entropy with the degree of disorder, with the direction of spontaneous processes determined by an increase in disorder. Thus what we have concluded here is that for an isolated thermal system the stable equilibrium state is the state of maximum disorder.

Sometimes you will hear people say that the existence of life is in contradiction with the second law, because living systems take thermal energy from the Sun and turn it into the order of a beautiful flower or a thinking human race that can organize parts of the entire planet. This reasoning is incorrect; a living being is not an isolated system. It is the whole system of Sun plus living creatures on Earth that is better approximated as isolated, and the entropy of this system is indeed increasing.

CONCEPTUAL EXAMPLE 20–8 Suppose you had never heard of engines, and only knew the second law of thermodynamics in the form $\Delta S \geq 0$. Is this enough to show that it is impossible to construct a device that transfers thermal energy from the ocean and converts it into an equivalent amount of work (which could be used, for example, to run the New York subways) without any other effect?

Answer The system in this case is the ocean together with wherever the thermal energy taken from it is used or dispersed. Let's denote the thermal energy taken from the ocean by Q. This implies that the reservoir, the ocean, absorbs thermal energy $-Q$. The entropy change of the ocean is therefore $\Delta S = -Q/T$. This is negative and if it were the only entropy change would violate the second law in the form $\Delta S \geq 0$. There must be entropy change somewhere else in the system, and hence there must be a heat flow somewhere else—the entire heat flow Q cannot be converted to work. The impossibility of taking heat flow and turning it into an equivalent amount of work is the Kelvin form of the second law (Section 20–2).

20–6 Entropy and Ideal Gases

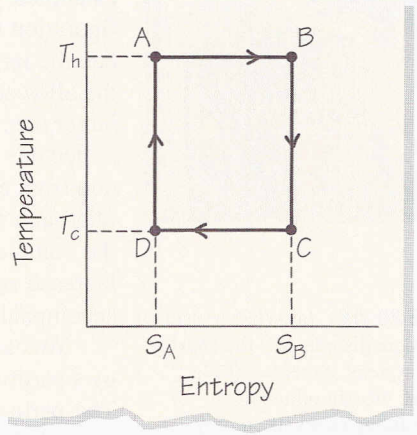
When a gas is ideal, we can calculate its entropy change in reversible transformations. We demonstrated this when we used a combination of constant-volume and isothermal transformations to calculate the entropy of an ideal gas, resulting in Eq. (20–15). That result generalized to n moles is

$$S(B) - S(A) = C_V \ln\frac{T_B}{T_A} + nR \ln\frac{V_B}{V_A}. \qquad (20\text{–}22)$$

ENTROPY OF AN IDEAL GAS

[We have used $\ln a - \ln b = \ln(a/b)$.] This result gives the entropy change in terms of the temperature and the volume. We could alternatively express it in terms of the pressure and volume by using the equation of state, which allows us to write $T_B/T_A = (p_B V_B)/(p_A V_A)$. If we additionally use $\ln(p_B V_B/p_A V_A) = \ln(p_B/p_A) + \ln(V_B/V_A)$, we find

$$S(B) - S(A) = C_V \ln\frac{p_B}{p_A} + (nR + C_V)\ln\frac{V_B}{V_A} = C_V \ln\frac{p_B}{p_A} + C_p \ln\frac{V_B}{V_A}, \qquad (20\text{–}23)$$



where we recall that $C_p = C_V + nR$ [Eq. (18–33)].

We used reversible paths to calculate the change in entropy. But because entropy is a state function, the same result obtains for *any* transformation, reversible or irreversible between the same states. In particular, we may use Eq. (20–22) to calculate the change of entropy in a free expansion of a gas at a fixed temperature, an irreversible process. Equations (20–22) and (20–23) can be used for any process whose end points can be put on any graph, be it a p–V plot, a T–V plot, or a p–T plot.

CONCEPTUAL EXAMPLE 20–9 (a) Plot the steps of a Carnot cycle on an S–T plot. (b) What is the significance of the area enclosed by the closed path thus formed in the S–T plane?

Answer (a) We shall follow the steps ABCD as in Fig. 20–5a. The S–T graph is shown as Fig. 20–15. The first step, AB, is an isothermal transformation. With our choice of vertical T axis, this is a horizontal line at $T = T_h$. The step BC is adiabatic. This means that there is no heat flow into the system and therefore the entropy does not change, and so the step is represented by a vertical line corresponding to a constant value of S—call it S_B. The next step is again isothermal so that the transformation CD is a horizontal line in the direction of decreasing S at the horizontal level of T_c. The last step, DA, is again *isentropic* (no change in entropy), so that it is represented by a vertical line at S_A.

(b) Although it is easy to find the area directly—it is just $(T_h - T_c) \times (S_B - S_A)$—the interpretation follows from an integral representation. The area under the upper horizontal line is equal to $\int_A^B T\,dS = \int_A^B T\frac{dQ}{T} = \int_A^B dQ$. The integral is taken along the T_h isotherm, and the result is the total heat flow from the higher temperature reservoir, that is Q_h. From this we must subtract the same integral along the T_c isotherm, and by the same token, the result is Q_c. The total area is therefore $Q_h - Q_c = W$, the work done. This is the same result that one finds by calculating the enclosed area in the p–V plane.

▲ **FIGURE 20–15** The Carnot cycle on an S–T plot. The area of the cycle is W, the work done.

EXAMPLE 20–10 You have 3.0 mol of an ideal gas in thermal contact with a thermal reservoir at $T = 300$K. The gas undergoes free expansion (no work is done) from 12 L to 24 L. What is the entropy change of the gas and of the universe? Repeat the exercise for an expansion from 12 L to 120 L.

Strategy The entropy change of the gas, being a state function, can be computed when the end states are known, as they are here, even if the transformation is irreversible. In this case, we can use Eq. (20–22) with fixed T. Because $\ln(1) = 0$, only the ratio of volumes is involved. What about the entropy change of the universe? To determine the entropy change in the rest of the surroundings, we must determine the heat flow to the thermal reservoir. The gas does no work in its expansion, so the heat flow out is equal to the change in internal energy. But this change is zero because the gas is ideal and because its internal energy depends only on the (unchanging) temperature. There is thus no heat flow to the thermal reservoir, and its entropy change, $\Delta Q/T$, is zero. The entropy change of the universe is therefore the entropy change of the gas. The fact that it is positive indicates that the transformation involved—in this case, free expansion—is irreversible.

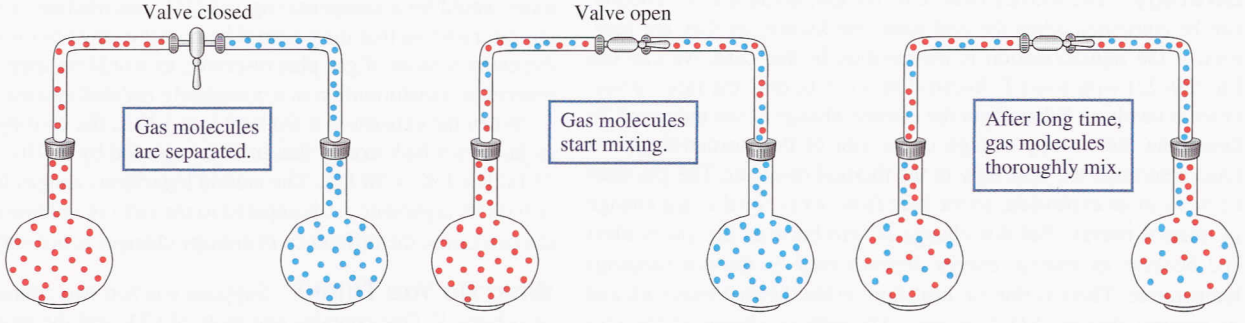
Working It Out From Eq. (20–22) with $T_B = T_A$, we find $\Delta S = nR\ln(V_B/V_A)$, so that numerically $\Delta S = (3.0\,\text{mol})(8.3\,\text{J/mol}\cdot\text{K})\ln[(24\,\text{L})/(12\,\text{L})] = (25\,\text{J/K})\ln 2 = 17\,\text{J/K}$. The entropy change of the gas, which is also the entropy change of the universe, is positive. (The numerical result would have been the same had the question dealt with an isothermal leg of a Carnot cycle. In that case there would be a compensating $-\Delta Q/T$ contribution of entropy to the reservoir, so that there would be no net change to the entropy of the entire system of gas plus reservoir, as would be appropriate to a reversible transformation in a completely isolated system.)

When the expansion is from 12 L to 120 L, the entropy change is as just described, except that $\ln(2)$ is replaced by $\ln(10)$, and $\Delta S = 25\ln(10)\,\text{J/K} = 58\,\text{J/K}$. The natural logarithm changes fairly slowly with its argument, so, compared to the ratio of volume changes in the two cases, the difference in entropy changes is not very great.

What Do You Think? Suppose you had two containers, each of volume V. One contains one mole of CO_2 and the other contains one mole of N_2O. Suppose you now connect the two containers by a tube, open the stopcock on the tube, and let the gases mix. Do you think the entropy will increase or stay the same?

(a)

(b)



▲ **FIGURE 20–16** (a) When a plate breaks, it is more disordered—the entropy of the "plate system" increases. (b) In urban renewal, the demolition of an abandoned building raises its entropy very quickly!

20–7 The Meaning of Entropy

The entropy of a system and all its surroundings—the universe—increases when an irreversible process takes place. In effect, increased entropy corresponds to a lost heat flow, and hence a lost ability to do work. The loss of heat flow represents energy that can never be turned into work because, by the nature of irreversible processes, the process cannot be reversed to recapture this heat flow without making other changes. Of course, the energy is not really lost; energy is always conserved. But it has been turned into the random motion of the microscopic constituents of the thermal system and cannot be sufficiently well "organized" to allow all of it to go into, say, lifting a weight. By organization we mean order; if all the molecules were moving in precisely the same direction, for example, they would be well ordered. They might have the same total energy as a disorganized gas, but *all* of their energy could be used to lift a weight. Any degree of irreversibility reduces our ability to do work because it increases the disorder. Let's consider this idea more closely.

We began our discussion of spontaneous processes in Section 20–1 with two examples. In one, a gas expands into an empty space, its molecules move from a configuration that has a low probability (all the molecules are in one corner) to one that has the largest possible probability (the molecules are spread uniformly throughout the allowed volume). Initially, all the molecules are confined in a small box inside a larger one. This initial state is more *ordered* than the final state because the individual molecules are more localized. A loss of order is associated with a change of the system from a state of low probability to one of higher probability. Equation (20–22) applied at a fixed temperature illustrates how entropy increases for an ideal gas when the volume increases. From this perspective entropy is a measure of disorder, and the increase of the entropy in an irreversible process is the increase in disorder that accompanies such processes (Fig. 20–16).

We can illustrate this idea quite concretely by mixing two gases initially separated by a partition (Fig. 20–17). Each gas starts out with the same temperature and pressure. The partition is opened, and the gases in the two parts mix. Before the partition is opened, the degree of order is greater: All the molecules of each gas are on their respective sides. After the partition is opened, the disorder is greater: Any one molecule is somewhere in the greater volume, rather than being on one side or the other. It is more probable that each gas will spread separately throughout the greater volume than that it will stay on its respective side. Thus, we would expect the entropy to increase when the partition is opened, which is in line with the idea that the mixing of the two sides is an irreversible process. This increased entropy is the **entropy of mixing**, illustrated quantitatively in the example below.

▲ **FIGURE 20–17** (a) Two gases are initially unmixed. (b) A valve is opened, and each gas diffuses into the other's flask. (c) The final state is more disordered than the initial state. The system's entropy has increased.

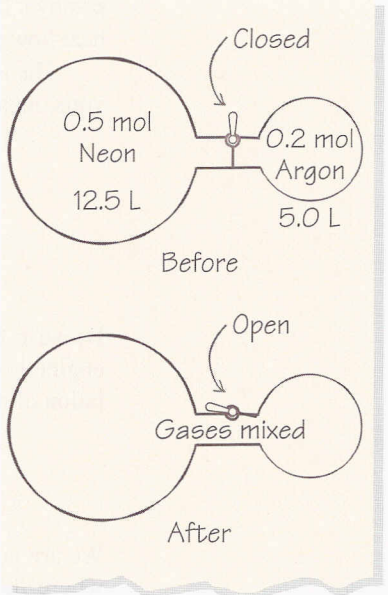
EXAMPLE 20–11 A quantity of 0.20 mol of argon gas contained in a volume of 5.0 L mixes with 0.50 mol of neon gas contained in a volume of 12.5 L, making a total volume of 17.5 L. Both gases are at the same temperature and can be regarded as ideal. Each volume is thermally isolated. What is the change in entropy?

Setting It Up We draw the situation in Fig. 20–18, showing the situation before and after mixing.

Strategy The gases start at the same temperature, and they will be at that same temperature after expansion. Only their volumes will have changed. Each will then have an entropy change given by Eq. (20–22) with the temperature term absent, $\Delta S = nR \ln(V_f/V_i)$. This applies for the two gases separately, and to find the total entropy change we add the results.

Working It Out We have

$$\Delta S_{Ar} = (0.20 \text{ mol})(8.3 \text{ J/mol} \cdot \text{K}) \ln[(17.5 \text{ L})/(5.0 \text{ L})]$$
$$= (1.7 \text{ J/K}) \ln 3.5 = 2.1 \text{ J/K}$$



and

$$\Delta S_{Ne} = (0.50 \text{ mol})(8.3 \text{ J/mol} \cdot \text{K}) \ln[(17.5 \text{ L})/(12.5 \text{ L})]$$
$$= (4.2 \text{ J/K}) \ln 1.4 = 1.4 \text{ J/K}$$

The entropy of mixing is the sum of the increases of entropy of the two gases, so that

$$\Delta S = \Delta S_{Ar} + \Delta S_{Ne} = 3.5 \text{ J/K}.$$

What Do You Think? Is it possible to arrange things so that the two gases, originally in the separate containers described above, spontaneously pass into a common container whose volume is 3.0 L?

▲ **FIGURE 20–18** The neon and argon gases mix when the valve is opened. What happens to the entropy?

The second example of a spontaneous process described in Section 20–1 was the fact that ice cubes melt when they are placed in hot tea. We also interpret this case, and more generally the fact that systems with different temperatures tend to the same intermediate temperature when they are placed in thermal contact in terms of an increase in disorder. In this case, the more ordered system is the cooler one. On average, the velocity vectors of the molecules of steam at a lower temperature are confined to a smaller range than are those of steam at a higher temperature. The heated system is more disordered because, on average, the velocity vectors spread over a greater range. Equation (20–22), this time applied for changing temperature but constant volume, describes how entropy increases for an ideal gas when temperature changes. More advanced treatments of statistical physics quantify the idea that entropy is a measure of disorder. We have already described how the thermodynamic approach connects entropy change to the second law. Here we claim that entropy change is associated with an increase in disorder. We draw the conclusion that the second law follows from the interpretation of entropy as disorder. In fact, a more rigorous treatment than we can perform here confirms this: *All the consequences of the second law of thermodynamics follow from the treatment of entropy as a measure of disorder.*

Engines and Entropy

The principle that entropy never decreases is a way of formulating the second law of thermodynamics that emphasizes the directionality of thermal processes. The application of this formulation to engines is less obvious because the entropy in a reversible cycle does not change. Here (see also Conceptual Example 20–8) we show how the entropy formulation of the second law applies to engines and leads to our earlier formulations of the second law.

Consider a thermal reservoir at temperature T_h. Can we construct an engine that, in a single cycle, extracts thermal energy through a (positive) heat flow Q_h from that reservoir to lift a weight and does nothing else? Let's suppose that we could do so. There is no change in the entropy of the weight that has been lifted and there is no change in the engine after a full cycle. Thus, in the isolated system that consists of the weight, the engine, and

the reservoir, the only entropy change is that of the reservoir, as given by $\Delta S = -Q_h/T_h$. This entropy change is negative and therefore violates the entropy formulation of the second law. We deduce that in order to satisfy the entropy formulation of the second law, there must be a second thermal reservoir (at temperature T_c) such that the net entropy change is positive. If this second reservoir is to have a positive entropy change, then there must be a heat flow Q_c into it. This gives rise to an entropy change $\Delta S' = Q_c/T_c$.

The isolated system, which now consists of the weight, the engine, and the two reservoirs, must satisfy the entropy formulation of the second law, namely $\Delta S + \Delta S' \geq 0$, or

$$-\frac{Q_h}{T_h} + \frac{Q_c}{T_c} \geq 0;$$
$$\frac{Q_c}{Q_h} \geq \frac{T_c}{T_h}.$$

Because the work done to lift the weight is $W = Q_h - Q_c$ and the efficiency of the engine is defined as $\eta \equiv W/Q_h = (Q_h - Q_c)/Q_h = 1 - (Q_c/Q_h)$, the entropy formulation of the second law leads to

$$\eta \leq 1 - \frac{T_c}{T_h}.$$

We are now on familiar ground. The equality applies for the reversible Carnot cycle, where there is no heat flow except at the two temperature extremes. In this case, ΔS_{tot} is zero, which requires that $(Q_c/Q_h) = (T_c/T_h)$, and the efficiency is $\eta = 1 - (T_c/T_h)$. For cycles with irreversibility, or for cycles such as the Stirling cycle in which there is heat flow at intermediate temperatures, the inequality sign holds. Thus, the entropy formulation of the second law implies that the Carnot engine is the most efficient type of engine.

We have now connected the two apparently dissimilar aspects of the second law of thermodynamics: the impossibility of constructing a perfectly efficient engine and the inevitable direction of spontaneous processes.

Order, Entropy, Probability, and the Arrow of Time

The title of this subsection carries all the catchwords that are associated with the second law of thermodynamics. Entropy as a state function was introduced through our study of engines, and the quantitative definition as given in Eq. (20–16) allowed us to learn how it changed in irreversible processes. There are other irreversible processes that do not involve thermodynamics. An example is a deck of cards arranged in order [4 aces, 4 kings, 4 queens, ... 4 threes and 4 twos]. We would call this an arrangement that has a great deal of *order* in it. Shuffle the deck. The order will be lost. Shuffle it over and over again, and different arrangements will appear, but order, as defined by the initial arrangement, will not reappear. We may say that the process of shuffling a deck leads to an *irreversible* loss of order. Can we apply the idea of entropy to such a process? One would expect that it should be possible, because the shuffling of the deck of cards bears some resemblance to what happens to molecules initially confined to a small box. When the lid of the small box is opened and the molecules are allowed to escape into a larger box that contains the small one, the system becomes much more disorderly. One would have a harder time finding a particular molecule in the larger box than in the confines of a smaller one. Furthermore, the process is irreversible: It is extremely improbable that all the molecules would go back into the small box. Common sense tells us that if the volume of the small box is 1/10 of the large one, then roughly 10% of the molecules might be found in the small one, but never 100% of them. What do the cards and the molecules have in common? In this context it is the notion of probability. We already saw in Chapter 19 that the kinetic theory of gases relies on probabilities through distributions which allow us to calculate the temperature as the average kinetic energy of molecules and relate pressure to the average momentum transfer to the walls of a container.

In fact, Boltzmann discovered a deep relationship between entropy and probability. We can give a hint of how this relationship works out by considering the very simple model of the small open box inside a large box, with molecules in the large box. If the small box has volume V_A and the large box containing it has volume V_B, the chance of a particular molecule being in the small box is V_A/V_B. A second molecule, independent of the first one, will have the same chance V_A/V_B of being found in the small box. This means that the chance of both of them being in the small box is $(V_A/V_B)^2$. With three molecules, the chance of all three being in the small box is $(V_A/V_B)^3$ and so on. Thus with n moles of gas, nN_A molecules, the probability of all of them being in the small box is $(V_A/V_B)^{nN_A}$. We are using the fact that probabilities for independent events multiply. But as we saw in Example 20–11, entropies add. How can we bring these facts together? If we have the relation $P_{12} = P_1 \times P_2$, then we can make this into an additive relation by taking logarithms of both sides: $\ln(P_{12}) = \ln(P_1) + \ln(P_2)$.

Apply this to the full set of molecules. The natural logarithm of $P = (V_A/V_B)^{nN_A}$ yields

$$\ln(P) = nN_A \ln(V_A/V_B).$$

Let us compare this with the change in entropy [Eq. (20–22)] in letting an ideal gas escape spontaneously (that is, without a change in temperature) from a volume V_A into a larger volume V_B. We found

$$S(B) - S(A) = nR \ln(V_B/V_A).$$

Taking into account that $R = kN_A$, where k is Boltzmann's constant and comparing the entropy calculation with the logarithm of the probability, we have the relation

$$\Delta S = k \ln(1/P) = -k \ln P. \qquad (20–24)$$

This relation between entropy and probability is in fact quite general, and it allows us to extend the notion of entropy to all processes in which irreversible changes occur.

The *arrow of time* is the name given to the universal appearance of directionality in processes in the world. This directionality is associated with the higher probability of a disordered state relative to an ordered state. Figure 20–16 dramatizes this directionality. A few boxes of TNT and an abandoned building represent a much more ordered state than the one that appears after the explosion. As we mentioned when we first discussed spontaneous processes, the indications of an arrow of time all around us is not in contradiction with the reversibility of the fundamental laws of nature at a microscopic level.

The elementary forces between the microscopic constituents of matter are, with one very tiny exception discussed in Chapter 45, indifferent to the direction of time, or *invariant under time reversal*. In other words, aside from the exception, this invariance applies to all the fundamental forces in nature, including the electromagnetic forces that govern the collisions of gas molecules. Nevertheless, we have seen that there is a preferred direction of time—an **arrow of time**—in which dropped eggs break rather than reassemble and leap up. Spontaneous processes, in which entropy increases, proceed in one direction and not the other.

We have learned that the reason is statistical. It is not against any physical laws for a broken egg to reassemble itself. It is just so unlikely that it would never happen in many lifetimes of the universe. The overwhelming majority of collisions between gas molecules lead to more disordered situations. The arrow of time expresses not a definite preferred direction of time in a fundamental sense but an overwhelming likelihood that out of a random sequence of microscopic interactions, less ordered situations will result. Irreversibility means only that the spontaneous reversal of the "irreversible" process is so unlikely as not to be worth considering.

Summary

The second law of thermodynamics limits the efficiency of cyclic engines and governs the direction of spontaneous processes in thermal systems. Cyclic engines do work in repeated cycles by extracting a heat flow from hotter external systems, converting part of that heat flow into work, and rejecting a heat flow to cooler thermal systems. The efficiency of such an engine is defined by

$$\eta \equiv \frac{W}{Q_h}, \tag{20–1}$$

where W is the work done in one complete cycle and Q_h is the total positive heat flow the cycle extracts from its sources of fuel.

Two equivalent ways to state the second law of thermodynamics are the Kelvin form and the Clausius form. Each of these emphasizes the role of engines and thermodynamic processes. The Kelvin form states that it is impossible to convert thermal energy from a body at a given temperature into an equivalent amount of mechanical work with no other effect; the Clausius form states that it is impossible to transfer thermal energy from a colder body to a hotter body with no other effect.

In the Carnot cycle, which involves four reversible steps that occur at just two temperatures, a working fluid undergoes alternate adiabatic and isothermal transformations. It is the most efficient cycle possible that operates between two temperatures T_h and T_c. No matter what the nature of the working fluid, the efficiency of the Carnot engine is

$$\text{for any Carnot cycle: } \eta_C = 1 - \frac{T_c}{T_h}. \tag{20–7}$$

The Carnot cycle that operates between two temperatures is more efficient than any other cycle that operates between the same temperature extremes. Any element of irreversibility also decreases the efficiency.

When the reversible cycles of work-producing engines are run in reverse, they act as refrigerators or heat pumps. Work is done on both of these machines while they extract a heat flow from a cold reservoir and release a heat flow to a hot reservoir.

The thermodynamic variable, entropy, S, measures the amount of disorder in a thermal system. Like thermal energy, it is a function of state, and only *changes* in entropy have physical significance. Entropy changes are path independent. For infinitesimal reversible transformations,

$$dS = \frac{dQ}{T}. \tag{20–18}$$

For an ideal gas, entropy can be expressed as a function of T and V as

$$S(B) - S(A) = C_V \ln\frac{T_B}{T_A} + nR \ln\frac{V_B}{V_A}. \tag{20–22}$$

Note that entropy decreases as temperature decreases.

The path independence of entropy changes is equivalent to the fact that, for a reversible cycle,

$$\oint \frac{dQ}{T} = 0, \tag{20–17}$$

a result known as Clausius' theorem. More generally, we include the possibility of an element of irreversibility by modifying Clausius' theorem to Clausius' inequality,

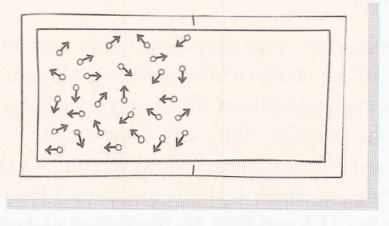
$$\oint \frac{dQ}{T} \leq 0. \tag{20–20}$$

The $<$ sign holds when there is irreversibility. If the change $A \rightarrow B$ is irreversible, the following relation holds:

$$S(B) - S(A) > \int_{A,\,\text{irrev}}^{B} \frac{dQ}{T}. \tag{20–21}$$

In particular, for transformations of thermally isolated systems, we find that $\Delta S \geq 0$.

A spontaneous process in an isolated system increases the system's entropy, and the state of maximum entropy is the state of stable equilibrium. The increase of entropy expresses the inevitable increase in the disorder of thermally isolated systems.



Understanding the Concepts

1. If the ocean is viewed as a reservoir at one temperature and the atmosphere as a reservoir at another temperature, when can thermal energy flow spontaneously from the ocean to the air?
2. When the brakes are applied, a car decelerates and then stops. A film of the process run in reverse obviously looks fake. Does the process in reverse violate the second law of thermodynamics? If so, in what way?
3. The historian Herman Daly has called the second law of thermodynamics "the law of random, ravage, and rust." Is he right?
4. Why is it not possible for an engine—even a Carnot engine—to have an efficiency of one?
5. In Russia the heat exhaust from nuclear power plants is sometimes used to heat local cities. Does this increase the efficiency of the "engine"? If so, how?
6. Suppose that a gas obeys the van der Waals equation of state. What is the efficiency of a Carnot engine that uses this gas as a working fluid in terms of the temperatures of the hot and cold reservoirs?
7. In what climates are heat pumps most likely to be used?
8. A professor spends a couple of hours straightening up his office—putting books away, filing papers, throwing old exam papers away, and so on. He has created a less probable configuration out of a more probable configuration. Has he violated the second law of thermodynamics?
9. You have a small bottle initially filled with a mysterious gas X in a tightly sealed air-filled room. Gas X is not a component of air. Both gases are initially at 1 atm of pressure. The bottle turns out to be permeable to gas X, but perfectly nonpermeable to any gas in air. What will happen?
10. Imagine a microscopic device at the boundary between two containers of a gas that could sense the arrival of a particularly fast molecule heading from container A toward container B and could open a tiny door to let that molecule through. The same device, which is known generically as a *Maxwell demon*, could sense the arrival of a particularly slow molecule heading from container B toward container A and could let the molecule pass through. How would such a device violate the second law of thermodynamics? Is such a device feasible?†
11. Give examples of things you have observed recently that exemplify the second law of thermodynamics. Discuss the entropy change associated with them.
12. Would heat pumps that use an underground water reservoir be more efficient than those that use the outside air as a thermal reservoir if the pumps are employed to (a) heat in the winter? (b) cool in the summer?
13. Are electric resistive heaters 100% efficient?
14. List and discuss some processes not already mentioned that will not violate the first law of thermodynamics but will violate the second law.
15. When gasoline is burned in the chamber of a piston, chemical energy is turned into mechanical energy that is used to propel an automobile. How is this process consistent with the second law of thermodynamics?
16. If you were to run a film of an egg that drops to the floor, you would have little trouble determining if the film were running backward or not. Yet if the film were in extreme closeup, so that you were observing the interaction of molecules in the dropped egg, you would be hard pressed to say if the film were running forward or backward. How are these two statements consistent?
17. Is it possible to cool a house by leaving a refrigerator door open? What would be the net effect if you were to leave the door open?
18. Turbocharged engines take hot exhaust gas and send it back to the engine to heat up the intake air passing into the engine. Is this a satisfactory way to increase the efficiency of an engine?
19. Is the entropy of a gas an extensive quantity (such as volume) or an intensive quantity (such as pressure or temperature)? (See Problem 17–3.)
20. Biological systems use energy (ultimately from the Sun) in organizing highly ordered organisms, such as humans. Does this mean that biological systems violate the second law of thermodynamics?

Problems

20–1 Beyond Energy Conservation

1. (I) An engine produces 3.8×10^5 J of mechanical energy accompanied by a total heat flow of 7.6×10^5 J into the engine. What is its efficiency?
2. (I) Suppose that you toss a pair of dice. Make a list of all the possible outcomes, and calculate the probability of getting totals of 2, 3, 4, . . . 12, respectively.
3. (II) Six tokens, numbered one to six, are put into a hat. The tokens with even numbers are white; the ones with odd numbers are black. Suppose you draw four tokens at random, without putting them back into the hat. (a) List all the possible outcomes, without regard to order (for example, 1234 and 2134 do not count as separate outcomes). (b) What is the probability of drawing the tokens with 1, 2, 3, 4 on them? (c) What is the probability of drawing two white and two black tokens?
4. (II) N molecules of a gas are placed in the left half of a chamber and kept from entering the right half by a membrane. The membrane is then removed and the molecules distribute themselves uniformly throughout the whole volume (Fig. 20–19). What is the probability that, at some time during their subsequent random motion, they will all collect in the left half of the

▲ **FIGURE 20–19** Problem 4.

†For an interesting discussion of Maxwell demons, see Charles H. Bennett, "Demons, Engines, and the Second Law," Scientific American, Nov. 1987, pp. 108–116.

chamber, for the cases $N = 2$, 100, 10^6, and 10^{23}? [*Hint*: This is equivalent to the probability of getting nothing but heads in 10^{23} coin tosses. To get an idea of this number in scientific notation, use the fact that $\frac{1}{2} \cong 10^{-0.3}$.]

5. (II) It is difficult to carry out experiments with just a few molecules. Here is an analogue to the problem of 10 molecules and on whether they are on the left or the right side of a container. Assume that you have 10 fair coins. Each coin gets tossed to produce a series of 10 heads or tails. Compare the probability that you end up with 10 heads (a maximally ordered array) with the probability of getting five heads and five tails in any order.

6. (II) You have a small 1-L bottle initially filled with a mysterious gas X in a tightly sealed air-filled room whose dimensions are 3 m × 3 m × 3 m. Gas X is not a component of air. Both gases are initially at 1 atm of pressure. The bottle turns out to be permeable to gas X but perfectly opaque to any gas in air. What will be the equilibrium pressure in the bottle, if any?

20–3 The Carnot Cycle

7. (I) What is the maximum efficiency of a steam engine whose boiler (the hottest-temperature reservoir in contact with the engine) is at 160°C and whose condenser (the coldest-temperature reservoir in contact with the engine) is at 35°C?

8. (I) A heat engine absorbs heat from a thermal reservoir at 550K, but the engine's maximum efficiency is only 38%. What must the temperature of the reservoir be to raise the efficiency to 41%?

9. (I) A heat engine receives heat from a thermal reservoir at 750K and transfers it to a thermal reservoir at 340 K. The efficiency of the engine is only 70% of the maximum possible. (a) What is the engine's actual efficiency? (b) How much work does the engine produce for each calorie of heat input?

10. (I) Temperature differences in the ocean have been proposed as a possible energy source in the tropics. Surface water at 29°C could act as a hot reservoir, and deep water at 3.0°C could serve as a cold reservoir. Ammonia gas could be a working fluid in a heat engine that runs between the two thermal reservoirs. What is the maximum efficiency of such an engine?

11. (II) A Carnot engine absorbs thermal energy from a reservoir at 450°C. Its efficiency is 0.55, and the work delivered by the engine is 5.0 kWh. (a) What is the temperature of the cold reservoir? (b) How much thermal energy flows into the system, and how much is rejected?

12. (II) What is the maximum efficiency of a heat engine that operates between 430°C and 125°C? If this engine generates 9800 J of mechanical energy, how many calories does it absorb from the hot reservoir, and how many calories does it transfer into the cold reservoir?

13. (II) A locomotive steam engine operating with a total train mass of 9.9×10^6 kg climbs a hill of height 1000 m in 10 minutes. If the steam engine produces steam at a temperature of 390K and exhausts the steam at 300K, and if the engine were at the theoretically best efficiency possible, what would be the rate, in mass per unit time, at which steam is exhausted? Real steam engines are much less efficient than the theoretical maximum.

14. (II) An athlete metabolizes energy at a rate such that his power output is 0.35 horsepower. (a) Assuming that the efficiency of his "engine" is 25%, how much thermal energy is dissipated? (b) If the dissipation is primarily through the evaporation of sweat, how much sweat is evaporated per minute?

15. (II) An inventor claims to have built an engine that takes in 3.0×10^8 J of thermal energy at 450K, rejects 1.4×10^8 J of thermal energy at 250K, and delivers 1.0×10^8 J of work in 1 h of cyclic operation. Is there anything wrong with this claim?

16. (II) A power plant generates 800 MW of electric power. At what rate does the plant generate waste heat if its efficiency is 28%? Assuming that the plant operates between 480°C and 80°C, what is the maximum efficiency possible?

17. (II) An ideal diatomic gas is used in a Carnot engine with thermal reservoirs at 77 K and 300 K. What is the ratio of the maximum volume to the minimum volume if the pressure drops by a factor of 2 during the isothermal expansion? [*Hint*: For a diatomic gas, $\gamma = 1.4$.]

18. (II) Prove that two reversible adiabatic paths cannot intersect. Do this by assuming that they do, constructing a cycle that consists of the two paths and another reversible transformation, and showing that such a cycle would violate the second law of thermodynamics (Fig. 20–20). (This result is simply shown for an ideal gas. Your proof should apply to a nonideal gas as well.)

▲ **FIGURE 20–20** Problem 18.

19. (III) Any element of irreversibility makes a Carnot engine and, in fact, any engine, less efficient. Let engine A be a pseudo-Carnot engine, meaning that it has some irreversibility somewhere along the cycle; let engine B be an ideal Carnot engine—the two arranged in size so that they exhaust the same heat flow Q_c. If engine A is more efficient than engine B, then by combining the two engines such that A runs normally and B runs backward, as in Figure 20–6, show that you arrive at a contradiction of the Kelvin form of the second law of thermodynamics. Now that you have shown that engine A must be less efficient than engine B, why can the preceding argument not be reversed, running the Carnot cycle forward and the pseudo-Carnot cycle backward to get a contradiction of the second law?

20. (III) Show that if it is possible to build an engine that violates the Kelvin form of the second law of thermodynamics, it is also possible to build an engine that violates the Clausius form of the second law. [*Hint*: Consider a Carnot engine driven by the Kelvin-violating engine.]

20–4 Other Types of Engines

21. (I) An air conditioner is rated at 8000 Btu/h. Assuming maximum possible efficiency, an exhaust temperature of 38°C, and an interior temperature of 22°C, what is the electrical power consumption? (The work done on the air conditioner is supplied by electricity.)

22. (I) What is the coefficient of performance for an ideal Carnot heat pump operated between outside air at 40°C and a deep water well at 8°C? Would the coefficient of performance be

larger or smaller if your heat pump followed any other type of cycle?

23. (I) Two refrigerators can each be approximated as Carnot cycles run in reverse. Each refrigerator works with the same cold temperature reservoir $T_c = 273\text{K}$. Refrigerator 1 evacuates to a hot reservoir at temperature $T_h = 293\text{K}$, while refrigerator 2 evacuates to a hot reservoir at a temperature of $T_h = 303\text{K}$. Compare the coefficients of performance of these refrigerators. (Real refrigerators will have coefficients of performance substantially less than these.)

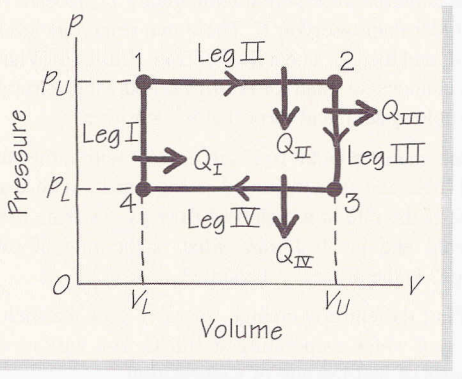
24. (I) A heat pump acts like a refrigerator that cools the outside of a house and gives rise to a heat flow to the inside of the house. If the outside temperature is +3°C and the inside temperature is 21°C, what is the maximum amount of British thermal units a pump can deliver per kilowatt-hour of electric energy supplied? (The work done on the pump has electric energy as its source.)

25. (I) Consider the diesel cycle in Fig. 20–9a. In which portions of the cycle is there heat flow into or out of the engine? What is the work done in the transformation $2 \rightarrow 3$ in terms of T_2 and T_3?

26. (II) An "ideal refrigerator," a Carnot engine that operates in reverse, has a compressor as its engine. It does work W to extract heat Q_c from a cold reservoir at temperature T_c and dumps heat Q_h into a hot reservoir at T_h. Use the known efficiency of a Carnot engine that operates between T_h and T_c and the conservation of energy for one cycle to show that the coefficient of performance $K_{\text{ref}} \equiv Q_c/W$ for the compressor is given by $K = T_c/(T_h - T_c)$. Note that K_{ref} is large when the cold and hot reservoirs have nearly the same temperature.

27. (II) A refrigerator with coefficient of performance $K_{\text{ref}} = 5.1$ (see Problem 26) gives rise to a heat flow out of the cooling compartment at a rate of 400 cal/min. What is the required power of the motor that operates this refrigerator?

28. (II) To compensate for a given energy loss when a refrigerator is opened too often, the refrigerator's compressor must do work. Take $T_c = 2.0°\text{C}$ and $T_h = 29°\text{C}$, and suppose that the refrigerator's coefficient of performance is 35% of its ideal value. What is the rate at which the compressor does work; that is, what is the power consumption for a given rate of heat loss dQ/dt?



29. (II) The specifications of a freezer claim that it can remove 80 cal/s heat flow from the compartment at −20°C and release 94 cal/s into the room at 25°C while using 60 W of electrical energy to drive the compressor. Can you trust this statement?

30. (II) In order to make an ice cube from water, a refrigerator must extract 1400 cal of heat at the temperature of the freezer, −12°C. The room temperature is 30°C. What minimum work must an ideal refrigerator do?

31. (II) You can buy a 5-lb bag of ice for about $2. Estimate the fraction of this price that pays for the electric energy needed to run the ice-making machine. Assume that the inside of the machine is at −10°C, that the outside temperature is 30°C, that the initial temperature of the water is 20°C, and that the coefficient of performance is 30% of the ideal. Electrical energy costs $0.10/kWh.

32. (II) The temperature inside a Carnot refrigerator placed in a room at 68°F is 38°F. The heat flow from the refrigerator into the room is 0.95×10^8 J/h. How many watts are needed to operate the refrigerator?

33. (II) A heat engine operates on the cycle shown in Fig. 20–21, with heat absorbed or ejected on each leg as indicated. Its operating fluid is an ideal gas with heat capacity at constant volume C_V. (a) What are temperatures T_3 and T_4 at points 3 and 4, respectively, in terms of the indicated pressures and volumes?

▲ **FIGURE 20–21** Problem 33.

(b) What is the internal energy change along leg IV, ΔU_{IV}? Include the sign. (c) What is Q_{IV} in terms of ΔU_{IV} and the indicated pressures and volumes? (d) What is the efficiency of the engine in terms of the indicated pressures and volumes and C_V?

34. (II) Consider the ideal Stirling cycle shown in Fig. 20–8, working between a maximum temperature T_h and a minimum temperature T_c, and a minimum volume V_1 and a maximum volume V_2. Suppose that the working gas of the cycle is 0.1 mol of an ideal gas with $c'_V = 5R/2$. (a) What are the heat flows to the cycle during each leg? Be sure to give the sign. For which legs is the heat flow positive? (b) What work is done by the cycle during each leg? Again, be sure to include the sign. (c) If, in the definition of the efficiency of this cycle, $\eta = W/Q_{\text{pos}}$, where Q_{pos} is the total positive heat flow to the engine, what is the efficiency of the cycle when $T_h = 700\text{K}$ and $T_c = 400\text{K}$? $V_1 = 0.5\text{ L}$ and $V_2 = 1.5\text{ L}$. Compare this efficiency to the efficiency of a Carnot cycle that operates between the same temperature extremes.

35. (II) The Otto cycle, represented in Figure 20–9b, runs between minimum and maximum volumes V_1 and V_2 and minimum and maximum temperatures T_1 and T_2, respectively. (a) Show that the efficiency is given by $\eta = 1 - (T_2 - T_3)/(T_1 - T_4)$. (b) Show that if the working fluid of the cycle is an ideal gas, the efficiency of this cycle can alternatively be written as $\eta = 1 - (V_1/V_2)^{\gamma - 1}$, where $\gamma = C_p/C_V$. The efficiency of this cycle is thus independent of the temperatures between which it operates, depending instead only on γ and on geometry. The ratio V_2/V_1 is the compression ratio. A typical compression ratio is 8, and $\gamma = 1.4$, which gives a predicted efficiency of 56%.

36. (III) The Brayton cycle is represented by Fig. 20–9c. Show that when its working fluid is an ideal gas, the cycle's efficiency is given by the same formula as that for the Otto cycle in the previous problem. In this case, V_1 and V_2 are not the extreme volumes of the engine but are the volumes at the start and finish of the adiabatic expansion step, respectively.

37. (III) Find the efficiency of the diesel cycle illustrated in Fig. 20–9a in terms of $\gamma = C_p/C_V$ and the temperatures at points 1, 2, 3, and 4. Assume that it contains 1 mol of an ideal gas. (Rudolf Diesel tried to produce an engine based on the Carnot cycle. He was not able to produce such an engine, but he came close: A diesel engine nearly matches a Carnot engine in efficiency. Diesel's engine is one of the most efficient in use today.)

20–5 Entropy and the Second Law

38. (I) Consider a large, isolated thermal system in two parts. One part is a thermal reservoir at temperature T_1, labeled I, and the other

part is a thermal reservoir at temperature T_2, labeled II. Reservoir I is colder than reservoir II. These two reservoirs are briefly connected, and there is a heat flow Q from II to I. (a) What are the entropy changes for I and for II? (b) Compute the entropy change for the whole system, and show that it is positive.

39. (I) One end of a metal rod is in contact with a thermal reservoir at 1273K, and the other end is in contact with a reservoir at 293K. If the rate at which heat flow passes from the hot end to the cold end is 30 J/min, what is the rate of total entropy change? Is the process reversible?

40. (II) Find the entropy change for (a) 1 g of ice melting at 0°C; (b) 1 g of water evaporating at 100°C. You will need to look up the heats of melting and of vaporization.

41. (II) One kilogram of iron at 80°C is dropped into 0.5 L of water at 20°C. Given that the specific heat of water is 1 cal/g · K and that of iron is 0.107 cal/g · K, calculate the final equilibrium temperature of the system and the increase in entropy.

42. (II) One hundred and twenty grams of water at 100°C is changed reversibly into steam at 100°C. (a) Describe such a process. (b) What is the change in entropy of the water and of the universe? (c) How would part (b) change if the process were irreversible?

43. (II) A boater dumps 8.7 kg of ice from his cooler into the lake at the end of a fishing trip. The ice is at −3°C, and the lake is at 18.7°C. What is the change in entropy of the new lake–ice cube system after the ice cubes come to equilibrium with the lake?

44. (II) Calculate the entropy change of the universe when a 1-kg block of copper at a temperature of 200°C is put in a lake at a temperature of 4°C. The total heat capacity of this block of copper is 375 J/K.

45. (II) Calculate the change in entropy of the universe if 0.3 kg of water at 70°C is mixed with 0.2 kg of water at 15°C in a thermally insulated container. [*Hint*: Even though this process is irreversible, the change in entropy can be calculated by devising a reversible process that leads from the given initial state to the expected final state.]

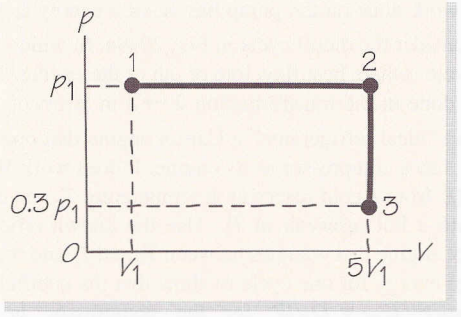
46. (III) Thermodynamic tables often give the specific heat of materials in the form of a list of coefficients a, b, c, d in the expression $c_p = a + bT + cT^2 + d/T$. How can you use these data to find the entropy change of the material as it undergoes a transformation from T_i to T_f?

20–6 Entropy and Ideal Gases

47. (I) Five moles of an ideal gas is in thermal isolation and undergoes free expansion from 35 L to 100 L. What is the entropy change of the gas? of the universe?

48. (I) The heat capacity at constant volume of a sample of gas is determined to be 22 J/K. If this amount of gas is heated in a constant-volume container from 273K to 840K, what is the change in entropy?

49. (I) One mole of an ideal gas expands at constant pressure from an initial volume of 250 cm^3 to a final volume of 650 cm^3. What is the change in entropy, assuming that the molar specific heat is $c'_V = 3R/2$?



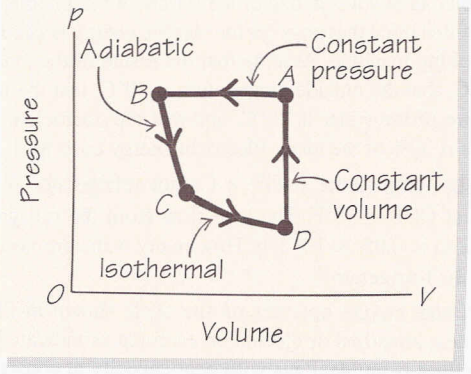
50. (I) One mole of ideal gas with molar specific heat $c'_V = 3R/2$ is heated from 273K to 350K at constant volume. What is the change in entropy?

51. (I) An ideal gas undergoes an isothermal compression. Does the entropy increase?

52. (II) Ten moles of a monatomic gas held in a tank at 17 atm escape from the tank isothermally at 27°C. What is the change in the entropy of the universe?

53. (II) One mole of a monatomic ideal gas at an initial pressure of 30 atm and a temperature of 600K is allowed to undergo a rapid (adiabatic) free expansion from a small vessel into a vessel of 50 times greater volume. Find the change in temperature and the increase in entropy.

54. (II) One mole of a monatomic ideal gas is carried in two steps from (p_1, V_1) to $(p_1, 5V_1)$ to $(0.3p_1, 5V_1)$ by reversible thermodynamic processes that are straight lines on a p–V diagram (Fig. 20–22). (a) What is the overall change in the gas's internal energy? (b) What is the overall work done by the gas? (c) How much net heat flow is added overall? (d) What is the net change in the entropy?



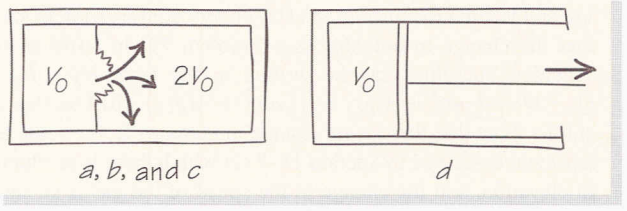
▲ **FIGURE 20–22** Problem 54.

55. (II) A gas obeys the well-known equation of state $pV = (\text{a constant})\,T$. The gas expands, doubling in volume. (a) Plot p versus V when the expansion is isobaric and when it is isothermal. (b) What work is done by the gas on its surroundings for both cases above? (c) What is the entropy change of the gas for both cases above?

56. (II) Show that in terms of temperature and pressure, the entropy of an ideal gas with constant heat capacities is $S(T, p) = C_p \ln(T/T_0) - nR \ln(p/p_0) + S(T_0, p_0)$.

57. (III) Dilute helium gas is taken through the following reversible cycle on a p–V diagram: AB is an isobaric compression; BC is an adiabatic expansion; CD is an isothermal expansion; DA is a constant-volume pressure increase (Fig. 20–23). Express the heat flow, work done on the system, change in internal energy, change in temperature, and change in entropy for each leg of the cycle in terms of the quantities T_A, T_B, T_C, and p_A. Pay attention to the signs.

▲ **FIGURE 20–23** Problem 57.



20–7 The Meaning of Entropy

58. (I) A total of 12 molecules are in a large box, which we mentally divide into two halves, a left half and a right half. Any one molecule is equally likely to be in either of the two halves. What is the probability that all 12 molecules will be found in the left half? How does your answer change if there are 120 molecules?

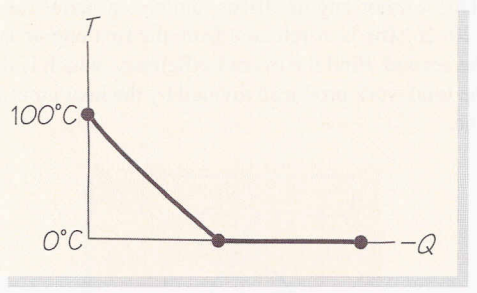
59. (II) An ideal gas in a cylinder with a movable piston is placed in thermal contact with a thermal reservoir, and the gas is slowly compressed. How does the entropy of the gas in the cylinder change? How does the entropy of the reservoir change? Is the answer to these questions in conflict with the second law of thermodynamics? Explain your answer.

60. (II) A box of volume 3.0 L contains 1.8 L of He in one side and 1.2 L of O_2 in the other, separated by a partition. The temperature is 290K, and the pressure in both sides of the box is 1.2 atm. The partition is removed. (a) Describe the new equilibrium configuration. (b) What is the change in entropy?

61. (II) A thermally isolated container of volume $3V_0$ is divided by a partition. In one portion, of volume V_0, there are n mol of a monatomic ideal gas at temperature T_0. The other portion is empty. The partition is then broken, and the gas expands to fill the entire container (Fig. 20–24). (a) What is the final temperature of the gas? (b) The change in entropy of the gas? (c) The change in entropy of the universe? (d) Suppose that the gas is originally confined to volume V_0 by means of a piston instead of a partition. The piston is then slowly withdrawn until a final volume of $3V_0$ is obtained. What is the change in entropy of the gas?

▲ **FIGURE 20–24** Problem 61.

General Problems



62. (II) A nuclear power plant requires 1450 MW of cooling. If environmental concerns limit the temperature rise of the cooling water to 9°C, how much water flow is required to cool the heat generated by the plant? If the water is at an initial temperature of 287K, what is the entropy change per kilogram of water?

63. (II) Fifty grams of oxygen gas at 320K do 80 J of work while 40 cal of heat flow is absorbed by the gas. (a) What is the change in internal energy? (b) In the temperature of the gas? (c) In entropy, assuming that the change is isobaric?

64. (II) Calculate the entropy change when 1 kg of water is cooled from 100°C to 0°C. Calculate the entropy change when the water turns to ice at 0°C (Fig. 20–25). The latent heat of fusion is 80 cal/g.

65. (II) Sketch on an S–T diagram the following thermodynamic reversible transformations: (a) An adiabatic transformation at constant volume, involving a pressure change. (b) A rough picture of the Stirling cycle.

66. (II) You have a box of volume V divided by an imaginary partition (molecules pass right through it) into two parts, volumes V_1 and V_2. You start out with N_1 molecules of gas g_1 and N_2 molecules of gas g_2, all spread evenly through the box. What is the probability that you find all the g_1 molecules in V_1 and all the g_2 molecules in V_2? Work out the numbers for $V_1 = V/3$ and $V_2 = 2V/3$ while $N_1 = N_2 = 100$. Repeat, but for $N_1 = N_2 = 1000$.

▲ **FIGURE 20–25** Problem 64.

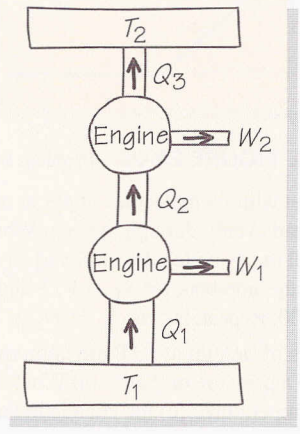
67. (II) Two moles of helium at STP are compressed in an isothermal process to a pressure of 2 atm. (a) What is the final volume? (b) the final temperature? (c) the change in entropy?

68. (II) A Carnot engine for which the working fluid is 1 mol of an ideal gas with $c'_V = (5/2)R$ operates between two thermal reservoirs of temperatures $T_h = 550$K and $T_c = 350$K. When the gas is in contact with the hot reservoir, its minimum volume is $V_1 = 0.70$ L, and when it is in contact with the cold reservoir, its maximum volume is $V_3 = 8.0$ L. (a) What is the efficiency of this engine? (b) For one cycle, what is the net energy change of the gas? (c) The net entropy change of the gas? (d) The net change in the entropy of the universe? (e) What is V_2, the maximum volume when the gas is in contact with the hot reservoir?

69. (II) Three moles of oxygen at STP undergoes an adiabatic compression to a final pressure of 3.0 atm. (a) What is the final volume? (b) The final temperature? (c) The change in entropy?

70. (II) One liter of nitrogen at STP is adiabatically compressed to a volume of 0.50 L when a membrane breaks and the nitrogen gas undergoes free expansion back to 1.0 L. (a) What is the final pressure? (b) The final temperature? (c) The change in entropy?

71. (II) A heat engine operates between the temperatures of 400K and 300K, doing 100 J of work. This work is used to run a refrigerator between the same temperatures. (a) Calculate the heat transfer between each reservoir and the engine or the refrigerator, assuming that both of them have ideal efficiency/coefficient of performance. (b) Repeat the calculation if the heat engine's efficiency is only 80% of the ideal. (c) Repeat the calculation for the case of an ideal heat engine but for a refrigerator whose coefficient of performance is 80% of the ideal.

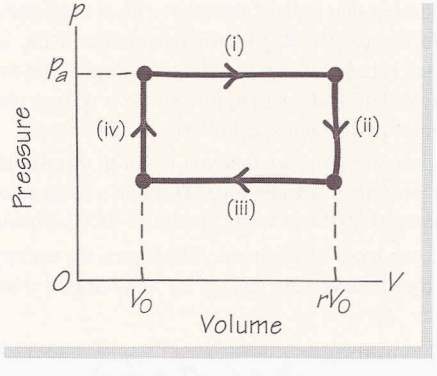


72. (II) An inventor proposes that you invest in a newly developed engine. It purports to absorb 140,000 Btu at a temperature of 700°C, and reject 60,000 Btu at a temperature of 400°C. Should you invest?

73. (II) For one mole of a van der Waals gas, the energy change dE for a given temperature change dT and volume change dV takes the form

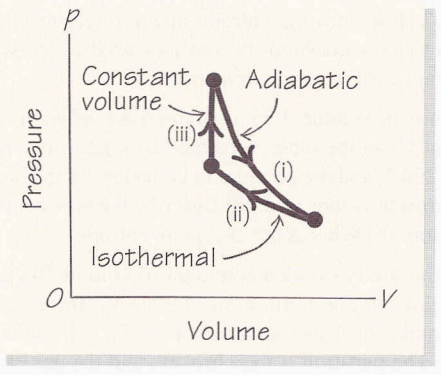
$$dE = C_V\,dT + \frac{a}{V^2}dV,$$

where in this problem we'll assume that C_V has no temperature dependence. Your gas undergoes free expansion from V_i, T_i to V_f, T_f. Does the temperature (a) increase, (b) decrease, or (c) remain unchanged? [*Hint*: In free expansion the energy is unchanged. This energy has the form $E(T,V) = C_V\int_{T_0}^{T} dT + \int_{V_0}^{V}\frac{a}{V^2}dV$.]



74. (II) One Carnot engine drives another in series, as shown in Fig. 20–26. The heat released from the first engine is absorbed by the second. Find the overall efficiency, which is determined by the total work produced divided by the heat input to the first engine.

▲ **FIGURE 20–26** Problem 74.

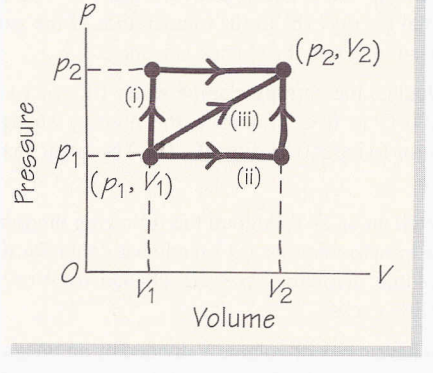


75. (II) A coal-fired, 300-MW generating plant operates between 750K and 400K, with an efficiency 60% of the maximum efficiency possible. At what rate is waste heat flow produced? Suppose that water is used to carry off the waste heat flow, and it does so by being heated by 12°C. How much water must flow through the machinery per second?

76. (II) Consider the reversible thermodynamic cycle of the following form (Fig. 20–27): (i) One mole of a monatomic ideal gas at temperature T_a and pressure p_a is allowed to expand isobarically until the volume has increased by a factor r. (ii) The gas is then cooled so that its absolute temperature is reduced by a factor of 2, with the cooling performed at constant volume. (iii) The gas is then compressed isobarically to its original volume. (iv) Finally, the gas is heated to its starting temperature, T_a, at constant volume. (a) What is the mechanical work done by the engine? (b) The heat transfer in the four legs of the cycle? (c) The efficiency of the cycle?

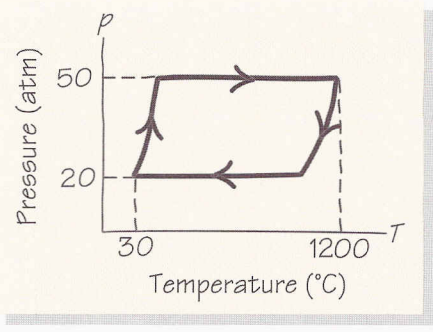
▲ **FIGURE 20–27** Problem 76.

77. (II) A heat engine operates in a reversible cycle with the following steps (Fig. 20–28): (i) An ideal gas characterized by $\gamma = 1.4$ expands adiabatically, so that it cools from an initial temperature of 330°C to 30°C; (ii) it is compressed isothermally until it reaches its initial volume; and (iii) it is then heated at constant volume until it reaches its initial temperature. Calculate the efficiency of the cycle and compare it with the Carnot efficiency that corresponds to these temperatures.



▲ **FIGURE 20–28** Problem 77.

78. (II) Suppose that there is steady flow of a mass M of gas through a turbine. Gas enters the turbine at an elevation z_1, pressure p_1, internal energy U_1, and speed v_1, and leaves at an elevation z_2, pressure p_2, internal energy U_1, and speed v_2. Thermal energy Q is supplied to the turbine. Work W is done by the turbine, and V_1 and V_2 are the respective volumes occupied by mass M on entering and leaving the turbine. (a) Use energy conservation to show that the change in enthalpy (see Problem 79) in terms of the specified quantities can be written in the form $H_2 - H_1 = Q - W + \frac{1}{2}mv_1^2 + Mgz_1 - \left(\frac{1}{2}mv_2^2 + Mgz_2\right)$. (b) Use this result to show that there is no change in enthalpy in the Joule experiment described in Section 18–7 (in which there is no change in elevation, and the change in the speed of the gas is so small that $v_2^2 - v_1^2$ can be neglected).



79. (II) A useful quantity called enthalpy, H, is defined by $H = U + pV$. Calculate the enthalpy of an ideal gas as a function of temperature.

80. (III) Three reversible paths, legs i, ii, and iii, connect points (p_2, V_2) and (p_1, V_1) in Fig. 20–29. (a) Calculate $\int_1^2 dW$ and $\int_1^2 dQ$ for the three paths. (b) Calculate $\int_1^2 dQ/T$ for the three paths.

▲ **FIGURE 20–29** Problem 80.

81. (III) The Brayton cycle is used to extract work from a high-temperature, gas-cooled nuclear reactor with helium (a monatomic ideal gas) as the working fluid. The helium enters a compressor, and its pressure is raised adiabatically. It is then heated at constant pressure to a high temperature in the reactor core. The energy is supplied by the fission of uranium or plutonium. The helium then enters a turbine, in which it is allowed to expand adiabatically. It then passes through a precooler, in which heat is rejected at constant pressure until it reaches the initial conditions. Suppose that helium enters the compressor at 30°C and a pressure of 20 atm. It is compressed to 50 atm and then heated to 1200°C in the reactor core (Fig. 20–30). (a) What are the temperatures at the end of compression and expansion? (b) What are the heat flows per kilogram of helium in each cycle? (c) How much net work is done per kilogram of helium in each cycle?

▲ **FIGURE 20–30** Problem 81.

Chapter 21

◀ Investigations of the nature of lightning were important in the understanding of electrical phenomena. Here, Benjamin Franklin is represented performing a kite experiment, whose description he published between 1751 and 1753. The painting is inaccurate in that Franklin flew the kite before lightning struck, he did not stand on the open, and a key was attached to the string, which was then charged by the clouds. In fact, whether Franklin actually performed the experiment is not known.

Electric Charge

Electricity, together with magnetism, governs virtually all that we see of the physical world. Electromagnetic forces control the structure of atoms and all materials. Light and other electromagnetic waves are pervasive. The understanding of these forces is one of the great success stories of science. In this chapter, we introduce electric charge, a property of atomic constituents, and we discuss the fundamental law of the interaction of two charges at rest, Coulomb's law. This force law is as fundamental as the universal law of gravitation. The interaction between charges has the same space dependence as gravitation, but the force described by Coulomb's law can be either attractive or repulsive.

21–1 Charge—a Property of Matter

Over the last century, we have become more and more dependent on electricity in our everyday lives, and most people are aware that electric charges exist. The experimental evidence for electric charges and the understanding of charge developed over a long time period. We begin with a very brief sketch of this development.

A Brief History of the Study of Electricity and Magnetism

The word *electricity* has its roots in the Greek word for "amber" (*electrum*), and the first written mention of the curious effects of rubbed amber dates from the fifth century B.C. It was not until the 1700s that the critical discovery that electric forces can be either

repulsive or attractive was made. The idea developed that a quantity (which we now call electric charge) is associated with electric forces. Among the many important names associated with these discoveries are Stephen Gray, Charles Dufay, and Benjamin Franklin.

Benjamin Franklin is best known for his exploitation of the existing idea that electrical phenomena were associated with a kind of fluid contained in matter. He surmised that repulsion and attraction were the result of an excess or deficiency of the fluid. Although we now know that view is not quite right, implicit in Franklin's model is what we can recognize as the phenomenon of the conservation of charge. For example, if the "fluid" were to flow out of an object, it would leave behind a deficiency. Franklin introduced the terms "positive" and "negative" for the two types of charge and also set the standard sign convention in which the electron, the actual particle that moves in conductors, has negative charge. Franklin was known for his spectacular (and dangerous) experiments with lightning, which he recognized as an electrical effect. Franklin and his friend Joseph Priestley, as well as Henry Cavendish, are linked with the discovery that *the fundamental force between electric charges is proportional to the inverse square of the distance between them*. This law was confirmed more directly by John Robison and then by Charles Coulomb in the mid- and late eighteenth centuries, respectively. This inverse-square law is now known as **Coulomb's law**.

The nature of magnetism and its relation to electricity became clearer starting around 1820, primarily through the work of Hans Christian Oersted, André-Marie Ampère, and Michael Faraday. James Clerk Maxwell completed the unification of electricity and magnetism in the 1860s: Electricity and magnetism were aspects of a single fundamental set of phenomena, electromagnetism. This subject will occupy us for many chapters to come.

The Significance of Electric Forces

In this chapter we introduce a second basic force of nature. To the law of universal gravitation we add knowledge of the electrical interaction, as represented by the Coulomb force. Gravitational forces have an inverse-square dependence on the distance between interacting pointlike objects, and as we shall see, the same is true for the electric force. Both forces are proportional to the product of a characteristic attribute of the two objects—mass for the gravitational force and electric charge for the Coulomb force.

On the cosmic scale, gravity looms large. It is the force that keeps Earth rotating around the Sun, and the Moon rotating around Earth. The reasons why gravitation dominates electric forces on the astronomical scale are twofold. First, astronomical bodies have a great deal of mass. Second, astronomical bodies are almost exactly charge neutral, so the electric forces between them are relatively small. On anything less than an astronomical scale, however, the electric forces are normally much larger than the gravitational ones; apart from the direct effects of Earth's gravity, our everyday experience depends far more on the electric force than on the gravitational one.

As we shall see through study of the hydrogen atom, the electric force dominates the gravitational force on a microscopic scale. Even though a full explanation requires the inclusion of magnetic forces and quantum physics, we can now state that the electric force is responsible for

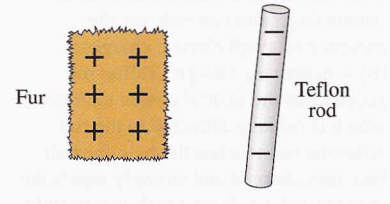
1. electrons binding to a positive nucleus, forming a stable atom;
2. atoms binding together into molecules;
3. atoms or molecules binding together into liquids and solids;
4. all chemical reactions; and
5. all biological processes.

The electric force is also responsible for such nonfundamental forces as friction and other contact forces. Electric energy fuels our homes, starts our cars, and runs our factories. We can say that electrical forces are dominant in the behavior of matter as we know it.

Matter and Electric Charge

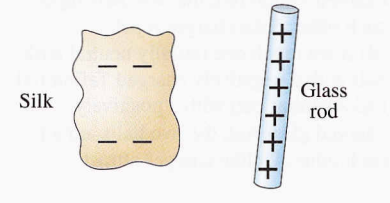
In most of our discussions to this point, we have characterized bulk matter—and the atoms that make up matter—by a single attribute: mass. When we probe the structure of atoms more deeply, we find that atoms are made up of electrons and nuclei, which are characterized by an additional attribute, **electric charge** (usually labeled q). Electric charges exert (electric) forces on one another that are proportional to the product of their charges, just as masses exert gravitational forces on one another that are proportional to the product of their masses. Charges come in two types, termed positive and negative, and have the fundamental property that opposite charges attract and like charges repel. Electrons and nuclei carry opposite charges, and as we will describe in more detail later, it is the attractive electrical forces between them that hold the atom together. The set of phenomena associated with the forces between stationary charges form the subject of **electrostatics**.

A correct description of atoms requires quantum mechanics. But we can give a qualitative classical picture—the remarks about charge in this picture carry over to a quantum-mechanical picture. An atom's electrons (labeled by e) each carry the same unit of negative charge, $q_{\text{electron}} = -e$. (Note that the same symbol e stands for the electron and a charge quantity.) The electrons are bound in shell-like regions around the much heavier nucleus, which consists of electrically neutral neutrons (labeled n) and positively charged protons (labeled p). The proton charge is equal in magnitude but opposite in sign to that of the electron, $q_{\text{proton}} = +e$. When the number of protons in an atom equals the number of electrons, the atom is **electrically neutral**—it has no net charge.



Chemical elements differ in the number of protons in the nuclei of their atoms. With no ionization, the number of protons is the same as the number of electrons surrounding the nucleus. Chemical properties are closely linked to the behavior of the atom's electrons. The electrons that are, on average, closest to the nucleus are more strongly bound to the nucleus and are more difficult to dislodge from the atom and less available to interact with other atoms. The outermost electrons—farther away from the nucleus—are attracted less strongly and are more easily dislodged. The ease with which the outermost electrons can be removed from the atom, as well as how strongly an atom attracts other electrons, greatly influences the properties of the elements and how they interact chemically with one another. An atom that has lost one or more electrons and is thus left with a positive charge is called a *positive ion*, and a *negative ion* is an atom that has gained extra electrons. Bulk matter is typically electrically neutral or very nearly so. Even if there are chemical phenomena that produce positive and negative ions within the matter, these will appear in equal numbers to produce a neutral bulk.

Although bulk matter is overall neutral, it will have electrical properties that are associated with the outer electrons of its atoms. If the outer electrons of atoms in bulk matter are *weakly bound* to their respective nuclei, they behave as though they are almost free, and can move through the material almost unimpeded. Such materials—metals for the most part—are said to be good **conductors** of electricity; the term refers to how easily charge can move through the material. A certain class of materials—**superconductors**—have electrons that, in effect, move with *no* inhibition when the material is made sufficiently cold. The electrons of most nonmetallic solids do not travel easily; such solids, including rubber, glass, and plastics, are **insulators**. Silicon, germanium, and a large number of synthetic combinations of materials are substances that we can make into insulators or conductors by controlling either their electrical properties or their temperature. Such substances are called **semiconductors**, and they play an important role in electronic devices—transistors and so forth.



We can transfer charges back and forth between different materials by rubbing them together, allowing electrons to move from one material to the other. For example, when we rub a Teflon rod with fur, electrons are transferred from the fur to the Teflon rod (see Fig. 21–1a, b). The fur then has an excess positive charge: It has lost some electrons. The Teflon rod to which the electrons have been carried will have an excess of electrons and is now negatively charged. When charge is carried from one object to another in this way, the objects are said to be **charged by friction**. Both objects will be charged. We can similarly transfer electric charge by rubbing a glass rod on silk. The glass acquires a positive charge, because it transfers electrons to the silk, which in turn acquires an equal but opposite (negative) charge (Fig. 21–1c).

(a)

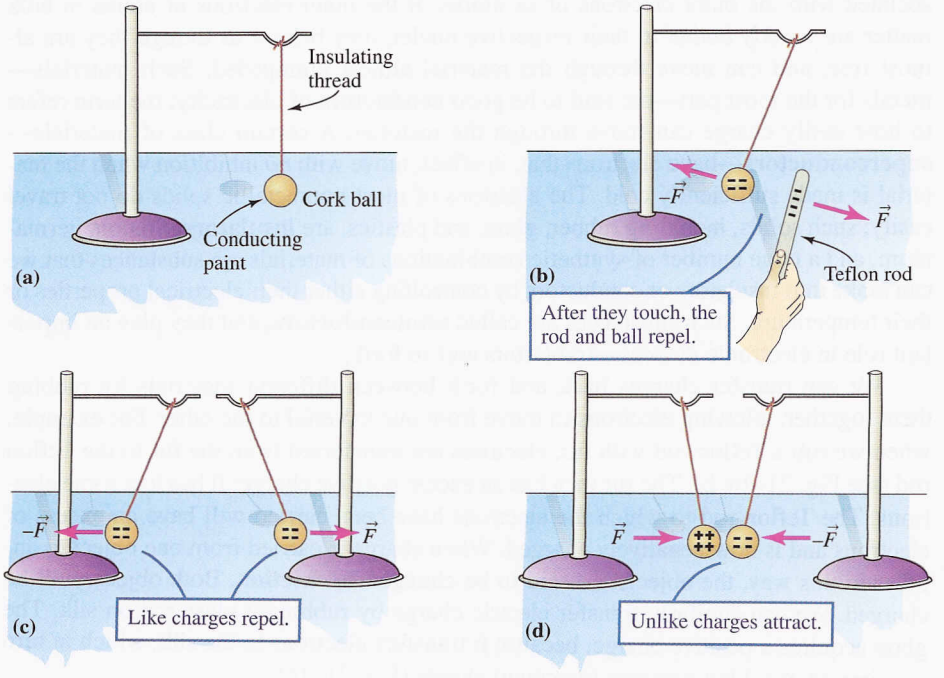
(b)

(c)

▲ **FIGURE 21–1** When Teflon is rubbed against fur (a, b) and glass is rubbed against silk (c), electric charge is transferred.

THINK ABOUT THIS. . .

IF WE ACCUMULATE A CHARGE, WHERE DOES IT EVENTUALLY GO?

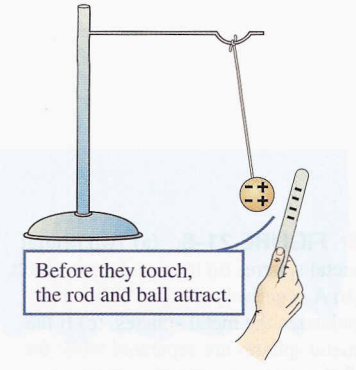


▲ **FIGURE 21–2** The large copper rod that is being pounded into the ground will serve as the electrical ground for the household electrical service box.

When we walk across a carpet on a dry winter day, we may slowly accumulate a charge through the rubbing of our shoes on the carpet fibers. We specify that the air must be dry because if it is not, then this charge is easily transferred to water molecules in the air and carried off. And your shoes should be good insulators, because otherwise the charge will travel back to the carpet. Without these possibilities, you may later touch a radiator or another person. Your accumulated charge is then shared with the second object, sometimes in sudden and shocking fashion. (The passage of the charge may even be visible as a spark, an interesting subject on its own that we'll discuss in Chapter 25.) But just what is the object with which you are sharing your charge if you touch the radiator? The answer is that the metal pipes of the radiator may form a very long path, ultimately connecting you to Earth as a whole. If the carpet itself touches Earth through a sequence of conductors, you got your charge from Earth, and you are simply returning that charge to Earth. Even if the carpet is not well connected with Earth, by sharing your accumulated charge with Earth as a whole, your portion of it will be very small—Earth is large! By touching an object—here, it is you—to Earth, we say that the object is **grounded**. When a negatively charged object is grounded, electrons flow from the object to the ground, leaving the object (very nearly) neutral. If, instead, an object has an excess positive charge, then electrons flow from the ground and neutralize the object. The electric shock associated with a carpet is small, but there is potential for more damaging electric shocks around the home from the electricity supply. We therefore tend to ground any objects that might become highly charged, so that any excess charge will travel into Earth and not to you (Fig. 21–2).

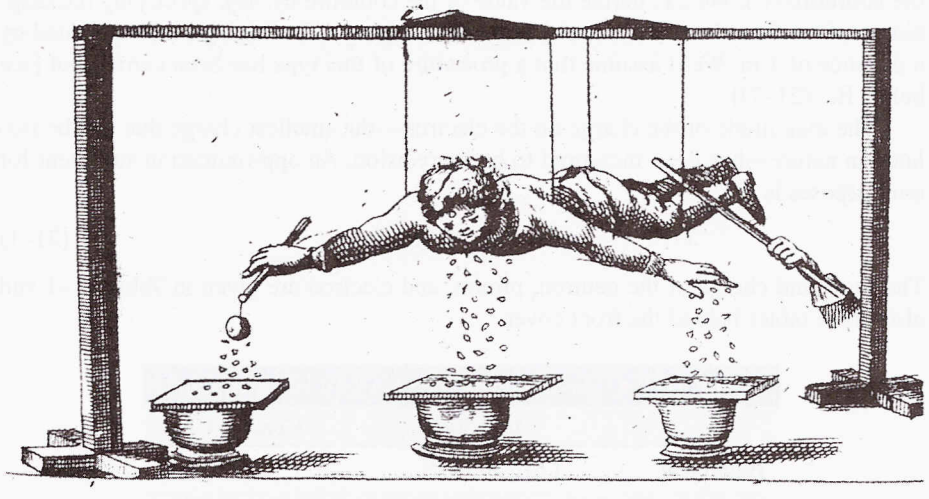
Evidence That Charges Are of Two Types

A small mass will react to forces more visibly than a large mass, so we use small (initially neutral) masses to study the effects of forces between charges. We can do this by using small balls made of cork and coated with a conducting paint that allows charge to move around easily on the surface. Such a ball is hung by a thin insulating thread (Fig. 21–3a). If we touch a negatively charged Teflon rod to a cork ball, the ball is immediately repelled by the rod (Fig. 21–3b). If we touch the negatively charged Teflon rod to *two* suspended (neutral) cork balls, the balls will then strongly repel each other (Fig. 21–3c). Similar behavior occurs between two cork balls that have been touched by a positively charged glass rod, as they will both have acquired a positive charge. However, if we touch the Teflon rod to one cork ball and the glass rod to one cork ball, the oppositely charged balls attract each other (Fig. 21–3d).



▶ **FIGURE 21–3** (a) An insulated cork ball covered with a thin layer of conducting paint can indicate the presence of small electric charges. (b) A negatively charged Teflon rod approaches the neutral coated cork ball, which is initially attracted to the rod. After the rod touches the ball, the ball becomes charged and strongly repels the charged rod. (c) If we touch two initially neutral cork balls with a negatively charged Teflon rod, the two balls repel each other: Like charges repel. (d) If we touch one initially neutral cork ball with a negatively charged Teflon rod and a similar ball with a positively charged glass rod, the two balls attract each other: Unlike charges attract.

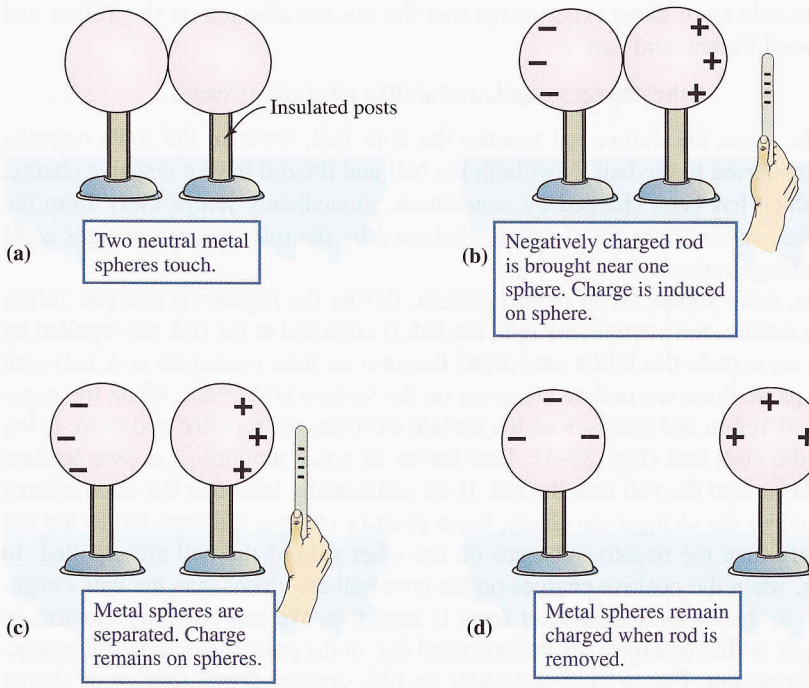
We conclude from these experiments that the electric charges on the Teflon and glass rods are different, and that



Like charges repel, and unlike charges attract.

For example, when the Teflon rod touches the cork ball, some of the rod's negative charge is transferred to the ball. Now both the ball and the rod have a negative charge. The ball, which has been charged by conduction, immediately jumps away from the rod. Our other observations are similarly explained by the rule that like charges repel and unlike charges attract.

Another, more subtle, effect is also present. Before the negatively charged Teflon rod actually touches the neutral cork ball, the ball is *attracted* to the rod, not repelled by it. How can we explain this initial attraction? Because we have coated the cork ball with conducting paint, there are mobile electrons on the surface of the ball. When the negatively charged Teflon rod comes near, the mobile electrons are repelled and move to the far side of the cork ball (Fig. 21–4). That leaves an equal amount of excess positive charge on the area of the ball near the rod. If we additionally infer that the electric force is stronger when the charges are closer, those positive charges are attracted to the rod more strongly than the negative charges on the other side of the ball are repelled. In other words, when the positive charges on the cork ball are closer than the ball's negative charges to the Teflon rod, the *net* force is attractive. We call this phenomenon, in which charges within an object are redistributed due to the presence of external charge, **charge polarization**. Figure 21–5 illustrates an 18th-century demonstration of charge polarization. The fact that electrical forces between interacting charges weaken with distance—the inference that we had to make to explain the initial attraction of the ball and rod—is of great importance, and we shall return to it.



▲ **FIGURE 21–4** The neutral cork ball is initially attracted to the charged Teflon rod because some electrons on the ball move to the far side due to the repulsive force from the rod. The positive charges on the ball are on average closer to the rod, so the attractive force on them due to the rod is greater than the repulsive force on the redistributed electrons.

◀ **FIGURE 21–5** An eighteenth-century experiment on static electricity by Stephen Gray. The boy, suspended in air, carries a net charge (positive, let's say). As a result, charge polarization is induced in electrically neutral bits of paper near him. Negative charges on each paper bit tend to move toward the boy, leaving positive charges on the part of the paper bit farthest from the boy. The result is a net attractive force between the boy and each bit of paper.

Charge by Induction

An experiment closely related to the charge polarization experiments explains how initially neutral conductors can obtain a *charge by induction*, or an *induced charge*. Consider two neutral metal spheres, each standing on an insulated post and in side-by-side contact, so that they form a single conductor (Fig. 21–6a). If we bring a negatively charged Teflon rod close to one sphere, mobile electrons in the spheres move to the opposite side of the far sphere, leaving opposite charges on the two spheres (Fig. 21–6b). The spheres have a total charge of zero, but one is positive and the other negative. While the Teflon rod is still near, we separate the two spheres, leaving them oppositely charged (Fig. 21–6c). If we now remove the Teflon rod, the charges induced by the rod will remain on the two metal spheres (Fig. 21–6d). The spheres have been **charged by induction**. These charges can be transferred to two coated cork balls, by bringing a ball in contact with each sphere. The cork balls attract, demonstrating that the charges are opposite in sign. Note that only conductors can be charged by induction.

▶ **FIGURE 21–6** (a) Two neutral metal spheres on insulated posts touch. (b) A negatively charged Teflon rod polarizes the metal spheres. (c) If the metal spheres are separated while the Teflon rod is nearby, the spheres are charged oppositely. (d) When the Teflon rod is removed, the two metal spheres are still charged oppositely. Note that the total charge of the two spheres remains zero throughout.

Units of Charge

While the amount of charge on an electron is fixed, the numerical value of this amount of charge depends on how the scale for charge is defined. The SI unit of charge is called the **coulomb** (C). We can define the value of the coulomb by, say, specifying the magnitude of the force between two objects, each carrying 1 C of charge, and separated by a distance of 1 m. We'll assume that a procedure of this type has been carried out [see below Eq. (21–7)].

The magnitude of the charge on the electron—the smallest charge that can be isolated in nature—has been measured to high precision. An approximation sufficient for our purposes is

$$e \cong 1.60 \times 10^{-19}\,\text{C}. \tag{21–1}$$

The mass and charge of the neutron, proton, and electron are given in Table 21–1 and also in the tables behind the front cover.

TABLE 21–1 • Mass and Charge of Atomic Constituents

	Mass (kg)	Charge (C)
Neutron, n	1.675×10^{-27}	0
Proton, p	1.673×10^{-27}	1.602×10^{-19}
Electron, e^-	9.11×10^{-31}	-1.602×10^{-19}

EXAMPLE 21–1 A glass rod rubbed with silk has a charge of +110 nC (110×10^{-9} C). By how many electrons is the rod deficient?

Setting It Up We have made an unspoken (and reasonable) assumption that the rod has started off electrically neutral. Thus the rod acquires a positive charge through either an excess of positive charge or a deficiency in negative charge. In thinking in terms of a deficiency, we are saying that the positive charge has come from transferring electrons from the rod.

Strategy Because we know that each electron has a charge of magnitude e, we can find the number of transferred electrons by dividing the remaining charge by e.

Working It Out We have

$$\text{transferred electrons} = \frac{\text{net charge}}{\text{charge magnitude of each electron}}$$

$$= \frac{110 \times 10^{-9}\,\text{C}}{1.6 \times 10^{-19}\,\text{C/electron}}$$

$$= 6.9 \times 10^{11}\ \text{electrons}.$$

What Do You Think? Could we detect the number of missing electrons by the change in mass of the charged rod? You can find the mass of the electron in Table 21–1. *Answers to* ***What Do You Think?*** *questions are given in the back of the book.*

EXAMPLE 21–2 The largest American Eagle gold coin has a mass of 28.4 g. The atomic number of gold—the number of protons in the nucleus of an atom of gold—is 79, and thus the number of electrons in a neutral gold atom is also 79. The atomic mass of gold is 197, which means that 1 mol of gold has a mass $m_{\text{Au}} = 197$ g. How many electrons are contained in one pure gold coin? What is the total negative charge contained in the coin?

Setting It Up The only piece of information not specifically contained here is the fact that a mole of any element contains Avogadro's number, $N_A = 6.02 \times 10^{23}$, of atoms.

Strategy Avogadro's number N_A is the number of atoms in 1 mol of gold; the number of atoms in a given mass m of the gold is the ratio $(m)/(m_{\text{Au}})$ times N_A. We multiply this number by 79 electrons/gold atom to find the total number of electrons in the coin. Finally, we multiply the resulting number by the charge of one electron to find the total negative charge.

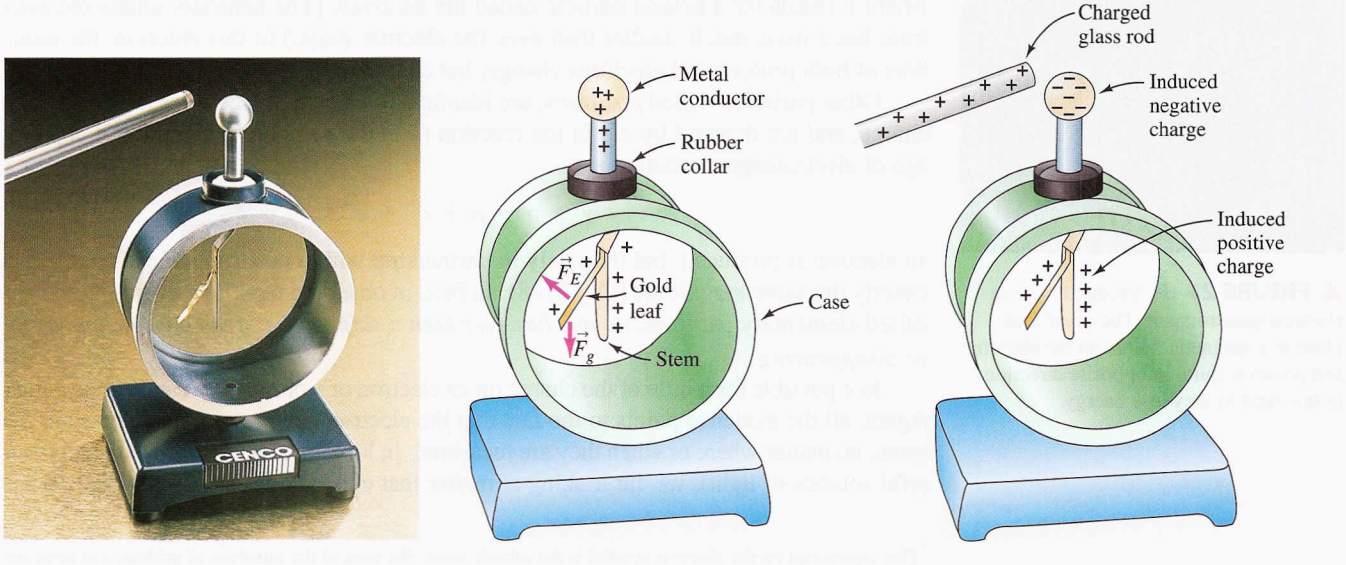
Working It Out The number of gold atoms in a mass of $m = 28.4$ g is

$$\frac{m}{m_{\text{Au}}}N_A = \frac{(28.4\text{ g})}{(197\text{ g/mol})}(6.02 \times 10^{23}\text{ atoms/mol})$$
$$= 8.68 \times 10^{22}\text{ atoms.}$$

The total number of electrons is then

$$\text{number of electrons} = (79\text{ electrons/atom})(8.68 \times 10^{22}\text{ atoms})$$
$$= 6.86 \times 10^{24}\text{ electrons.}$$

The total charge of these electrons is



$$\text{total electron charge} = (\text{number of electrons})(\text{charge per electron})$$
$$= (6.85 \times 10^{24}\text{ electrons})(-1.60 \times 10^{-19}\text{ C/atom}) = -1.1 \times 10^{6}\text{ C.}$$

What Do You Think? (a) If every electron were removed from the coin, what would be the charge left behind? (b) If one electron were removed from each gold atom, what would be the charge of the coin?

The Electroscope

The *electroscope* is a device used to detect excess free charge (Fig. 21–7a). There are two ways to use the electroscope. First, when charge is directly transferred to the electroscope by touching the metal ball at the top of the electroscope with a charged rod, the gold leaf inside separates from the vertical metal stem. This follows because the charge that is transferred to the electroscope is distributed throughout it, including to the leaf and stem; these each carry a charge of the same sign and hence repel one another, as in Fig. 21–7b. The leaf moves away from the stem until the vertical component of the electrostatic repulsion is balanced by the force of gravity on the leaf. Addition of more charge moves the leaf still more, and the angle made by the leaf is a measure of the amount of charge involved.

We also find that if we bring a charged rod near the metal ball at the top of the uncharged electroscope, the gold leaf still separates. What is happening? The overall charge on the electroscope is zero, and since the rod never actually touches the electroscope, the overall charge remains at zero. However, when the charged rod (positively charged, say) is brought close to the metal ball at the top of the electroscope, a negative charge is induced on the ball, as electrons are attracted by the positive charge on the rod. The positive ions collect on the leaf and stem, leaving them both positively charged. Again the leaf and stem repel (Fig. 21–7c). (An example of how this approach can be made more quantitative is given in Problem 10.)

▼ **FIGURE 21–7** (a) An *electroscope*, a device that detects the presence of charge. (b) When free charge is added to the metal conductor, the gold leaf and the vertical metal stem repel, causing the gold leaf to move away from the stem. (c) When a charged object is brought close to the metal ball at the top, a charge is induced on the ball, leaving a charge of the opposite sign on the stem and leaf. They again repel.

THINK ABOUT THIS. . .

HOW DO SMOKE DETECTORS WORK?

The smoke detectors common in many homes depend on the separation of charges. They contain a small radioactive source centered within a cylinder that is open at one end. The source steadily emits alpha (α) particles (nuclear constituents) with enough energy to knock electrons from air molecules with which the α particles collide. The outer cylinder contains a negative charge, and the positive ions produced when the air molecules are broken up are attracted to it. The rate at which the ions arrive at the outer cylinder is measured electronically. When there is a house fire, large organic molecules such as those contained in bacon fat or pinewood resin enter the cylinder. These large molecules are an easy target for the α particles, and as electrons are more loosely bound in these molecules, they are also more likely to be removed from the molecule in the collision. The increased number of ions arriving at the cylinder sets off the alarm. The only disadvantage to this system is that any large molecule in the air—paint solvents or ordinary cooking smoke, for example—will set off the alarm. Many detectors have on/off switches for such cases.

21–2 Charge Is Conserved and Quantized

The simple experiments described in Section 21–1 strongly suggest that *charge is conserved*. Further experiments show that the **conservation of charge** is a fundamental physical law: *Net* charge is the same before and after any interaction. Moreover, charge conservation is *local*. That means that if we have a big box, the charge is conserved not only in the box as a whole but in any subvolume, down to as small as we can measure with precision. If there is less charge in a subvolume than before, then that amount of charge will have crossed the boundary on its way out.

Evidence of Charge Conservation

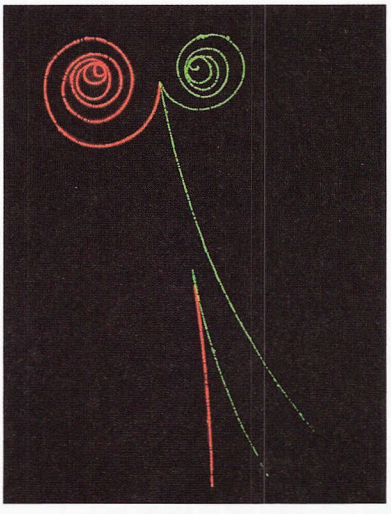
The reactions of subatomic particles such as nuclei or their constituents allows us to test charge conservation at a fundamental level. Let's look at some of these reactions. One of the reactions between atomic nuclei that takes place in a nuclear reactor is[†]

$$n + {}^{235}_{92}\mathrm{U} \rightarrow {}^{143}_{56}\mathrm{Ba} + {}^{90}_{36}\mathrm{Kr} + 3n + \text{energy}.$$

Here, the total number of protons (92) is the same on both "sides" of the reaction.

Even when the number of electrons or protons changes during a reaction, the total charge remains unchanged. Thus, another reaction that can take place in a nucleus is *electron capture*,

$$e^- + p \rightarrow n + \nu,$$



where ν stands for a neutral particle called the *neutrino*. (The neutrino, unlike the neutron, has a mass much smaller than even the electron mass.) In this reaction, the numbers of both protons and electrons change, but charge is still conserved.

Other particles, called *positrons*, are identical to electrons except for the *sign* of the charge, and are denoted by e^+. In the reaction (γ is the symbol for the photon, a package of electromagnetic radiation)

$$\gamma + p \rightarrow p + e^+ + e^-,$$

an electron is produced, but then only in partnership with a positron, whose charge has exactly the same magnitude (Fig. 21–8). In fact, in observed reactions involving the so-called elementary particles, *no one has ever seen a single case of net charge appearing or disappearing*.

Is it possible for a little of the charge on an electron or a proton to wear off, like paint? Again, all the evidence points to the fact that the electron and the proton charges are the same, no matter where or when they are measured. In looking at quasars (distant and powerful sources of light), we are looking at matter that existed billions of years ago (it has

▲ **FIGURE 21–8** Production of an electron–positron pair. The event took place in a magnetic field, and the electron and positron spiral in opposite directions in this field as they lose energy.

[†]The superscript on the element symbol is the atomic mass, the sum of the numbers of protons and neutrons in one atom; the subscript is the number of protons.

taken that long for the light to reach Earth). Observations of the color of the light that quasars emit suggest that, to a very high accuracy, the properties of their atoms are identical to the properties of atoms here on Earth. This implies that the charge of electrons and protons are not only identical but have remained constant over billions of years.

CONCEPTUAL EXAMPLE 21–3 A new theory makes the unusual proposition that the equality of the magnitude of the electron and proton charge was not always true, so that perhaps a billion years ago they differed by one part in a billion. What sort of arguments could you advance to check whether this is true or not?

Answer We have already mentioned a couple of effects that a change in magnitude of both the electron and proton charges would make: differences in the color (spectrum) of the light emitted by atoms, for example. Such effects follow when, even though changed, the electron and proton each carry charge of *identical* magnitude. Here we are asked what would happen if the magnitudes were not the same, and that has even more dramatic consequences. If the relative numbers of electrons and protons were unchanged, it would mean that the entire universe would have a net charge. Indeed, each atom would also have a net charge, all of the same sign, and unless the difference in charge were extremely tiny, the repulsive force between atoms would overwhelm the attractive gravitational forces that allow matter to clump into galaxies and stars. Bulk matter would not form in the way that we know it, at least not on the time scale of the universe.

Charge Quantization

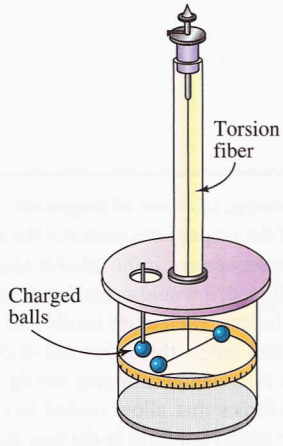
We have already indicated that charges appear to be organized in discrete amounts. The magnitude of this minimum amount of charge is that of one electron. Greater charges are always multiples of these values. The facts that, within experimental accuracy, charge occurs in integral multiples of the electron charge, known as **charge quantization**, and that charges are never observed with values smaller than the electron charge were first established in 1909 through the pioneering experiments of Robert Millikan.

In summary, we can say that

Charge is conserved absolutely

and that

Free charge is quantized in positive or negative integral multiples of e.



THINK ABOUT THIS. . .

DO QUARKS CARRY CHARGE THAT IS LESS THAN THE ELECTRON CHARGE?

In 1964, Murray Gell-Mann and George Zweig proposed that protons and neutrons are composed of even more fundamental particles, called **quarks**, whose charges are either $2e/3$ or $-e/3$. Thus the proton, say, contains three quarks whose total charge adds up to $+e$: two charge $(+2e/3)$ quarks and one charge $(-e/3)$ quark. There is strong experimental evidence that quarks really do make up particles such as protons, but strangely enough, and for reasons that are only partially understood, quarks cannot be isolated—they cannot be removed and separated from a proton in the way that a hydrogen atom can be separated into an electron and a proton. Despite many searches, quarks or any other freely moving object carrying fractional electron charges have never been observed. Most physicists now believe that only combinations of quarks possessing a net charge that is an integer multiple of e can ever be isolated and independently observed. We refer to any charge that can be isolated as **free charge**.

21–3 Coulomb's Law

Encouraged by Benjamin Franklin, Joseph Priestley concluded in the mid-eighteenth century from Franklin's and his own experiments that the electric force between two charged objects varies as the inverse square of the distance between the objects. Priestley made this deduction after he observed that there is no charge on the inside surface of a closed or nearly closed metal vessel—all the charge is on the outside surface—and that the force on a charged object placed inside such a vessel is zero. This is like the phenomenon we discussed in Chapter 12: There is no gravitational force on an object inside a uniform spherical shell of matter. As we argued in Chapter 12, this result is a direct consequence of the $1/r^2$ nature of the force law. By analogy with gravitation, Priestley argued that the electric force responsible for his observations must have a $1/r^2$ dependence.

▲ **FIGURE 21–9** Coulomb's torsion balance, used to verify the inverse-square form of the force between electric charges.

In 1785, Charles Coulomb directly determined the force law for electrostatics. He performed the relevant experiments with a torsion balance similar to the one Henry Cavendish would use in 1798 to measure the gravitational constant, G (Fig. 21–9). The role played by massive balls in the Cavendish experiment (see p. 342) is here played by charged ones. Coulomb showed that the electrostatic force is central—directed on the line between the charges—and varies as

$$F \propto \frac{1}{r^2}, \tag{21–2}$$

where r is the distance between the centers of the charge sources. By changing the charge on the balls, Coulomb inferred that the force is proportional to the product of the charges q_1 and q_2 on the balls:

$$F \propto q_1 q_2. \tag{21–3}$$

To demonstrate the results of Eq. (21–3), we can ground one cork ball, neutralizing it, and charge another identical ball, giving it net (unknown) charge q. After we touch the two balls together, they each have a charge of $q/2$. Then we measure the force between these two balls. Next, we ground one ball again to neutralize it, and touch the balls together once more. Thus, each has a charge of $q/4$, and we measure the force between them to have decreased by a factor of 4 for the same amount of separation. This set of results is consistent with Eq. (21–3): In the first case, $F \propto (q/2)(q/2) = q^2/4$; in the second, $F \propto (q/4)(q/4) = q^2/16$.

Combining Eqs. (21–2) and (21–3) gives us a first view of Coulomb's law, the electrostatic force law. The magnitude of the force is

$$F = \frac{k|q_1 q_2|}{r^2}, \tag{21–4}$$

where k is a proportionality constant. The force is attractive when the charges have opposite sign and repulsive when they have the same sign. Moreover, the force obeys superposition: The force on a given charge from a collection of charges is the sum of the forces due to each charge in the collection.

The constant k plays the same role that the constant G plays in Newton's law of universal gravitation. The magnitude of k depends on the units used for charge—here we use a system of units that is consistent with the SI. It is then possible to define the coulomb by assigning a value to k:

$$k = \frac{1}{4\pi\varepsilon_0}, \tag{21–5}$$

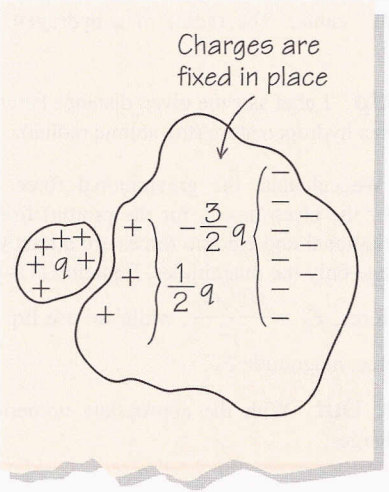
where ε_0 is known as the *permittivity of free space*. (We shall see later that the value of ε_0 follows directly from the defined value of the speed of light, so in this sense ε_0 is itself defined.) To four significant figures, the permittivity is

$$\varepsilon_0 \cong 8.854 \times 10^{-12}\ \mathrm{C^2/N \cdot m^2}. \tag{21–6}$$

The value of k (to four significant figures) follows from Eqs. (21–5) and (21–6):

$$k = 8.988 \times 10^9\ \mathrm{N \cdot m^2/C^2}. \tag{21–7}$$

Now that we have assigned a value to k, we can tentatively define the coulomb. From Eqs. (21–4) and (21–7), we say that



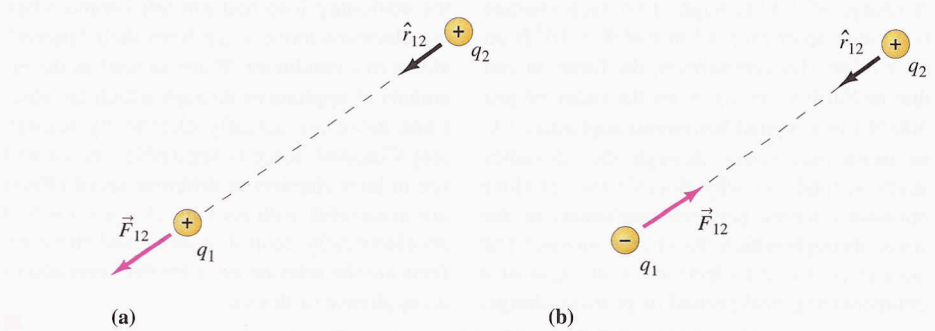
When the force between two identical charges separated by 1 m is equal to the numerical value of k in newtons (8.988×10^9 N), these charges are each 1 C.

The definitive definition of the coulomb will come after we have discussed the forces between electric currents in Chapter 29.

CONCEPTUAL EXAMPLE 21–4 An electrically neutral object can be divided into a piece with charge $+q$ and another piece with charge $-q$. If these pieces are widely separated, they attract one another. Is there any way to break a neutral object into two pieces that repel each other?

Answer If an electrically neutral object is divided into two charged pieces, charge conservation demands that the two pieces are oppositely charged with charges of equal magnitude. If these two pieces are separated by distances large compared to their size, then they will look like point charges to one another and so attract. However, things can be different when the pieces are separated by relatively short distances, because then by distributing the charges properly within the pieces, we can use the distance dependence of Coulomb's law to produce a net repulsion. For example, imagine that we have one large and one small piece—the small piece with charge of $+q$ and the large piece with overall charge $-q$. However, we have distributed the charge in the large piece as in Fig. 21–10. According to Coulomb's law, the effect on a given charge of a nearby charge is much bigger than the effect of distant charge. The effect of having the positive charge concentrated at the side of the large piece that is closest to the positively charged small piece means that the overall force between the pieces is repulsive—the two pieces repel at short distances, even though at large distances they attract. While this scenario might be difficult actually to prepare, it reminds us that the distance dependence of the force between charges, with its potentially very large $1/r^2$ factor, can have important effects.

What Do You Think? Consider the larger piece with its charge arranged as in Fig. 21–10. If charge were free to flow within this piece, is this the way the charge would arrange itself?



▲ **FIGURE 21–10** Two oppositely charged objects can repel at short distances if it is possible to rearrange the charge within one of them. Here the net charge $-q$ in the right-hand object has been shifted so that there is a positive piece very close to the positively charged object on the left. The magnitude of Coulomb forces falls off rapidly with distance, so that this arrangement could produce repulsion over short distances.

The electric force between point charges, the **Coulomb force**, has a direction and is described by a vector. We write Coulomb's law as

$$\vec{F}_{12} = \frac{1}{4\pi\varepsilon_0}\left(\frac{q_1 q_2}{r_{12}^2}\right)\hat{r}_{12}, \qquad (21\text{–}8)$$

COULOMB'S LAW

where $\vec{F}_{12}$ is the force exerted on point charge q_1 due to point charge q_2 when they are separated by a distance r_{12}. Newton's third law tells us that the force exerted on point charge q_2 due to point charge q_1 is then $\vec{F}_{21} = -\vec{F}_{12}$. The unit vector $\hat{r}_{12}$ is directed from q_2 to q_1 along the line between the two charges (Fig. 21–11). Note that if q_1 and q_2 have opposite signs, Eq. (21–8) indicates that the force is attractive, along $-\hat{r}_{12}$. But rather than remembering the subscripts on $\vec{F}$ and the unit vector $\hat{r}$, it is easier to remember that like charges repel and unlike charges attract.

◀ **FIGURE 21–11** $\vec{F}_{12}$ is the force on q_1 due to q_2. The force is in the direction (a) $\hat{r}_{12}$ for like charges, and (b) $-\hat{r}_{12}$ for opposite charges.

EXAMPLE 21–5 Compare the electric force and the gravitational force between the single proton and single electron in a hydrogen atom. Assume a purely classical model of the hydrogen atom, in which the electron moves in a circular orbit around the proton, which is at the atom's center. The radius of a hydrogen atom is about 5×10^{-11} m.

Setting It Up Label as r the given distance between the proton and electron in a hydrogen atom (the atomic radius).

Strategy We calculate the gravitational force, obtaining the masses (m_e for the electron, m_p for the proton) from Table 21–1. Both the gravitational and electric forces are attractive in this case, and we calculate only the magnitudes. Equation (12–4) gives us the gravitational force, $F_g = \dfrac{Gm_em_p}{r^2}$, while we use Eq. (21–8) to find the electric force, magnitude F_E.

Working It Out With the appropriate numerical values for masses and charges,

$$F_g = \frac{(6.67 \times 10^{-11}\,\text{N}\cdot\text{m}^2/\text{kg}^2)(9.11 \times 10^{-31}\,\text{kg})(1.67 \times 10^{-27}\,\text{kg})}{(5 \times 10^{-11}\,\text{m})^2} = 4 \times 10^{-47}\,\text{N}.$$

$$F_E = \frac{(9 \times 10^9\,\text{N}\cdot\text{m}^2/\text{C}^2)(1.6 \times 10^{-19}\,\text{C})^2}{(5 \times 10^{-11}\,\text{m})^2} = 9 \times 10^{-8}\,\text{N}.$$

$$\frac{F_E}{F_g} = \frac{9 \times 10^{-8}\,\text{N}}{4 \times 10^{-47}\,\text{N}} \cong 2 \times 10^{39}.$$

This calculation of the ratio could more easily have been carried out directly because it is independent of r — the common factor $1/r^2$ would cancel in the ratio. We have shown that on the atomic scale, the electric force is much greater than the gravitational force and that we are justified in ignoring gravitation at the atomic level.

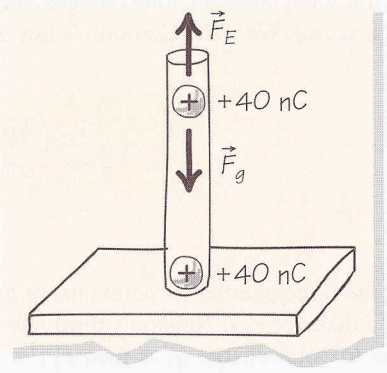
What Do You Think? If the force due to gravitation is so much smaller than that of the electric force, why do we even notice it?

EXAMPLE 21–6 Two small cork balls are both charged to 40 nC and placed 4.0 cm apart. What is the magnitude of the electric force between them? Each cork ball has a mass of 0.46 g. Compare the magnitude of the electric force between them to the weight of one of the balls. What will happen if the balls are arranged vertically within a tube, with one ball placed 4 cm above the other?

Setting It Up Denote each charge by Q, each mass by m, and the separation of the balls by d. Figure 21–12 shows the cork balls (in the arrangement appropriate for the last question).

Strategy We use Coulomb's law, Eq. (21–8), to find the electric force between the balls, magnitude F_E, and then use $W = mg$ to find the weight.

Working It Out The electric force has magnitude



$$F_E = \frac{kQ^2}{d^2} = \frac{(9 \times 10^9\,\text{N}\cdot\text{m}^2/\text{C}^2)(40 \times 10^{-9}\,\text{C})^2}{(4.0 \times 10^{-2}\,\text{m})^2} = 9.0 \times 10^{-3}\,\text{N}.$$

The weight of each cork ball is

$$W = mg = (0.46 \times 10^{-3}\,\text{kg})(9.8\,\text{m/s}^2) = 4.5 \times 10^{-3}\,\text{N}.$$

We conclude that if the balls start in a vertical orientation as in Fig. 21–12, separated by 4 cm, the (repulsive) electric force would lift the upper cork ball. The electric force would balance the gravitational force only if the balls started out a little farther apart—you could easily calculate that distance.

What Do You Think? What would have happened if the experiment with the vertical placing were carried out as above, but each ball had twice the mass?

▲ **FIGURE 21–12** A small object can be suspended in space when equal but opposite gravitational and electric forces act on it.

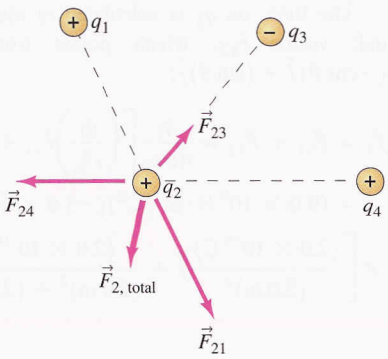
THINK ABOUT THIS. . .

ARE THERE COULOMB FORCES BETWEEN HOME APPLIANCES?

A charge of 1 C is huge: Two such charges one meter apart exert a force of 9×10^9 N on each other. (By comparison, the force on you due to Earth's gravity is on the order of just 500 N.) In a typical household appliance, 1 C or more may move through the appliance every second, so why doesn't this produce enormous forces between appliances or the wires through which the charge moves? The answer is that the electrons move against a compensating background of positive charge, the stationary ions that are left behind when the electrons move away from their "parent" atoms in a conductor. Wires as well as the elements of appliances through which the electrons move are actually electrically neutral. Any Coulomb force is negligible. As we will see in later chapters, a different set of effects are associated with moving charges, even in an electrically neutral system, and these effects are the relevant ones for the operation of an appliance or device.

21–4 Forces Involving Multiple Charges

What happens if multiple charges are present? Experiment shows that the **principle of superposition** applies: The force on any one charge due to a collection of other charges is the vector sum of the forces due to each individual charge. In this respect, the Coulomb force is again like the gravitational force. The superposition principle allows us to find the force due to a set of charges on another charge or, for that matter, on another set of charges.



As an example of how superposition is applied, consider four charges, numbered 1, 2, 3, 4 (Fig. 21–13). The total force on, say, charge q_2 is the *vector sum* of the forces due to the other individual charges, q_1, q_3, and q_4:

$$\vec{F}_{2,\text{total}} = \vec{F}_{21} + \vec{F}_{23} + \vec{F}_{24}. \tag{21–9}$$

If there are N charges—$q_1, q_2, \ldots, q_N$—all acting on a charge q, the total force $\vec{F}$ on charge q is the vector sum of the individual forces $\vec{F}_i$ on charge q due to charge q_i:

$$\vec{F} = \sum_{i=1}^{N} \vec{F}_i = \frac{q}{4\pi\varepsilon_0} \sum_{i=1}^{N} \frac{q_i}{r_i^2} \hat{r}_i \tag{21–10}$$

The vector $\hat{r}_i$ is the unit vector from charge q_i to charge q. We have moved the common factor $q/4\pi\varepsilon_0$ out of the sum.

▲ **FIGURE 21–13** The superposition principle applies for multiple charges. The total force on charge q_2 is the vector sum of the individual forces on q_2 due to charges q_1, q_3, and q_4.

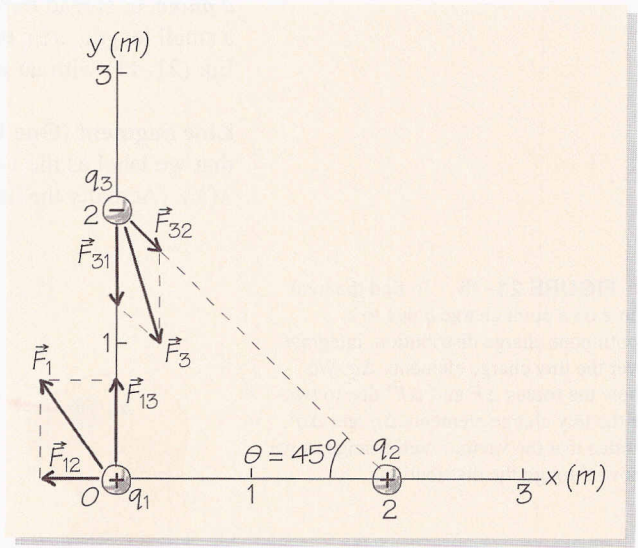
Problem-Solving Techniques

It is helpful to keep the following techniques in mind when looking at problems involving electric forces on a given charge in the presence of several other fixed charges or continuous distributions of charges:

1. Draw a clear diagram of the situation. Be sure to distinguish between the fixed external charges and the charges on which the forces must be found. The diagram should contain coordinate axes for reference.
2. Do not forget that the electric force that acts on a charge is a vector quantity; when many charges are present, the net force is a vector sum. In calculations, it is usually simplest to use unit vectors in a Cartesian coordinate system.
3. Search for symmetries in the distribution of charges that give rise to the electric force. When symmetries are present, the net force along certain directions will be zero. For example, if a point charge is midway between two identical charges, we know without performing any calculations that the net force on it will be zero.

EXAMPLE 21–7 Consider three point charges $q_1 = q_2 = 2.0$ nC and $q_3 = -3.0$ nC placed at the vertices of the triangle shown in Fig. 21–14. Find the net forces on q_1 and q_3, assuming that only Coulomb forces act.

Strategy The force on q_1, say, is due to the presence of charges q_2 and q_3. We find the vector forces on q_1 due to each of the charges q_2 and q_3 separately, then add them vectorially to find the net force on q_1. Coulomb's law depends on distance, and we will take these distances from Fig. 21–14. We can then do a similar calculation for the force on q_3.



Working It Out The force on q_1 is

$$\vec{F}_1 = \vec{F}_{12} + \vec{F}_{13} = \frac{q_1}{4\pi\varepsilon_0}\left[\left(\frac{q_2}{r_{12}^2}\right)\hat{r}_{12} + \left(\frac{q_3}{r_{13}^2}\right)\hat{r}_{13}\right].$$

From Fig. 21–14, we can deduce that $\hat{r}_{12} = -\hat{\imath}$ and $\hat{r}_{13} = -\hat{\jmath}$. Thus

$$\begin{aligned}\vec{F}_1 &= (9.0 \times 10^9\ \text{N}\cdot\text{m}^2/\text{C}^2)(2.0 \times 10^{-9}\ \text{C}) \\ &\quad \times \left[\frac{(2.0 \times 10^{-9}\ \text{C})}{(2.0\ \text{m})^2}(-\hat{\imath}) + \frac{(-3.0 \times 10^{-9}\ \text{C})}{(2.0\ \text{m})^2}(-\hat{\jmath})\right] \\ &= (-9.0 \times 10^{-9}\ \text{N})\hat{\imath} + (14 \times 10^{-9}\ \text{N})\hat{\jmath}.\end{aligned}$$

The direction of force $\vec{F}_1$ is shown in Fig. 21–14.

▲ **FIGURE 21–14** The positions of three point charges are indicated. Charges q_1 and q_2 are positive, while q_3 is negative. Forces $\vec{F}_{12}$ and $\vec{F}_{13}$ on charge q_1, and their resultant, $\vec{F}_1$, as well as forces $\vec{F}_{31}$ and $\vec{F}_{32}$ on charge q_3, and their resultant, $\vec{F}_3$, are drawn.

(continues on next page)

The force on q_3 is calculated in much the same way, with the unit vector $\hat{r}_{32}$, which points from q_2 to q_3, given by $(-\cos\theta)\hat{i} + (\sin\theta)\hat{j}$:

$$\vec{F}_3 = \vec{F}_{31} + \vec{F}_{32} = \frac{q_3}{4\pi\varepsilon_0}\left[\left(\frac{q_1}{r_{31}^2}\right)\hat{r}_{31} + \left(\frac{q_2}{r_{32}^2}\right)\hat{r}_{32}\right]$$

$$= (9.0 \times 10^9\ \text{N}\cdot\text{m}^2/\text{C}^2)(-3.0 \times 10^{-9}\ \text{C})$$

$$\times\left[\frac{(2.0 \times 10^{-9}\ \text{C})}{(2.0\ \text{m})^2}\hat{j} + \frac{(2.0 \times 10^{-9}\ \text{C})}{(2.0\ \text{m})^2 + (2.0\ \text{m})^2}((-\cos\theta)\hat{i} + (\sin\theta)\hat{j})\right].$$

The angle θ is 45°, or $\pi/4$ rad, so $\vec{F}_3$ becomes

$$\vec{F}_3 = (-14 \times 10^{-9}\ \text{N})\hat{j} + (4.8 \times 10^{-9}\ \text{N})\hat{i} - (4.8 \times 10^{-9}\ \text{N})\hat{j}$$
$$= (4.8 \times 10^{-9}\ \text{N})\hat{i} - (19 \times 10^{-9}\ \text{N})\hat{j}.$$

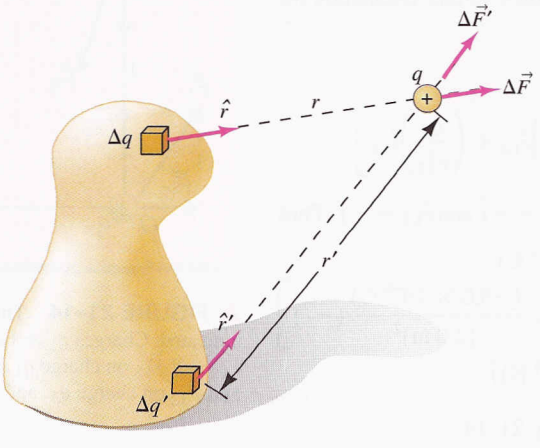
What Do You Think? If q_1 and q_2 are fixed at the given locations, can we place q_3 at some point such that the net force on it is zero? If the point exists, is it a stable equilibrium point?

Continuous Distributions of Charges

The fact that charge is quantized will have no physical consequence when we deal with charges that are much larger than e. Such charges are composed of large numbers of electrons or protons. We can normally treat a large collection of point charges as a *continuous distribution* of charge. This is entirely analogous to thinking of a large object as a continuous distribution of mass, even though we know it is made of individual atoms. The techniques for treating continuous charge distributions will be very similar to the techniques we developed for treating continuous mass distributions.

We consider first the interaction of a point charge q with a large continuous charge distribution (Fig. 21–15). The force on q due to the tiny element of volume shown, which contains charge Δq and is a distance r from q, is

$$\Delta\vec{F} = \frac{q}{4\pi\varepsilon_0}\frac{\Delta q}{r^2}\hat{r}.$$



In turn, the net force on q is the sum over the forces due to the elements Δq:

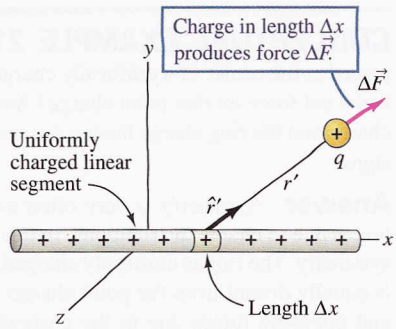
$$\vec{F} = \sum\Delta\vec{F} = \sum\frac{q}{4\pi\varepsilon_0}\frac{\Delta q}{r^2}\hat{r} = \frac{q}{4\pi\varepsilon_0}\sum\frac{\Delta q}{r^2}\hat{r}. \qquad (21\text{–}11)$$

We have to keep in mind that this is a vector sum.

At this point, we have not been very specific about how actually to do the sum. Just as for masses we found a more concrete way to proceed by working with a mass density, here it is useful to use the idea of a *charge density*. We separate the cases according to whether the continuous distribution of charge is distributed *along a line*, spread *over a plane*, or spread *throughout a volume*. In each case, we replace the finite charge Δq in a small length, area, or volume with the infinitesimal charge dq, and replace the sum in Eq. (21–11) with an integral. Let us look at each of these distributions in more detail:

Line Segment (One Dimension): If the charge distribution is distributed along a line that we label as the x-axis, we denote the *linear charge density* (charge/unit length) by $\lambda(x)$. (Actually the line of charge does not have to be a straight line; x really serves as a

▶ **FIGURE 21–15** To find the total force on a point charge q due to a continuous charge distribution, integrate over the tiny charge elements Δq. We show the forces $\Delta\vec{F}$ and $\Delta\vec{F}'$ due to two of the tiny charge elements Δq and $\Delta q'$. Notice that the vector $\hat{r}$ will change as we move through the distribution.



way to label where you are along the distribution here.) The charge on an infinitesimal length dx of the line is

$$\text{for a charged line: } dq = \lambda(x)\, dx. \tag{21–12}$$

Note that λ can be a function of x; that is, the charge density can vary along the line. The force can be on the point charge q is then (Fig. 21–16)

$$\vec{F} = \frac{q}{4\pi\varepsilon_0} \int \hat{r}' \frac{\lambda(x)\, dx}{r'^2}. \tag{21–13}$$

Notice the meaning of the integration: We move along the line of charge, and each point along the line is a different distance r' and at a different direction $\hat{r}'$ from the charge q. Later we look at some examples to see how this works in practice. The line segment need not be straight. We must follow it wherever it goes in the integration of Eq. (21–13)—we will in the more general case refer to the integration as a line integral, as we did in our treatment of work (Chapter 6).

▲ **FIGURE 21–16** A one-dimensional charge distribution and the infinitesimal force on a point charge due to an infinitesimal piece of it.

Surface (Two Dimensions): Here the charge is distributed across a surface. We denote the *surface charge density* (charge/unit area) by σ. The density σ could be a constant (uniform charge density), or it could vary from point to point on the surface. The charge on an infinitesimal area dS of the surface is (Fig. 21–17)

$$\text{for a charged surface: } dq = \sigma\, dS. \tag{21–14}$$

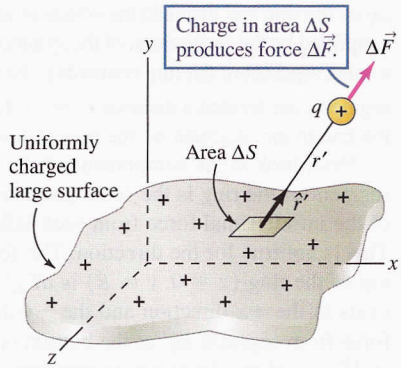
The force on the point charge q is (Fig. 21–17)

$$\vec{F} = \frac{q}{4\pi\varepsilon_0} \int_{\text{surface}} \hat{r}' \frac{\sigma\, dS}{r'^2}. \tag{21–15}$$

Here, we are integrating over all the elements of the surface, as indicated by the subscript of the integral sign. In practice, such integrals can be done by working out one-dimensional integrals.

Volume (Three Dimensions): When the charge is distributed through a volume, we write the *volume charge density* of the distribution as $\rho(\vec{r}')$, which means that the infinitesimal charge dq contained in the infinitesimal volume dV is

$$dq = \rho\, dV. \tag{21–16}$$

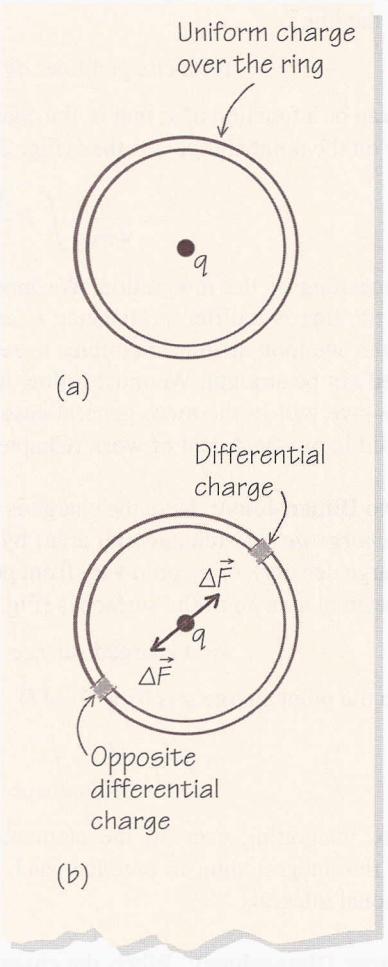


In terms of the charge density of the continuous charge distribution, the *net* force due to the volume element shown in Fig. 21–15 is

$$\vec{F} = \frac{q}{4\pi\varepsilon_0} \int_{\text{volume}} \hat{r}' \frac{\rho\, dV}{r'^2}. \tag{21–17}$$

The integration is over the entire volume of the charge distribution, and that is why we have used the subscript. Again, such integrals often involve simpler one-dimensional integrals in practice.

In each of these cases, the argument of the charge distribution ρ is the vector displacement $\vec{r}'$, as it is the vector displacement from an element of the charge distribution to the point charge on which the force acts that is important. We may, however, have a *uniform* charge distribution, in which charge is distributed evenly throughout a region. In that case, the linear charge density λ is the total charge on the line divided by the length of the line, the surface charge density σ is the total charge on the surface divided by the area of the surface, and the volume charge density ρ is the total charge in the three-dimensional region divided by the volume of the region. All three quantities are constants that can be removed from the integral for the net force. Keep in mind that a uniform charge distribution is not possible with a conductor, within or on which charges are free to move.



The integrals that express the force may be simple to perform, particularly if there is some symmetry in the distribution. Without the symmetry, it may be hard to find an analytical answer for the integral, but numerical integration using a computer is always possible.

▲ **FIGURE 21–17** A two-dimensional charge distribution and the infinitesimal force on a point charge due to an infinitesimal piece of it.

CONCEPTUAL EXAMPLE 21–8 A point charge q is placed at the center of a uniformly charged ring (Fig. 21–18a). What is the net force on that point charge? Analyze this for both the point charge and the ring charge having the same sign and having different signs.

Answer Symmetry is very often a useful tool in dealing with forces due to charge distributions. In this case there is a good deal of symmetry. The ring is uniformly charged, and every point on the ring is equally distant from the point charge. There will always be equal and opposing forces due to the charged ring on either side of the charge q, as in Fig. 21–18b where we have identified areas of the ring that exert equal and opposing forces on point charge q. It does not matter whether q is positive or negative, because it will be repelled equally or attracted equally in all directions in the plane of the ring. The net force is zero, and no complex mathematical calculation is needed.

▶ **FIGURE 21–18** (a) The ring is uniformly charged. (b) Sections on opposite sides of the ring exert forces on the charge at the center that cancel.

EXAMPLE 21–9 Find the force on a point charge q_1 located on the axis of a uniformly charged ring of total charge Q. The radius of the ring is R, and q_1 is located a distance L from the center of the ring.

Setting It Up The geometry of the ring and point charge is shown in Fig. 21–19a, with appropriate labeling.

Strategy We want to find the force on q_1 due to a differential charge dq on the ring and then add the effects of all the parts of the ring. This is simplified by the recognition of the symmetry of this situation. Consider a small segment of the ring containing charge dq (Fig. 21–19a). *All* such segments are located a distance $r' = \sqrt{L^2 + R^2}$ from charge q_1, and the line to *any* segment on the ring makes the angle θ with the x-axis.

Next, look at the components of the force on q_1. Because every segment of the ring is the same distance r' from q_1, the *magnitude* of the infinitesimal force from each infinitesimal slice is the same. This is not true for the direction. The force from segment dq at the top of the ring ($z = 0, y = R$) is $d\vec{F}_{dq}$, and this force has components in the $+x$-direction and the $-y$-direction (Fig. 21–19b). The force from segment dq' at the bottom of the ring ($z = 0, y = -R$) is $d\vec{F}_{dq'}$, and this force has components in the $+x$-direction and the $+y$-direction. If the magnitude dq equals the magnitude dq', the y-components of the force will cancel each other while the x-components of the force will add. The y-components are the components perpendicular to the axis of the ring. This cancellation will hold for every perpendicular component of the force because we can always consider the charge elements in pairs. Thus we need compute only the component F_x by adding the (identical) infinitesimal components dF_x from each little element.

Working It Out The x-component from the element shown in Fig. 21–19a is

$$dF_x = \frac{q_1}{4\pi\varepsilon_0}\frac{dq}{r'^2}\cos\theta = \frac{q_1}{4\pi\varepsilon_0}\frac{\cos\theta}{(R^2 + L^2)}dq.$$

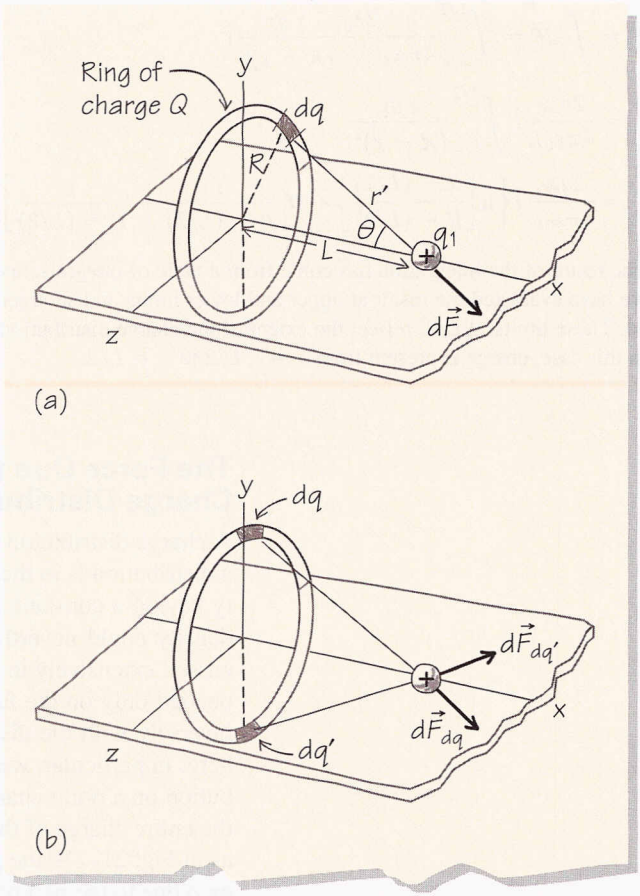
The net force has only an x-component and is the sum over the infinitesimal x-components:

$$F_x = \int dF_x = \int \frac{q_1}{4\pi\varepsilon_0}\frac{\cos\theta}{(R^2 + L^2)}dq.$$

At this point we see the symmetry come into play again: the coefficient of dq in the expression for dF_x is the same for every element and can therefore be placed outside the integral sign. Thus

$$F_x = \frac{q_1}{4\pi\varepsilon_0}\frac{\cos\theta}{(R^2 + L^2)}\int dq = \frac{q_1 Q}{4\pi\varepsilon_0}\frac{\cos\theta}{(R^2 + L^2)}.$$

We have used the fact that $\int dq = Q$, the entire charge. Finally, from trigonometry we find



$$\cos\theta = \frac{L}{\sqrt{R^2 + L^2}},$$

so

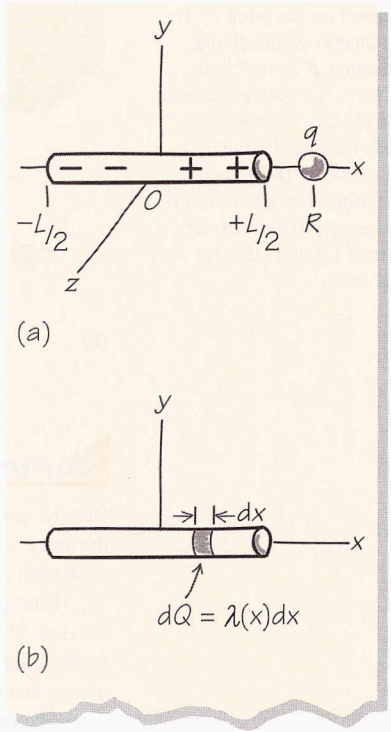
$$F_x = \frac{q_1 Q}{4\pi\varepsilon_0} \frac{L}{(R^2 + L^2)^{3/2}}. \qquad (21\text{–}18)$$

A check is always desirable, and we can immediately find one: When the point charge q_1 is very far from the ring, the ring should appear as a distant point of total charge Q, and the force should take on the Coulomb form $q_1 Q/(4\pi\varepsilon_0 L^2)$; this is indeed the limit of Eq. (21–18) when $L \gg R$.

What Do You Think? What is the force on q_1 when $L = 0$? (This is a second check on the result.)

▶ **FIGURE 21–19** (a) The force on a point charge q_1 due to a ring with total charge Q. First we find the force between the point charge and a tiny ring segment with charge dq. (b) Only the x-component of the force needs to be determined, because the y- and z-components will cancel due to symmetry.

EXAMPLE 21–10 A straight rod of length L is aligned along the x-axis, with the ends at $x = \pm L/2$. The total charge on the rod is zero but the charge density is not; it is given by $\lambda(x) = 2\lambda_0 x/L$ (positive to the right of the origin, negative to the left). Find the force on a charge q located at a point $x = R$ on the x-axis, to the right of the right-hand end of the rod.



Setting It Up The geometry of the rod and of the charge on it is shown in Fig. 21–20a. The point charge for which we want to find the acting force is also indicated, at $x = R > L/2$.

Strategy We start by dividing the rod into elements that can be treated as points as far as figuring the force they exert on charge q. Thus we consider a thin slice of the rod with charge dQ located at point x, with thickness dx; this slice will have charge $dQ = \lambda(x)\,dx$. This is drawn in Fig. 21–20b. We find the force between each element of this type and q and then add these forces in the form of an integral. Although the symmetry in this case is not very marked, the integral will turn out to be an elementary one.

Working It Out With $dQ = \lambda\,dx = \dfrac{2\lambda_0}{L} x\,dx$, the infinitesimal force exerted by this charge on charge q is given by

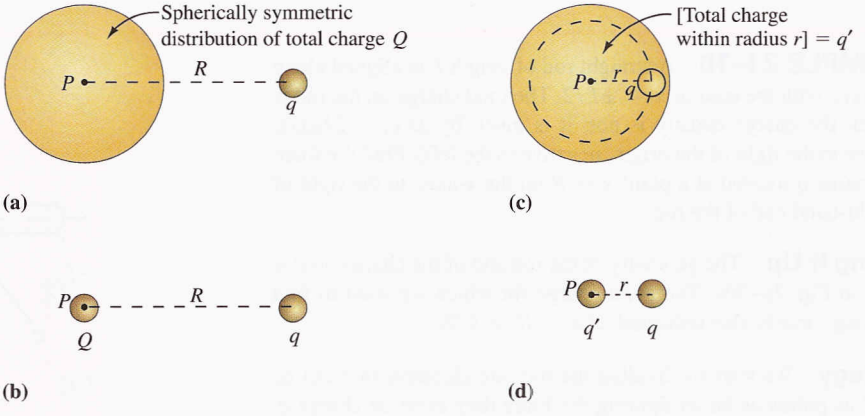
$$d\vec{F} = \frac{q}{4\pi\varepsilon_0} \frac{2\lambda_0}{L} x\,dx \frac{1}{(R - x)^2} \hat{\imath}.$$

This force is aligned with the x-direction, as the unit vector indicates. The summation over the force due to the different slices to give the total force will also be aligned this way. This summation takes the form

▲ **FIGURE 21–20** (a) A nonuniform charge density. (b) Isolating a section of the charge on the rod.

(continues on next page)

$$\vec{F} = \int d\vec{F} = \int_{-L/2}^{L/2} \frac{q}{4\pi\varepsilon_0}\frac{2\lambda_0}{L}\frac{x\,dx}{(R-x)^2}\hat{i}$$
$$= \frac{2q\lambda_0}{4\pi\varepsilon_0 L}\hat{i}\int_{-L/2}^{L/2}\frac{x\,dx}{(R-x)^2}$$
$$= \frac{2q\lambda_0}{4\pi\varepsilon_0 L}\hat{i}\left\{\ln\left[\frac{R-(L/2)}{R+(L/2)}\right] + R\left[\frac{1}{R-(L/2)} - \frac{1}{R+(L/2)}\right]\right\}.$$



The result of the integration has come from a table of integrals, and we have evaluated the result at upper and lower limits and subtracted. These limits, $\pm L/2$, reflect the extent of the charge distribution. In this case, charge is present from $x = -L/2$ to $x = L/2$.

If we drew a numerical plot of the factor in curly brackets in the expression for the force, we would see that this force is positive—if the charge q is positive it acts to push it to the right. This is sensible because the right side of the rod is positively charged, and the point charge is closer to the right side of the rod. The space variation of the coulomb force makes the repulsion from the closer part of the rod more important than the attraction from the farther part of the rod.

What Do You Think? Assuming the charge q is positive, what is the force on it when it is placed very close to the right end of the rod?

The Force Due to a Spherically Symmetric Charge Distribution

A charge distribution that is *spherically symmetric* is often quite easy to analyze. Such a distribution is in the form of a sphere centered at, say, point P, with the charge density having a constant value at a given (radial) distance from P. (Notice that the charge density could nevertheless vary with the radial distance from P.) This case was discussed extensively in Chapter 12 for the gravitational force. The results for gravity depended only on the fact that the force due to each bit of the charge distribution varies inversely with the distance from it squared, and so we can use the Chapter 12 results here. In particular, we can say that the force of the spherically symmetric charge distribution on a point charge q outside the distribution (Fig. 21–21a) is the same as though the entire charge of the distribution were concentrated at P (Fig. 21–21b). Moreover, if as in Fig. 21–21c the point charge q is inside any part of the distribution, then the force on q due to the part of the distribution that lies outside q is zero (Fig. 21–21d).

▶ **FIGURE 21–21** (a) A spherically symmetric charge distribution of total charge Q is centered on the point P. The force on a point charge q outside the distribution a distance R from P is the same as (b) the force it would experience if a point charge Q were located at P. (c) If q lies inside the distribution a distance r from P, and q' is the total charge that lies within a sphere of radius r centered on P, then it experiences the same force it would have (d) if there were a point charge q' at P.

Summary

Electric charge occurs in two forms, which we label as positive and negative charge. Charges of the same sign repel each other, and charges of unlike sign attract each other. In SI units, charge is measured in coulombs.

Much of the behavior of materials under the influence of electric forces is characterized by the ease with which electrons are dislodged from their constituent atoms and molecules and move through the material. Metals are normally good conductors of electric charge, whereas most nonmetals are not and are called insulators.

The basic electric charge is that of the electron. The electron has a charge of $-e$, and the proton has a charge of $+e$, with $e = 1.602 \times 10^{-19}$ C. Electric charge in matter is quantized in multiples of e. Charge is conserved in all interactions, meaning that the net charge before an interaction is the same as the net charge after the interaction.

The electric (Coulomb) force exerted by the point charge q_2 on the point charge q_1, when these are separated by a distance r_{12} is given by Coulomb's law:

$$\vec{F}_{12} = \frac{1}{4\pi\varepsilon_0}\left(\frac{q_1 q_2}{r_{12}^2}\right)\hat{r}_{12}, \tag{21–8}$$

where the factor $1/(4\pi\varepsilon_0)$ sets the units of charge.

The principle of superposition applies when multiple charges are present. The Coulomb forces on a point charge q due to all other charges add together vectorially. For continuous charge distributions, this addition takes the form of an integration, and the force of such a distribution on q depends on the charge distribution. For charges distributed on a line, over a surface, or through a volume, the force on the point charge q due to the distribution is, respectively,

$$\vec{F} = \frac{q}{4\pi\varepsilon_0}\int \hat{r}'\frac{\lambda(x)\,dx}{r'^2}, \tag{21–13}$$

$$\vec{F} = \frac{q}{4\pi\varepsilon_0}\int_{\text{surface}} \hat{r}'\frac{\sigma\,dS}{r'^2}, \tag{21–15}$$

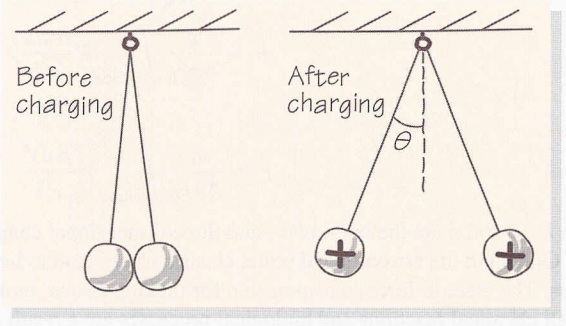
and

$$\vec{F} = \frac{q}{4\pi\varepsilon_0}\int_{\text{volume}} \hat{r}'\frac{\rho\,dV}{r'^2}. \tag{21–17}$$

Here λ, σ, and ρ are the one-, two-, and three-dimensional charge densities, respectively.

On all but the astronomical scale, electric forces tend to be much stronger than gravitational forces. The electric force is responsible for making atoms, molecules, solids, and liquids stable, and all chemical reactions and biological processes are a result of electrical interactions.

Understanding the Concepts



1. Two identical positive charges are placed on a table and fixed there. Find all the places on the table where the net force on a test charge due to the two charges is zero.
2. Particles of opposite charge attract with an inverse-square law. Are there analogues of Kepler's laws for a system composed of such a pair, and what are they?
3. A balloon rubbed on a sweater and placed on a wall will often stay on the wall for a while. Explain how this happens.
4. When you walk across a carpet, you often pick up enough electric charge to cause a spark when you touch a doorknob. In climates that are dry in winter, this phenomenon is much more common in the winter than in the summer. Why?
5. Two metallic spheres on insulating stands are placed on an air-track. The mass of one sphere is five times larger than the other, and the charges are both positive in the ratio 3:1. The two objects are held at rest and then let go. What determines how far the two objects each move in a short time interval? How would you find the ratio of the distances that they travel in that interval?
6. By using the apparatus discussed in Section 21–1, how could you determine what charge you accumulate by walking across a wool rug?
7. Atoms consist of negatively charged electrons bound to the positively charged nucleus by the Coulomb force. The electrons are rearranged when two different chemicals are brought together. Would you expect the electrons that are closer to the nucleus or the ones that are farther from the nucleus to be more involved in chemical reactions?
8. Neutrons and protons are believed to be made of two types of charged particles called quarks, having charge $-1/3\,e$ and $2/3\,e$, as mentioned in Section 21–2. List the possible combinations of only three quarks that make up neutrons and protons.
9. When we unpack boxes, we often find that the "peanuts" used for cushioning stick to our hands, and it is difficult to shake them off. Why?
10. Some materials lose electrons easily by rubbing, so why are many of the objects around us not charged at all times?
11. *Earnshaw's theorem* states that a point charge cannot be in stable equilibrium while purely electrostatic forces act on the point charge. Consider a ring that is uniformly positively charged, with a positive charge at the center. It appears that the center charge suffers an identical repulsive force from every direction. How can the theorem be true?
12. How is the existence of a battery, which sends negative charges out of one of its contact points, consistent with the conservation of charge?
13. You have a cork ball with a charge of -4.8×10^{-19} C and three uncharged cork balls. Can you devise a method of touching cork balls together in sequence that will give a charge of -0.8×10^{-19} C to one of the balls?
14. You are given objects with two different charges. Can you determine whether the charges on these objects attract or repel? Can you determine with no further information whether the charges on the objects are positive or negative?
15. We spoke of generating a spark on a winter's day when we touch a conducting line to Earth and become grounded. Automobile tires are such good insulators that a car body is not connected to Earth by a conductor. How do you explain the spark that occurs when you touch a car door after you have rubbed the car upholstery?
16. Suppose that the electric charge of a fundamental particle such as an electron depends on the speed v of the particle, so that $e = e_0[1 + (\kappa v^2/c^2)]$, where e_0 is the particle's "rest charge," c is the speed of light, and κ is some tiny number. Discuss ways in which you might measure κ. Is there any experimental reason why κ must be small, if not zero?
17. Does the modification of the electric charge proposed in Question 16 necessarily violate the principle that it should not be possible to detect the absolute velocity of an object by means of any experiment?

18. The color of the light emitted by quasars is evidence that the charge on electrons has not changed over billions of years. Is saying that the charge on electrons and protons is unchanged equivalent to the statement that charge is conserved?
19. Suppose that electrons had charge $-e$ and protons had charge $+e(1 + \delta)$, with δ very small. Would there necessarily be an additional repulsive $1/r^2$ force between the Moon and Earth, for example, that could overpower the gravitational attraction between these bodies?
20. Consider a uniform, spherical positive charge distribution. A negative charge is placed at the center. Discuss the net force on that point charge. Discuss what happens to the point charge if it is placed a bit off center.
21. Describe what happens to $\vec{F}_1$ and $\vec{F}_3$ of Example 21–7 if the charge q_2 is doubled.
22. How would we know if at Alpha Centauri, the nearest star system nearest to us, the electric force had a $1/r^3$ dependence rather than the $1/r^2$ dependence on Earth?

Problems

21–1 Charge—A Property of Matter

1. (I) A cork ball is charged to +1 nC. How many fewer electrons than protons does the ball have?
2. (I) A uranium atom has undergone a violent collision that has stripped off 21 of its electrons. What is the charge of the resulting atom? If a uranium nucleus contains 92 protons and 146 neutrons, what is the charge of the nucleus?
3. (I) What is the total charge of all the electrons in 1 g of CO_2?
4. (I) Three identical metallic spheres are connected by wires, and a charge Q is placed on one of them. The wires are then removed. One of the spheres is then connected by wire to the ground. That wire is then removed. This particular sphere is then connected by a wire to one of the other spheres. What is the charge on each of the spheres when the process is completed?
5. (I) If you could remove 1 electron in 10^{13} from the gold coin of Example 21–2, how many would you be removing per atom, on the average?
6. (I) How many protons are contained in the gold coin of Example 21–2?
7. (II) A cork ball that is covered with conducting paint and charged to -4×10^{-10} C is touched by an identical but uncharged cork ball; the balls then separate. This second cork ball is then touched by a third uncharged cork ball, and they separate. What is the charge of each ball at the end, and how many excess electrons does each ball have?
8. (II) A cork ball covered with conducting paint is charged to -1.04×10^{-13} C. You have three similar but uncharged cork balls. Describe a method by which to produce a cork ball with a charge of -0.13×10^{-13} C. Do you need all three extra balls? Explain.
9. (II) An aluminum ball of mass 0.1 g is given a negative charge of 1 μC. What is the fractional increase in the number of electrons the ball contains?
10. (II) Two cork balls of mass 0.2 g hang from the same support point by massless insulating threads of length 20 cm (Fig. 21–22). A total positive charge of 3.0×10^{-8} C is added to the system. Half this charge is taken up by each ball, and the balls spread apart to a new equilibrium position. (a) Draw a free-body diagram for each cork ball. (b) What is the tension in the threads before the charge is added, and what is it after? (c) What is the value of angle θ in the figure? This device is a type of electroscope, or *electrometer*, a meter that measures electric charge. Angle θ measures the amount of charge on the balls if we can be sure that the charge is divided between them equally. This constraint is circumvented when the electrometer is made of a single strip of conducting material draped at its midpoint over a hook; the charge is then distributed over the strip equally, and half the strip repels the other half.

▲ **FIGURE 21–22** Problem 10.

11. (II) Silicon is the most abundant material on Earth's surface. (a) Assume that Earth is made of silicon (28 g/mol), and calculate the total number of negative charges contained within Earth. (b) When we neutralize a cork ball that has a charge of 1 μC by grounding it to Earth, what fractional change are we making in the total negative charge contained within Earth?

21–2 Charge Is Conserved and Quantized

12. (I) One possible result of the high-energy collision of two protons is the reaction $p + p \rightarrow X + p$. What is the electric charge of particle X?
13. (I) *Antiparticles* have the same mass as their counterpart particles but have an opposite charge. For example, the antiparticle of an electron, e^-, is the positron, e^+. Most antiparticles are denoted by a bar over the particle, so $\bar{p}$ is the antiparticle of the proton, and it has a charge of $-e$. Which of the following reactions satisfy the conservation of charge:
    (a) $p + \bar{p} \rightarrow e^+ + e^- + e^+ + e^- + 2n$;
    (b) $e^+ + e^- \rightarrow 2p + n + 2\gamma$,
    (c) $e^+ + e^- \rightarrow e^+ + e^- + p + \bar{p} + 2\gamma$;
    (d) $n + p \rightarrow e^- + p + \bar{p}$
14. (I) How much charge is contained in 6.5×10^{-4} g of electrons?
15. (II) The electric charge of an object is independent of the object's motion. Suppose that this were not true, but that the charge of a particle such as an electron or a proton that moves at speed v has the form $e = e_0[1 + (v^2/c^2)]$, where e_0 is the particle's charge when at rest and $c \cong 3 \times 10^8$ m/s is the speed of light. What would the net charge on a hydrogen atom be, assuming that the atom consists of a proton at rest and an electron orbiting the proton at average speed $v \cong (1/137)c$?

21–3 Coulomb's Law

16. (I) How far apart must two protons be for the Coulomb force on each other to be the same as the weight of one proton on Earth's surface?

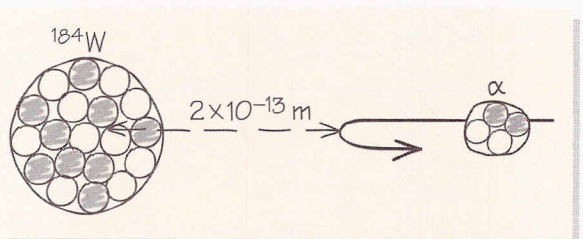
17. (I) A proton is believed to consist of two "up" quarks of charge $+2/3\ e$ and one "down" quark of charge $-1/3\ e$. Assume that all three quarks are equidistant from each other at the distance of 1.5×10^{-15} m. What are the electrostatic forces between each pair of the three quarks?

18. (I) Two small balls, each of mass 16 g, are each charged with +8.5 nC. What distance apart must they be if the force on one of them has the same magnitude as the weight of that ball?

19. (I) Two identically charged sodium ions separated by 4.5×10^{-9} m have a force between them of 1.1×10^{-11} N. What is the charge of each ion, and how many electron charges does this represent?

20. (I) Two small cork balls have the same charge. When their centers are placed 2 cm apart, the force between them is observed to be 0.18 N. What is the cork balls' charge? Why do we have to assume that the size of the cork balls is small compared to 2 cm?

21. (I) Two tiny cork balls, both of mass 0.10 g, each have just one electron charge, $q = -1.6 \times 10^{-19}$ C. They are separated by 15 cm, which is much greater than their sizes. What is the ratio of the magnitudes of the Coulomb force between them to the gravitational force they exert on each other? Why is this result so different from that of Example 21–5?



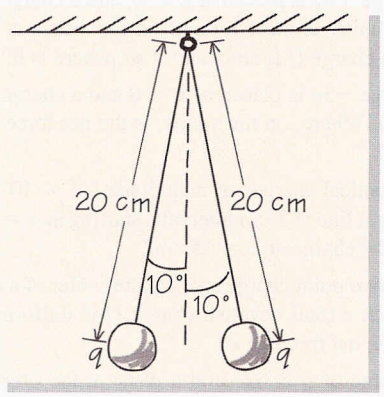
22. (II) The experiment of Cavendish to determine the gravitational constant (see Chapter 12) relies on the measurement of a force of about 7×10^{-7} N between two masses separated by a distance of 0.1 m. One possible source of error is a small electric charge on the balls. Assuming the charges are equal, what is the magnitude of the largest allowed charge, if the force is to be measured to at least a 0.05 percent accuracy?

23. (II) Suppose that we were to measure a charge in some new unit, which we will call the esu, so defined that Coulomb's law reads, in magnitude, $F = q_1 q_2 / r^2$, and so that $F = 1$ dyne (10^{-5} N) when $q_1 = q_2 = 1$ esu and $r = 1$ cm. (a) How many esu are there in 1 C? (b) What is the charge of the electron in esu? (The esu is an actual unit, the *electrostatic unit*.)

24. (II) An electron and a proton attract each other with a $1/r^2$ electric force, just like the gravitational force. Suppose that an electron moves in a circular orbit about a proton. (a) If the period of the circular motion is 24 h, what is the radius of the orbit? (b) If the period is 4×10^{-16} s, as it is in a hydrogen atom, what is the radius of the orbit?

25. (II) A charge q is split into two parts, $q = q_1 + q_2$. In order to maximize the repulsive Coulomb force between q_1 and q_2, what fraction of the original charge q should q_1 and q_2 have?

26. (II) An alpha particle (a helium nucleus, composed of 2 protons and 2 neutrons) is directed onto a particular tungsten nucleus (^{184}W, with 74 protons and 110 neutrons). The alpha particle stops and turns around at a distance of 6.0×10^{-12} m from the tungsten nucleus (Fig. 21–23). Ignore the effects of electrons, and treat the alpha particle and tungsten nucleus as pointlike. What is the Coulomb force on the alpha particle at its closest approach to the nucleus?



▲ FIGURE 21–23 Problem 26.

27. (II) An electron orbits in uniform circular motion about a much heavier—and therefore nearly stationary—proton at a distance of 3×10^{-10} m. (a) What are the magnitude and direction of the Coulomb force exerted on the electron by the proton? (b) What is the speed of the electron in its circular orbit? (c) What is the frequency of the circular orbit? (d) Calculate the spring constant of a spring with an electron mass at its end and the frequency of part (c).

28. (II) Two pointlike objects are placed 8.75 cm apart and are given equal charge. The first object, of mass 31.3 g, has an initial acceleration of 1.93 m/s^2 toward the second object. (a) What is the mass of the second object if its initial acceleration toward the first is 5.36 m/s^2? (b) What is the charge of each object?

29. (II) Two cork balls, each of mass 0.20 g, are hung by insulating threads 20.0 cm long from a common point. The cork balls are given an equal charge by a Teflon rod. The balls repel and deflect as shown in Fig. 21–24. What charge q was given to each cork ball? Assume uniform charge.

▲ FIGURE 21–24 Problem 29.

30. (II) Astronomical data tell us that Earth's radius is 6.4×10^6 m, that its mass is 5.98×10^{24} kg, that the Moon's mass is 7.36×10^{22} kg, and that the mean Earth–Moon separation is 3.8×10^8 m. Suppose that, instead of being electrically neutral, as we believe, Earth and the Moon each have an excess positive charge of 8.5×10^{15} C. (a) What is the magnitude of the electrical repulsion between Earth and the Moon? (b) What is the ratio of this repulsive force to the attractive gravitational force? (c) If the charge on Earth were distributed uniformly throughout its volume, what would the excess charge density be, in coulombs per cubic meter (C/m^3)? (d) Assume that the excess positive charge is due to excess protons, which have an electric charge of 1.6×10^{-19} C. Calculate the density of protons, in units of protons per cubic meter, that corresponds to the conditions in part (c). (e) Earth's mean density is 5.52×10^3 kg/m^3, and a proton has mass 1.67×10^{-27} kg. Protons account for about half of Earth's mass. Compute the density of all protons in Earth, and compare this to your answer in part (d).

31. (II) Three unknown charges q_1, q_2, and q_3 exert forces on each other. When q_1 and q_2 are 15.0 cm apart (q_3 is absent), they attract each other with a force of 1.4×10^{-2} N. When q_2 and q_3 are 20.0 cm apart (q_1 is absent), they attract with a force of 3.8×10^{-2} N. When q_1 and q_3 are 10.0 cm apart (q_2 is absent), they repel each other with a force of 5.2×10^{-2} N. Find the magnitude and sign of each charge.

32. (II) An electron has a mass of 0.9×10^{-30} kg and a charge of -1.6×10^{-19} C. Earth's mass is 6×10^{24} kg, and its radius is 6.4×10^{6} m. Suppose that Earth has a net negative charge Q at its center. (a) How large would Q have to be for the charge repulsion on an electron to cancel the gravitational attraction at Earth's surface? (b) Suppose that this net charge is due to a discrepancy between the positive proton charge and the negative electron charge. Assume that half of Earth's mass is due to protons, each of which has a mass of 1.6×10^{-27} kg (the rest is neutrons, assumed to be neutral; electrons do not contribute much to the mass). What is the size of the charge discrepancy, compared to the electron charge?

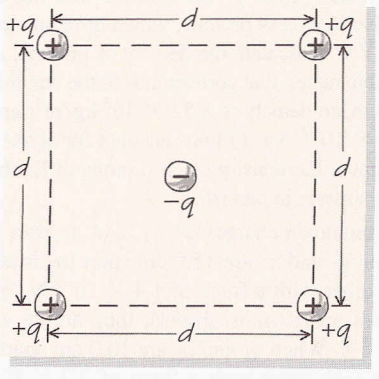
33. (III) Use the similarity between Coulomb's law and the law of universal gravitation to calculate the distance of closest approach between a point charge of $+10^{-6}$ C, which starts at infinity with kinetic energy of 1 J, and a fixed-point charge of $+10^{-4}$ C. Assume that the moving-point charge is aimed straight at the fixed-point charge. [*Hint*: The similarity to gravity consists of using the notions of potential energy and energy conservation.]

21–4 Forces Involving Multiple Charges

34. (I) A charge $+4q$ is placed at $x = 0$, and a charge $+7q$ is placed at $x = 5$ units. Is there a point on the x-axis at which the net force on a charge Q is zero, and if so, where is it?

35. (I) A charge $-5q$ is placed at $x = 0$ and a charge $+3q$ is placed at $x = 10$. Where, on the x-axis, is the net force on a charge Q zero?

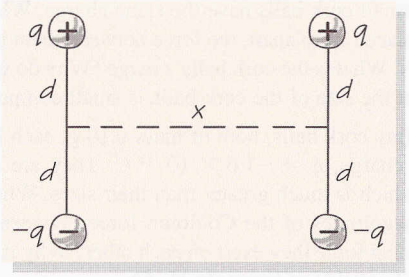
36. (I) Six identical charges of magnitude 3.6×10^{-8} C are placed on a straight line at 3-cm intervals, starting at $x = 0$. What is the force on the charge at $x = 15$ cm?



37. (I) A positive point charge q sits at the center of a circle of radius R on which a total negative charge Q is uniformly distributed. What is the net force on q?

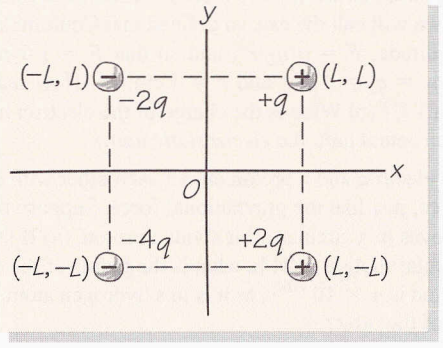
38. (II) A charge of q is fixed on a plane at the origin $(0, 0)$ of an xy-coordinate system, and a charge $3q$ is fixed at $(3\text{ cm}, -3\text{ cm})$. Where must a charge of $-2q$ be placed at rest for it to be in equilibrium (that is, so that it remains at rest)? Is the equilibrium stable?

39. (II) What is the total force on each of the three quarks in Problem 17 due to the other two quarks?



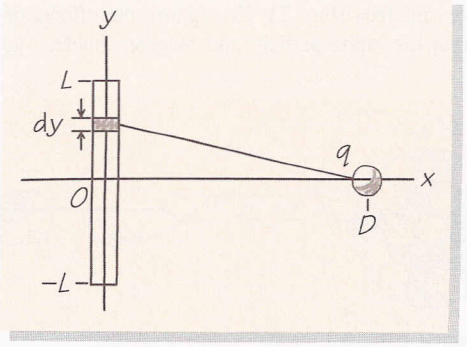
40. (II) Three negative charges of magnitude 0.6 μC are placed at the corners of an equilateral triangle of sides 18 cm. What is the net force on a charge of 1.5 μC placed at the midpoint of one of the sides?

41. (II) Four positive charges $+q$ sit in a plane at the corners of a square whose sides have length d, as in Fig. 21–25. A negative charge, $-q$, is placed in the middle of the square. (a) What is the net force on the negative charge? (b) Is the equilibrium point at the center a stable equilibrium for motion of the negative charge in the plane of the square? (c) for motion of the negative charge perpendicular to the plane of the square?



▲ FIGURE 21–25 Problem 41.

42. (II) Calculate the force between two identical dipoles consisting of dumbbells with equal and opposite charges q and $-q$ at the end of a rigid rod of length $2d$. The dipoles are parallel, as shown in Fig. 21–26, and they are a distance x apart. Derive a first-order approximation for $d \ll x$. [*Hint*: Use $(1 + y)^n \cong 1 + ny + \cdots$ for $y \ll 1$.]

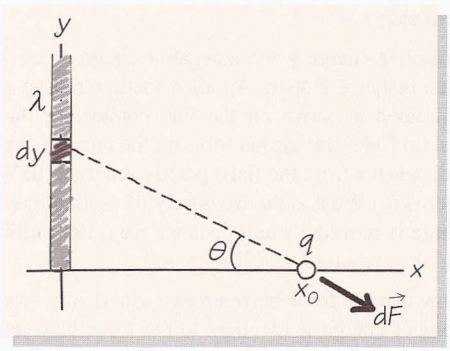


▲ FIGURE 21–26 Problem 42.

43. (II) Charges q, $2q$, $-4q$, and $-2q$ (q is positive) occupy the four corners of a square of sides $2L$, centered at the origin of a coordinate system (Fig. 21–27). (a) What is the net force on charge q due to the other charges? (b) What is the force on a new charge Q placed at the origin?

▲ FIGURE 21–27 Problem 43.

44. (II) A charge Q is distributed uniformly along a rod of length $2L$, extending from $y = -L$ to $y = L$ (Fig. 21–28). A charge q is placed on the x-axis at $x = D$. (a) In what direction is the force on q, given that Q and q have the same sign? (b) What is the



▲ FIGURE 21–28 Problem 44.

charge on a segment of the rod of infinitesimal length dy? (c) What is the force vector on charge q due to the small segment dy? (d) Express an integral that describes the total force in the x-direction. (e) Compute the integral in order to find the total force in the x-direction.

45. (II) A charge is spread uniformly along the y-axis, stretching infinitely far in both the positive and negative directions. The charge density (charge per unit length) on the y-axis is λ. Find the force on a point charge q placed on the x-axis at $x = x_0$.

46. (II) A charge is spread uniformly along the y-axis from $y = 0$ to $y = +\infty$. The charge density on the y-axis is λ (Fig. 21–29). Find the force on a point charge q placed on the x-axis at $x = x_0$.

▲ **FIGURE 21–29** Problem 46.

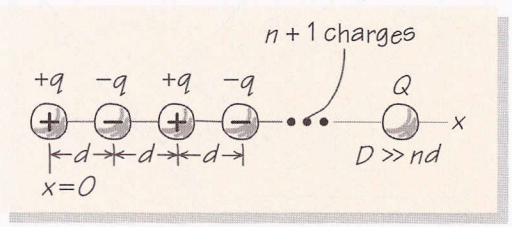
47. (II) A long, thin rod of length L that contains a uniform distribution of charge Q points away from a point charge q. The nearest part of the rod is a distance d from the point charge. What is the electric force exerted on the charge q by the rod?

48. (II) Two uniformly charged rings of radii 25 cm and 40 cm respectively are placed parallel to each other, with a common axis. Each carries a charge of 2.2×10^{-4} C. and their centers are 100 cm apart. Where, along the common axis, should a charge q be placed so that the net force on it is zero?

49. (II) In the problem above, but now with the two rings having the same radius, the charge q is constrained to move only along the common axis. Is the position of equilibrium one of stable or unstable equilibrium? Does this depend on the sign of the charge q? [*Hint*: You may need the mathematical result that for $d \ll D$, $(D^2 + ad + bd^2)^n = D^{2n} + nadD^{2n-2} +$ terms that can be neglected.]

50. (II) A charge Q is distributed uniformly over a thin ring of radius R. The ring is oriented in the xy-plane, with its center at the origin. Find the force on a charge q located at the origin, and discuss the stability of its motion in the xy-plane. How does this compare with the case of a point charge placed at the center of a sphere whose surface is uniformly charged?

51. (II) Use the results of Example 21–9 to calculate the force on a positive point charge of magnitude 0.65 μC located 5 cm above the center of a uniformly charged solid plate of radius 8 cm that carries a total positive charge of 1.6 μC. [*Hint*: Break the disk into concentric rings, use the results of Example 21–9 for each ring, and sum over the forces due to the rings.]



52. (II) Calculate the force exerted on a charge q by an infinite plane sheet with surface charge density (charge per unit area) σ. [*Hint*: Break up the plane into concentric rings centered below the charge, use the results of Example 21–9 for the force from each ring, then sum over the forces due to the rings.]

53. (II) Two rigid plates of equal size, made of different plastics, are rubbed against each other. This results in equal and opposite charges on the two plates. How large are these charges if it takes 0.1 N to separate the two plates? The area of each plate is 0.05 m^2, and the charge distribution may be assumed to be uniform. [*Hint*: Use the result of Problem 52.]

54. (II) Consider an infinite vertical sheet that carries a charge density of $+1.2 \times 10^{-6}$ C/m^2. A cork ball of mass 8 g is suspended by a string 50 cm long at a distance of 55 cm from the charged sheet. What is the string orientation (a) if a charge $q = 0.8 \times 10^{-8}$ C is placed on the cork ball? (b) if instead a charge $q = -3 \times 10^{-8}$ C is placed on the ball?

55. (II) A total charge of 0.75 μC is distributed uniformly over a thin, semicircular wire of radius 5.0 cm. What is the force on a charge of 0.30 μC located at the center of the circle?

56. (II) A succession of $n + 1$ alternating positive and negative charges q are located along the x-axis at the points $x = 0$, $x = d$, $x = 2d, \ldots, x = nd$. An isolated charge Q is placed as shown in Fig. 21–30 at the point $x = D$ a very long distance away from the origin ($D \gg nd$). (a) Write a general expression for the electric force on charge Q. (b) Approximate your result, using the condition $D \gg nd$. Keep only leading and next-to-leading terms. [*Hint*: Use $(1 + x)^{-2} \cong 1 - 2x$ for $x \ll 1$.]

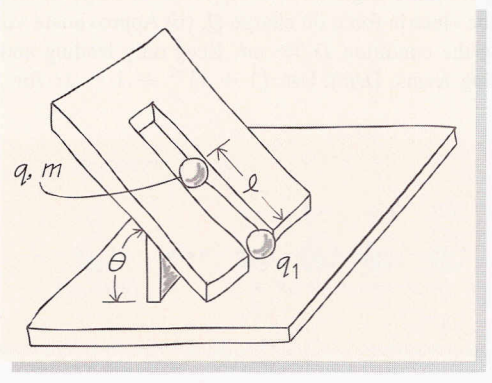
▲ **FIGURE 21–30** Problem 56.

57. (II) Charges $+q$, $-q$, $+q$, and $-q$ are placed along the x-axis, at positions $x = 0$, $x = 1$ cm, $x = 2$ cm, and $x = 3$ cm, respectively. What is the force on a charge $Q = +3q$ placed at the point $(x, y) = (1.5 \text{ cm}, y_0)$, where y_0 is a variable?

58. (III) Consider a charge of $e = 1.6 \times 10^{-19}$ C distributed uniformly over a sphere of radius $R = 0.5 \times 10^{-10}$ m. Place a point particle of charge $-e$ (-1.6×10^{-19} C) at the center of that sphere. Suppose that charge is displaced by a distance r (with $r < R$). Use the information given in Fig. 21–21 to show that the point charge will oscillate about the center of the sphere. Write down an expression for the frequency of oscillation in terms of R, the mass of the point charge m and the charge e. [*Hint*: If the acceleration for harmonic motion is given by $ma = -kr$, then the angular frequency of oscillation is $\omega = \sqrt{k/m}$.]

59. (III) What is the force per unit area between two infinite, uniformly charged plates with a surface charge density of $+10^{-5}$ C/m^2 and -10^{-5} C/m^2, respectively, when the distance between the plates is 10 cm? What if the distance between the plates is doubled? [*Hint*: You may use the result of Problem 52.]

General Problems



60. (II) A cone of height h whose radius at the open end is R carries a total charge Q. Assuming that the charge is uniformly distributed over the surface, what is the charge density in C/m^2?

61. (II) Earth has a net charge of about 6×10^5 C. Assume the charge is evenly spread on the surface of the Earth. A cork ball of

10-g mass is hanging from a thin thread so the cork ball is 10 cm from the Earth's surface. What charge would the cork ball have to have to just barely rise up due to the electric force repulsion from the Earth?

62. (II) How much charge $+Q$ should be distributed uniformly over a square, horizontal plate of dimensions 60 cm $\times$ 60 cm if a ball of mass 1.5 g and charge 0.8 μC is to remain suspended 1 mm over the surface of the plate? Take gravity into account in this problem. How would your answer change if the ball were to be suspended 2 mm over the plate? *Qualitatively*, how would your answer change if the ball were to be suspended 1 m over the plate?

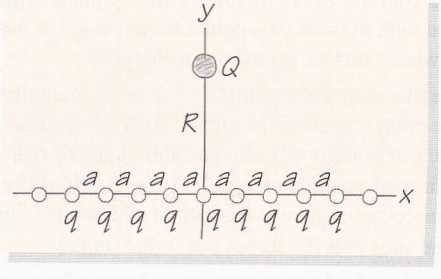
63. (II) A single charge $q_1 = +2 \times 10^{-8}$ C is fixed at the base of a plane that makes an angle θ with the horizontal direction. A small ball of mass $m = 0.5$ g and charge $+2 \times 10^{-8}$ C is placed in a smooth, frictionless groove in the plane that extends directly to the fixed charge (Fig. 21–31). It is allowed to move up and down until it finds a stable position $\ell = 8$ cm from the fixed charge. What is θ?

▲ **FIGURE 21–31** Problem 63.

64. (II) The nucleus of an iron atom contains 26 protons within a sphere of radius 4×10^{-15} m. What is the Coulomb force between two protons at opposite sides of this nucleus? The answer to this problem illustrates that the force that holds the nucleus together against the Coulomb repulsion of its constituents must be strong indeed.

65. (II) An electron moves in a circular planetary orbit around a proton. (a) If the centripetal force is the attractive Coulomb force, what is the speed of the electron in terms of the charge e and the radius of the circular orbit? (b) What is the angular momentum, L, of the electron in the orbit? (c) Express the speed in terms of e and L. (d) Express the radius of the orbit in terms of e and L. (e) Express in terms of e and L the time it takes for the electron to go around the circle once. (f) Evaluate all these quantities, given that $L = 1.05 \times 10^{-34}$ kg·m^2/s. This corresponds to a simplified version of the hydrogen atom.

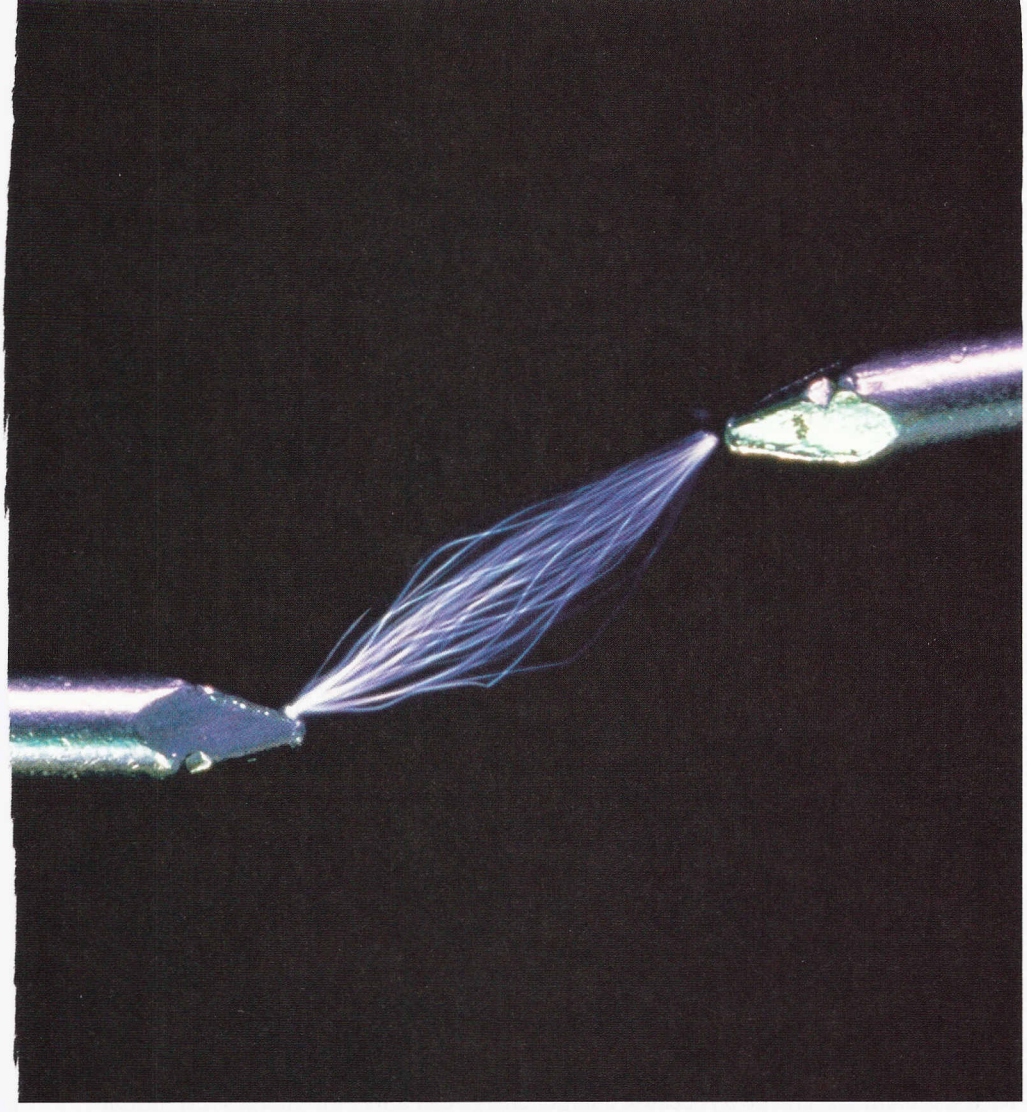
66. (II) Suppose that the proton charge were slightly larger than the electron charge, so that $q_{\text{proton}} = (1 + \delta)e$ and $q_{\text{electron}} = -e$, where $0 < \delta \ll 1$. (a) Given that there are approximately 1.25×10^{57} protons (and electrons) in the Sun, and approximately 1.15×10^{44} protons and electrons in Earth, what is the upper limit on δ set by the fact that the resultant Earth–Sun electric repulsion cannot be large enough to cancel the attraction due to gravity? The mass of the Sun is approximately 2×10^{30} kg, that of Earth is approximately 6×10^{24} kg, and $G = 6.7 \times 10^{-11}$ N·m^2/kg^2. Assume that the number of protons is equal to the number of electrons in the Sun as well as on Earth.



67. (II) Two fixed positive charges q are separated by a length ℓ. A third positive charge q of mass m is constrained to run on a line between the two fixed charges. (a) When the third charge is placed a distance x from the left-hand fixed charge, what is the net force on the third charge? Where is this force zero? In other words, where is the equilibrium point? (b) What is the net force as a function of the displacement of the third charge from the equilibrium point of part (a)? (c) For *small* values of the displacement from the equilibrium point, the third charge behaves as if a spring were acting on it. What is the value of the oscillation frequency?

68. (II) A positive charge q and a negative charge $-\alpha q$ ($\alpha > 1$) are fixed at a distance ℓ apart. Another positive charge q of mass m is constrained to move on the line connecting the two fixed charges. (a) Calculate the net force on the moving charge when it is at a distance x from the fixed positive charge. (b) Where is the force zero? (c) What is the frequency of oscillations if the moving charge is moved a small distance from its equilibrium position and then released, and if $\alpha = 40$?

69. (II) Show that the force between two spherically symmetric distributions of charge is identical to the force between two point charges that are located at the geometric center of each distribution and have the same total charge. [*Hint*: Use the fact that the force on a point charge due to distribution 1 is the same as if distribution 1 were concentrated at its center; then use similar reasoning for distribution 2, and then use Newton's third law.]

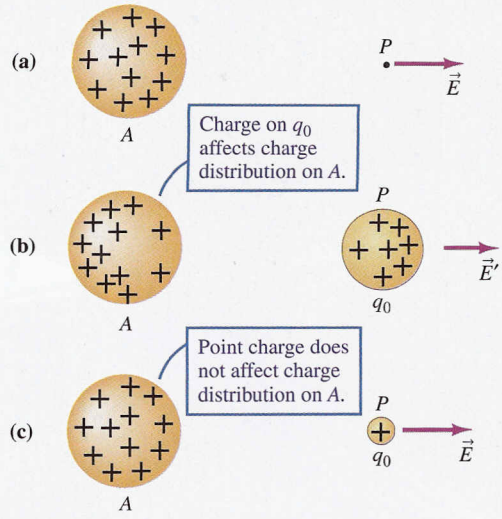


70. (III) Two rods, each of length $2L$, are placed parallel to one another a distance R apart. Each carries a total charge Q, distributed uniformly over the length of the rod. Write down an integral for the magnitude of the force between the rods, but do not evaluate it. Without working out any integrals, can you determine the force between the rods for $R \gg L$?

71. (III) Consider an infinite number of identical point charges q located at equally spaced points on the x-axis at the locations $x = na$ (n takes on integer values that range from $-\infty$ to $+\infty$) (Fig. 21–32). (a) Write an expression for the force on a charge Q, located at $x = 0$ and $y = R$, due to all the point charges q, and show the direction of the net force. (b) Take the limit of your result when the intercharge spacing $a \to 0$ and the charge $q \to 0$ such that $q/a = \lambda$ (a fixed charge density). Show that your expression can be written as an integral, and use dimensional analysis to determine the R-dependence of the force on charge Q.

▲ **FIGURE 21–32** Problem 71.

Chapter 22



◀ An electric field forms between two charged objects, here two nails. The field is particularly strong in regions where the charged objects have sharp points, strong enough to allow charge to jump between the two objects. The charge ionizes atoms in the air, forming a series of sparks.

Electric Field

Charges exert forces on one another over large distances and across empty space. This idea of "action at a distance" poses both conceptual and technical difficulties. Action at a distance suggests that the object responsible for the force on a second object somehow reaches out, measures the distance to the second object, and then acts. Michael Faraday set out a better way to look at action at a distance: The first object influences the surrounding space by setting up a *field* around itself that is present whether there is a second object or not. When the second object is located at a given point, the field at this point acts on that object. This important idea can be developed quantitatively and, like any really good idea, leads to further ideas that go far beyond the original concept in utility and insight. In this chapter, we introduce and develop the concept of an electric field produced by static charges; here and in future chapters we will learn how it can be useful both as a practical tool and as a basis for a deeper understanding of electromagnetism.

22–1 Electric Field

It is useful to think of a distribution of charges as giving rise to an **electric field**, which acts on any other charge placed in that field. We can detect the electric field at any particular point by placing a small positive **test charge** q_0 at that location and seeing if it experiences a force. A test charge is only a probe: It does not *produce* the electric field that we are trying to measure; the field is due to other charges. The electric field $\vec{E}$ can

▲ **FIGURE 22–1** (a) An electric field exists at a point P due to charges on the sphere A. (b) A test charge q_0 that is too large will cause a redistribution of the charges on sphere A. A different electric field, $\vec{E}'$, is produced at P by sphere A, because the charges on A have been redistributed. (c) If we make the test charge q_0 small enough, it will hardly affect the charges on sphere A. The electric field produced by A at point P is now the same as in part (a). In each case the electric field is due to the charge on sphere A.

be defined by measuring the magnitude and direction of the electric force $\vec{F}$ acting on the test charge. The definition of the field is

$$\vec{E} \equiv \frac{\vec{F}}{q_0}. \tag{22–1}$$

We use a *small* test charge q_0 because a larger charge can affect the charges responsible for the electric field, perhaps making them move (Fig. 22–1b). This would affect the field itself. Thus, we more properly define the electric field by (Fig. 22–1c).

$$\vec{E} \equiv \lim_{q_0 \to 0} \frac{\vec{F}}{q_0} \tag{22–2}$$

DEFINITION OF ELECTRIC FIELD

Both the electric force and the electric field are vectors. We know a vector such as the electric field completely when we know both its magnitude and its direction *at every point in space*: $\vec{E} = \vec{E}(\vec{r})$.

From the definition in Eq. (22–2), the SI units of electric field are newtons per coulomb (N/C). Table 22–1 gives the magnitudes of the electric fields in various physical situations.

TABLE 22–1 • Values of Electric Fields (N/C)

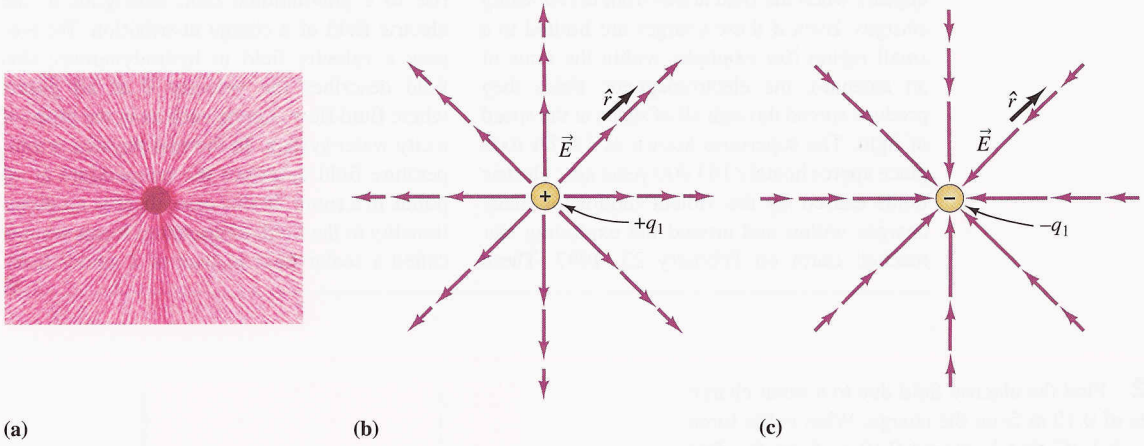
Interplanetary space	10^{-3}–10^{-2}
Atmosphere at Earth's surface in clear weather	100–200
Value sufficient to cause electrical breakdown in dry air	3×10^6
Just outside large sphere of a Van de Graaff accelerator	10^6
In the Fermilab particle accelerator	1.2×10^7
In atoms within the radius of an electron orbit	10^9
In the electromagnetic radiation of the most intense laser	10^{12}
Outside a uranium nucleus, at a distance from the center of twice the nucleus's radius	5×10^{20}

The Electric Field of a Point Charge

The simplest example of an electric field is the field associated with a point charge, q_1. Consider two point charges, q_1 and q_0, located a distance r apart. The Coulomb force on q_0 due to q_1 is given in Eq. (21–8),

$$\text{for a point charge: } \vec{F}_{01} = \frac{q_1 q_0}{4\pi\varepsilon_0 r^2}\hat{r}_{01}. \tag{22–3}$$

Here $\hat{r}_{01}$ is the unit vector pointing from q_1 to q_0. If q_0 is small, we use it as a test charge, and we can then use Eqs. (22–1) and (22–3) to find the electric field due to q_1:



$$\text{for a point charge: } \vec{E}_1 = \frac{\vec{F}_{01}}{q_0} = \frac{q_1}{4\pi\varepsilon_0 r^2}\hat{r}_{01}. \tag{22–4}$$

The value of the test charge has canceled, so the limiting process in Eq. (22–2) introduces no complications. Equation (22–4) specifies that $\vec{E}_1$ is in the same direction as $\vec{F}_{01}$. Figure 22–2 shows the direction of $\vec{E}_1$ as determined by moving our test charge to various points a distance r away from q_1. This field is radial (Fig. 22–2a). At this point we drop the subscripts on $\hat{r}_{01}$ and q_1, and we use the radial unit vector $\hat{r}$ (measured from the point charge q) to specify completely the electric field $\vec{E}_{\text{pt}}$ due to q:

$$\vec{E}_{\text{pt}} = \frac{q}{4\pi\varepsilon_0 r^2}\hat{r}. \tag{22–5}$$

FIELD OF A POINT CHARGE

The electric field points *away* from a positive charge, as shown in Fig. 22–2b. When the charge is negative, the electric field has the same magnitude but is opposite in direction. The electric field due to a negative charge points *toward* that charge, as in Fig. 22–2c.

(a) (b) (c)

▲ **FIGURE 22–2** (a) Threads floating in oil become aligned with the electric field of this point charge. (b) The direction of the electric field $\vec{E}$ due to a point charge q_1 is radial. The charge is positive, and the field points away from it. (c) When the charge is negative the field points toward it.

CONCEPTUAL EXAMPLE 22–1 As you approach the charge in Fig. 22–2c, the magnitude of the electric field is large, and the arrows representing the field will become larger and larger, eventually overlapping each other and even passing through the (negative) charge. Does this pose a difficulty?

Answer This is a difficulty only for the artist. Remember that the arrows are just a visual representation, an aid in understanding. The tail of the arrow is placed on the position where you want to characterize the electric field. The magnitude of the electric field goes as $1/r^2$, so it can become quite large close to the point charge. But the length of the arrow has nothing to do with the scale of the drawing of charge positions.

The Usefulness of the Field Concept

Once we know the electric field $\vec{E}_{\text{pt}}$ produced by a point charge q, we can find the force on any point charge q' placed in that field by using Eq. (22–1); that is,

$$\vec{F} = q'\vec{E}_{\text{pt}}. \tag{22–6}$$

More important, *any* distribution of charges—not simply a point charge—produces an electric field throughout space. We use the subscript "ext" (for external) on the field to emphasize that this field is present *independent* of the charge q' on which the force acts, and once we know $\vec{E}_{\text{ext}}$, *the force on any point charge q' in the field* is the generalization of Eq. (22–6):

$$\vec{F} = q'\vec{E}_{\text{ext}}. \tag{22–7}$$

FORCE ON A POINT CHARGE IN AN EXTERNAL FIELD

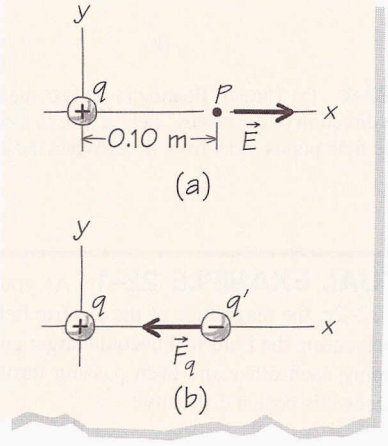
The field concept has practical uses. We can calculate (or measure with a test charge) the field from a charge distribution once and for all, and then use Eq. (22–7) to find the effect of that distribution on any other charges within the field—we'll see numerous examples of this.

THINK ABOUT THIS. . .

HOW DOES THE FIELD CONCEPT HELP?

Why don't we deal with forces between charges instead of fields? In the chapter introduction, we mentioned the role the field plays in resolving the conceptual difficulties of action at a distance. We shall see in Chapter 24 that the field carries energy. To preserve the important idea of energy conservation, the field is a *necessary* concept. But the real power of the field concept appears when the field arises from *accelerating charges*. Even if these charges are limited to a small region (for example, within the arms of an antenna), the electromagnetic fields they produce spread through all of space at the speed of light. The supernova known as 1987A took place approximately 163,000 years ago; electric fields caused by the violent motion of many charges within and around the exploding star reached Earth on February 23, 1987. These traveling fields caused electrons in terrestrial antennas to move; this was the signal that supernova 1987A had occurred. This description of the process is easy to grasp; more, it is really the only practical way that we have to describe the process.

The notion of a field is useful in many areas of physical science. A mass distribution gives rise to a gravitational field analogous to the electric field of a charge distribution. We employ a velocity field in hydrodynamics; this field describes the velocity $\vec{v}$ at all points where fluid flow occurs, such as in the pipes of a city water system. In thermal physics, a temperature field describes the temperature at all points in a room. In this case, there is no directionality to the field; temperature forms what is called a scalar field instead of a vector field.



EXAMPLE 22–2 Find the electric field due to a point charge $+1.4\ \mu\text{C}$ at a distance of 0.10 m from the charge. What is the force on a second charge $-1.2\ \mu\text{C}$ that is placed 0.10 m from the first charge?

Setting It Up Figure 22–3a shows the electric field at point P due to a charge q. In Fig. 22–3b, we place a second charge q' at point P.

Strategy Equation (22–5) allows us to find the electric field $\vec{E}_{\text{pt}}$ at point P due to the point charge q. We then use Eq. (22–6) to find the force on the second point charge q' placed in this electric field.

Working It Out From Eq. (22–5):

$$\vec{E} = \frac{q}{4\pi\varepsilon_0 r^2}\hat{r} = \frac{(9.0 \times 10^9\ \text{N}\cdot\text{m}^2/\text{C}^2)(1.4 \times 10^{-6}\ \text{C})}{(0.10\ \text{m})^2}\hat{r}$$
$$= (1.3 \times 10^6\ \text{N/C})\hat{r}.$$

▲ FIGURE 22–3

The field is directed radially outward from the position of q (Fig. 22–3b). If q had been negative, the field would point radially inward rather than radially outward.

For the force, Eq. (22–6) gives

$$F = |q'|E = (1.2 \times 10^{-6}\ \text{C})(1.3 \times 10^{6}\ \text{N/C}) = 1.6\ \text{N};$$
$$\vec{F} = (-1.6\ \text{N})\hat{i}.$$

Note that the direction of the force is in the opposite direction of the electric field at point P, that is, it is along $-\hat{i}$. The opposite charges attract (Fig. 22–3b). We could of course use Coulomb's law for the force between the two charges instead, Eq. (21–8).

What Do You Think? What would be the change in the electric field and force if q' were a positive charge instead of a negative one? *Answers to **What Do You Think?** questions are given in the back of the book.*

Superposition

In Section 21–4 we described how electric forces involving multiple charges superpose. The consequence of this is that if more than one point charge is responsible for producing a net electric field, that field is determined by the principle of superposition. The superposition principle states that the net electric force on an object is the vector sum of the forces due to individual point charges. Therefore *the net electric field is the vector sum of the fields of individual charges present*. The net force exerted on our test charge q_0 due to all the other charges in the region is

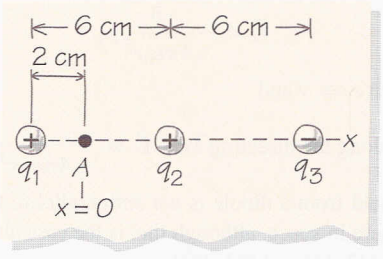
$$\vec{F}_{\text{net}} = \vec{F}_{01} + \vec{F}_{02} + \vec{F}_{03} + \cdots = \sum_i \vec{F}_{0i}. \tag{22–8}$$

Thus

$$\vec{E}_{\text{net}} = \frac{\vec{F}_{\text{net}}}{q_0} = \frac{\vec{F}_{01}}{q_0} + \frac{\vec{F}_{02}}{q_0} + \frac{\vec{F}_{03}}{q_0} + \cdots \tag{22–9}$$

$$= \vec{E}_1 + \vec{E}_2 + \vec{E}_3 + \cdots = \sum_i \vec{E}_i. \tag{22–10}$$

In Eq. (22–10), $\vec{E}_2$, for example, is the electric field due solely to the charge q_2 at the point in space where we have placed q_0. Using Eq. (22–5),



$$\vec{E}_{\text{net}} = \frac{1}{4\pi\varepsilon_0}\sum_i \frac{q_i}{r_i^2}\hat{r}_i. \tag{22–11}$$

FIELD OF A GROUP OF POINT CHARGES

In this equation, r_i is the distance from the ith charge q_i to the point at which the field is evaluated, and the unit vector $\hat{r}_i$ is directed from the position of the ith charge to the point where the field is evaluated.

EXAMPLE 22–3 Consider three charges placed on a line: $q_1 = +2\ \mu\text{C}$ at $x_1 = -2$ cm, $q_2 = +3\ \mu\text{C}$ at $x_2 = +4$ cm, and $q_3 = -2\ \mu\text{C}$ at $x_3 = +10$ cm. Find the electric field at point A, the origin of the coordinate system.

Setting It Up We sketch the configuration of charges in Fig. 22–4.

▲ **FIGURE 22–4** The electric field at point A is due to three charges. The distance x is measured from point A.

Strategy We solve this by a straightforward application of Eq. (22–11), the superposition of electric fields from point charges. Although it is generally important to remember that the required sum is vectorial, all the positions lie along a straight line in this case. The electric field at point A is

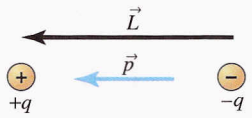
$$\vec{E}_A = \vec{E}_1 + \vec{E}_2 + \vec{E}_3,$$

where $\vec{E}_j$ ($j = 1, 2,$ or 3) is the field at point A due to charge q_j.

Working It Out Application of Eq. (22–11) gives

$$\vec{E}_A = \frac{1}{4\pi\varepsilon_0}\left[\frac{q_1}{x_1^2}(+\hat{i}) + \frac{q_2}{x_2^2}(-\hat{i}) + \frac{q_3}{x_3^2}(-\hat{i})\right]. \tag{22–12}$$

We must pay careful attention to signs. The unit vectors $\pm\hat{i}$ in parentheses indicate the direction of the unit vector $\hat{r}_j$, from the position of charge q_j to point A, but we must also include the signs of the individual charges. For example, the direction of $\vec{E}_3$ is $+\hat{i}$ because the negative sign of charge q_3 multiplied by $(-\hat{i})$ gives a direction $(+\hat{i})$. Putting the numbers into Eq. (22–12) gives



(continues on next page)

$$\vec{E}_A = (9 \times 10^9\ \text{N}\cdot\text{m}^2/\text{C}^2)\left[\frac{(2 \times 10^{-6}\ \text{C})}{(0.02\ \text{m})^2}\hat{i} + \frac{(3 \times 10^{-6}\ \text{C})}{(0.04\ \text{m})^2}(-\hat{i}) + \frac{(-2 \times 10^{-6}\ \text{C})}{(0.10\ \text{m})^2}(-\hat{i})\right]$$
$$= (3 \times 10^7\ \text{N/C})\hat{i}.$$

The net electric field at point A is in the $+x$-direction, or toward the right.

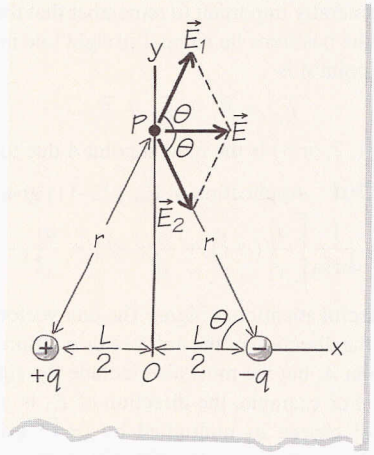
What Do You Think? If point A were halfway between q_2 and q_3, in what direction would the electric field point?

Electric Dipoles and Their Electric Fields

▲ **FIGURE 22–5** An electric dipole consists of equal but opposite charges separated by a distance L. The electric dipole moment $\vec{p}$ is directed from the negative charge to the positive charge.

The field of any single charge decreases as $1/r^2$. What happens if we have two charges, q_1 and q_2, spaced by a fixed distance L? Generally the field due to these charges will behave as $(q_1 + q_2)/r^2$ for $r \gg L$. Suppose now that the charges were equal and opposite. If these two charges were to sit precisely on top of one another, the two $1/r^2$ contributions to the field would exactly cancel to a zero electric field. But with the two charges separated by a finite distance, the field is not exactly zero, yet there is a partial cancellation and the field must fall off faster than $1/r^2$ for $r \gg L$. This arrangement—two charges, $+q$ and $-q$, of equal magnitude but opposite sign, that are separated by a fixed distance L—is an **electric dipole** (Fig. 22–5). We shall see that the field of the electric dipole decreases as $1/r^3$. This field depends only on the product qL, which is called the **electric dipole moment** of the neutral pair $(+q, -q)$; it is denoted by the letter p. We make $p = qL$ a vector through the displacement vector $\vec{L}$ directed from $-q$ to $+q$ (Fig. 22–5). The electric dipole moment $\vec{p}$ is then defined as

$$\vec{p} \equiv q\vec{L}. \qquad (22\text{–}13)$$



ELECTRIC DIPOLE MOMENT DEFINED

The vector $\vec{p}$ points from the negative charge to the positive charge.

EXAMPLE 22–4 Find the electric field of the electric dipole shown in Fig. 22–5 at a point P that lies along the perpendicular axis that bisects the line between the two charges and is at a large distance r ($r \gg L$) from each charge.

Setting It Up The sketch in Fig. 22–6 shows the point P, with xy-coordinates $(0, y)$.

Strategy We again use the superposition principle for point charges to find the net electric field $\vec{E} = \vec{E}_1 + \vec{E}_2$ at P, where the field $\vec{E}_1$ is due to the charge $+q$ and the field $\vec{E}_2$ is due to the charge $-q$. Since P is equidistant from both charges, the magnitudes of the two fields are the same, but $\vec{E}_1$ points away from $+q$, whereas $\vec{E}_2$ points toward $-q$. As usual, adding vectors means adding the components.

▲ **FIGURE 22–6** The net field at point P is parallel to the direction from $+q$ to $-q$.

Working It Out The y-components of $\vec{E}_1$ and $\vec{E}_2$ exactly cancel each other, and we are left with a net x-component toward the right that is twice the x-component of the field due to either charge:

$$\vec{E} = E_x\hat{i} = (E_{1x} + E_{2x})\hat{i} = 2E_{1x}\hat{i},$$

where

$$E_{1x} = \frac{q}{4\pi\varepsilon_0 r^2}\cos\theta.$$

From Fig. 22–6, we see that $\cos\theta$ is given by $\cos\theta = \dfrac{L/2}{r} = \dfrac{L}{2r}$.

Thus the total electric field of the dipole along the perpendicular bisector is

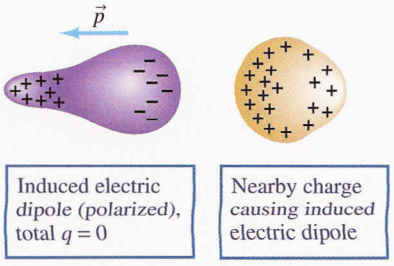
$$\vec{E} = \left(\frac{2q}{4\pi\varepsilon_0 r^2}\right)\left(\frac{L}{2r}\right)\hat{i} = \frac{qL}{4\pi\varepsilon_0 r^3}\hat{i}. \qquad (22\text{–}14)$$

We made no approximations here, and Eq. (22–14) is correct along the perpendicular bisector even when the distance from the charge pair is not large. The electric field decreases with r as $1/r^3$. This is the partial cancellation we spoke of earlier. Using Eq. (22–13) for the electric dipole moment, we can write Eq. (22–14) as

$$\vec{E} = -\frac{\vec{p}}{4\pi\varepsilon_0 r^3}. \qquad (22\text{–}15)$$

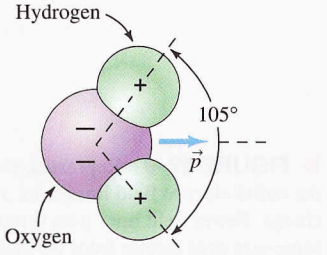
If $r \gg L$, then $r \cong y$ and

$$\text{along the bisecting axis: } \vec{E} \cong -\frac{\vec{p}}{4\pi\varepsilon_0 y^3}. \qquad (22\text{–}16)$$



The electric field from a dipole is *not* antiparallel to the dipole moment everywhere in space, although that is the case along the bisecting axis [Eqs. (22–15) and (22–16)].

What Do You Think? Is there any place in an electric dipole field that the value depends on only q or L and not on the product?



THINK ABOUT THIS. . .

WHEN DO ELECTRIC DIPOLES APPEAR IN NATURE?

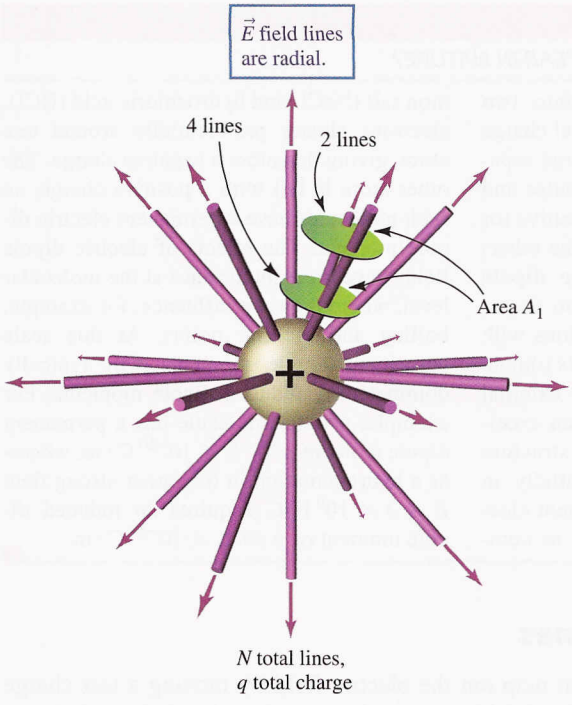
Electric dipoles can be divided into two types. External fields (due to external charge distributions) frequently induce charge separations in electrically neutral molecules and materials, leading to an excess of positive (or negative) charge on one side (and the other) and hence to an **induced electric dipole moment** (Fig. 22–7). There are also examples in nature of charge configurations with **permanent electric dipole moments** (dipole moments that are not induced by external fields). Many molecules—water is an excellent example (Fig. 22–8)—have a structure with electrons distributed preferentially in certain regions, and so have permanent electric dipole moments. In cases such as common salt (NaCl) and hydrochloric acid (HCl), electrons cluster preferentially around one atom, giving that atom a negative charge. The other atom is left with a positive charge, so such molecules have a permanent electric dipole moment. The effects of electric dipole fields have great importance at the molecular level, where they can influence, for example, boiling and melting points. At this scale permanent dipole moments will typically dominate any induced dipole moments. For example, a water molecule has a permanent dipole moment $p \cong 6 \times 10^{-30}\ \text{C} \cdot \text{m}$, whereas a hydrogen atom in the rather strong field $E = 3 \times 10^{6}\ \text{N/C}$ acquires an induced dipole moment of $p \cong 3 \times 10^{-34}\ \text{C} \cdot \text{m}$.

▲ **FIGURE 22–7** A nearby charge can induce a polarized charge, and hence an electric dipole, on a neutral object.

▲ **FIGURE 22–8** The water molecule, H_2O, is a permanent electric dipole. The electrons of both hydrogen atoms are shared with the oxygen atom, creating a strong electric bond that holds the molecule together (this is known as covalent bonding).

22–2 Electric Field Lines

We have already seen that we can map out the electric field by moving a test charge around in space. Unfortunately, the field is awkward to use in a visual sense. It is not easy to draw a vector at each point of a region of space that represents the magnitude and direction of the electric field at that point. The electric field can be more clearly visualized in terms of **electric field lines**. Their use was introduced by Michael Faraday around the middle of the nineteenth century, even before the concept of the electric field itself was clearly understood. Faraday used the phrase "lines of force." Electric field lines are continuous lines in space determined by the electric field, and in principle they fully describe the electric field. Keep in mind as we proceed that although the electric field itself has physical meaning, electric field lines are simply an aid to picturing the electric field and how a charge would react when placed in that field.



Electric field lines are determined according to two simple rules:

1. Electric field lines are drawn so that the tangent to the field line at each point specifies the direction of the electric field $\vec{E}$ at that point. This rule relates the *direction* of the electric field lines to the direction of the electric field. Note that we do not expect the electric field to change abruptly across any region of space that does not contain charge, so that the electric field lines in such regions are very nearly parallel to one another.
2. The *density* in space of electric field lines around a particular point is proportional to the strength of the electric field at that point (Fig. 22–9). What this means is that we take a small area oriented perpendicularly to the (nearly parallel) field lines and count the number of electric field lines that cross this small area; the line density is this number divided by the area. Thus the density is the number of lines *per unit area*. We'll explain below how we "count" the number of field lines.

Properties of Electric Field Lines

Let's draw the electric field lines of a positive point charge q. We know that the electric field points radially away from a positive charge at every location in space, so the lines are radial, pointing outward from the charge (Fig. 22–9). The field has the same magnitude at each point on a sphere centered on the charge, so the field lines are distributed uniformly about the charge. Finally, the magnitude of the electric field decreases with the distance r from the charge as $1/r^2$, so the density of lines falls off as $1/r^2$. And this is exactly how the density changes in Fig. 22–9 as long as we insist that electric field lines start (or stop, in the case of a negative charge) on the charge itself.

To establish this last point, suppose we draw N lines originating on our charge q (Fig. 22–9), and no lines appear (or disappear) as we move out. These lines radiate outward from the charge, and the number of lines that cut a sphere of radius R centered on the

▶ **FIGURE 22–9** Representation of the radial electric field lines from a point charge. Fewer field lines pass through the same-size area farther from the charge. Note that field lines extend out to infinity.

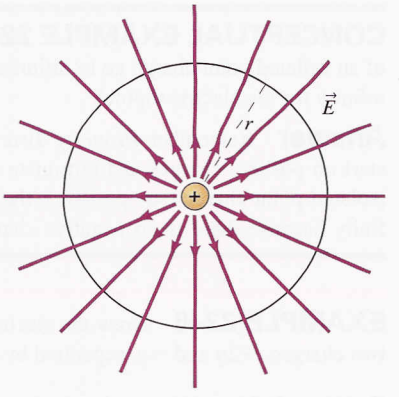
charge is this same number N. Since the lines are evenly distributed over the sphere, the density of the lines is $N/(\text{sphere area}) = N/(4\pi R^2)$. Thus the density of the lines is proportional to $1/R^2$, and we have obtained the correct field strength dependence on R.

We can now relate the number of lines coming out of our charge to the magnitude of the charge: we take N to be any number we like! But once we have done so, the number of lines that leaves (or arrives at) any other charge is determined. For example, the number of field lines leaving a positive charge $q/2$ is $N/2$ and, more generally, the number of field lines leaving a positive charge q_i is $N_i = (q_i/q)N$. This will ensure that point 2 is satisfied: The field line density will be *proportional to* the strength of the electric field.

From the rules that determine field lines and the discussion above we can make a useful list of properties of field lines:

Property One: *Lines can start or terminate only on charges, never in empty space.* This property guarantees the connection between the strength of the field and the density of the electric field lines. We showed this above only for a single point charge, but with the help of the superposition principle, we can show that this is true in general.

Property Two: The electric field lines of a point charge go off to infinity, and by superposition this will be true for any *localized* collection of charges with a net charge—by "localized" we mean that the distribution is confined to a finite space. At distances that are large compared with the size of the charge distribution, the net charge of the distribution appears to be localized at a point, and electric field lines will be distributed evenly over a distant sphere centered on the distribution. If the net charge of a localized distribution is zero, then the field lines will curve back, not reaching to infinitely large distances.



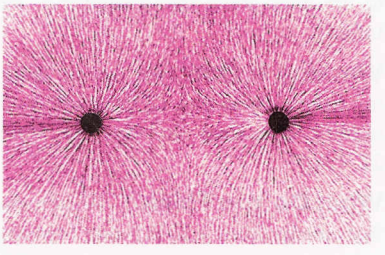
Property Three: Electric field lines originate on, and run outward from, positive charges. They run toward, and terminate on, negative charges. This reflects the fact that electric charges are the sources of electric fields, which point away from positive charges and toward negative charges.

Property Four: *No two field lines ever cross, even when multiple charges are present.* They cannot cross because the electric field has a definite magnitude and direction at any point in space. If two or more electric field lines were to cross at some point, then the direction of the electric field at that point would be ambiguous.

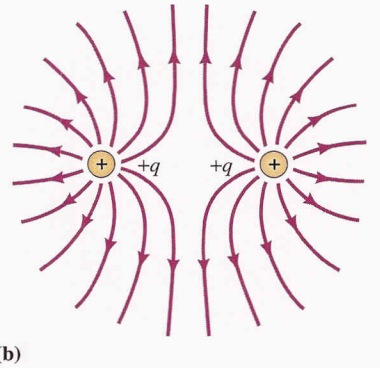
Drawing Electric Field Lines

The properties above are a helpful guide for drawing the field lines associated with a given set of charges or a continuous charge distribution. Symmetry is another tool—and often a powerful one—for this process. A point charge looks the same when viewed from any direction. It has spherical symmetry, and the field lines follow the only direction that respects this symmetry—namely, they are radial. Similarly, if we are dealing with a long line of charge, there is a symmetry around the line, and the field lines must project radially outward from the line of charge, perpendicular to a cylinder that surrounds the line.

A Warning: We often draw field lines on a flat page, and since field lines are in three-dimensional space, the flat page presents certain limits. For example, you might draw Fig. 22–10 as the representation of the field lines for an isolated charge. *If you use such a drawing for determining the field strength, it should be done with care.* Figure 22–10 shows a circle of radius r centered on a positive charge. You cannot simply count the field lines that cross a particular circumference of this circle to find the field strength, as that would be equivalent to dividing by a length, not an area. If you did divide the (fixed) number of lines by the circumference $2\pi r$, you would find a field strength that falls as $1/r$, not the correct $1/r^2$. Nevertheless, planar drawings of electric field lines like Fig. 22–10 remain useful for visualizing the field and its effect on other charges.



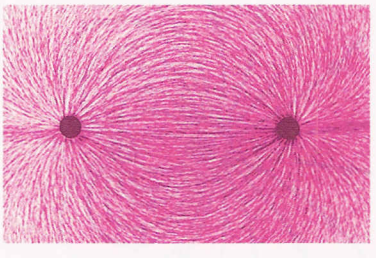
▲ **FIGURE 22–10** Electric field lines due to a point charge $+q$. Note the number of field lines that cross the circle (sphere) at radius r.



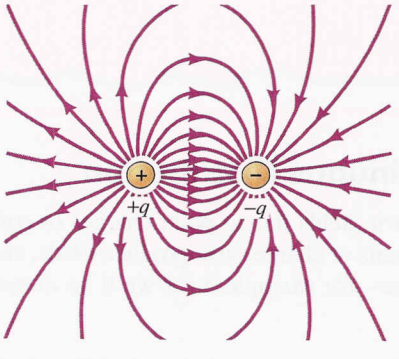
Some Examples

The easiest way to demonstrate the usefulness of electric field lines is to look at a couple of examples. Figures 22–11a and 22–11b show the electric field lines on a plane that passes through two positive charges of equal magnitude. The field lines all extend to infinity. The field lines that approach each other between the two positive charges appear to repel because two field lines cannot cross. If we were to place a positive test charge q' in Fig. 22–11b, the field lines at the charge's location would immediately show us the direction of the force on the charge (and likewise the acceleration).

Figures 22–12a and 22–12b depict the field lines of an electric dipole. The charges have equal magnitude, $\pm q$, so an equal number of field lines are attached to them, and every field line that originates on $+q$ terminates at $-q$. Near each charge the field lines are purely radial, but every line must eventually deviate from the radial direction in order to loop back to the other charge. Notice that the field lines in Fig. 22–12b are consistent with the field $\vec{E}$ determined in Example 22–4 (compare Figs. 22–12b and 22–6).



(a)



(b)

▲ **FIGURE 22–11** (a) The electric field lines due to two point charges $+q$, shown by threads in oil. (b) Schematic diagram of the field lines, which go off to infinity and appear to repel each other.

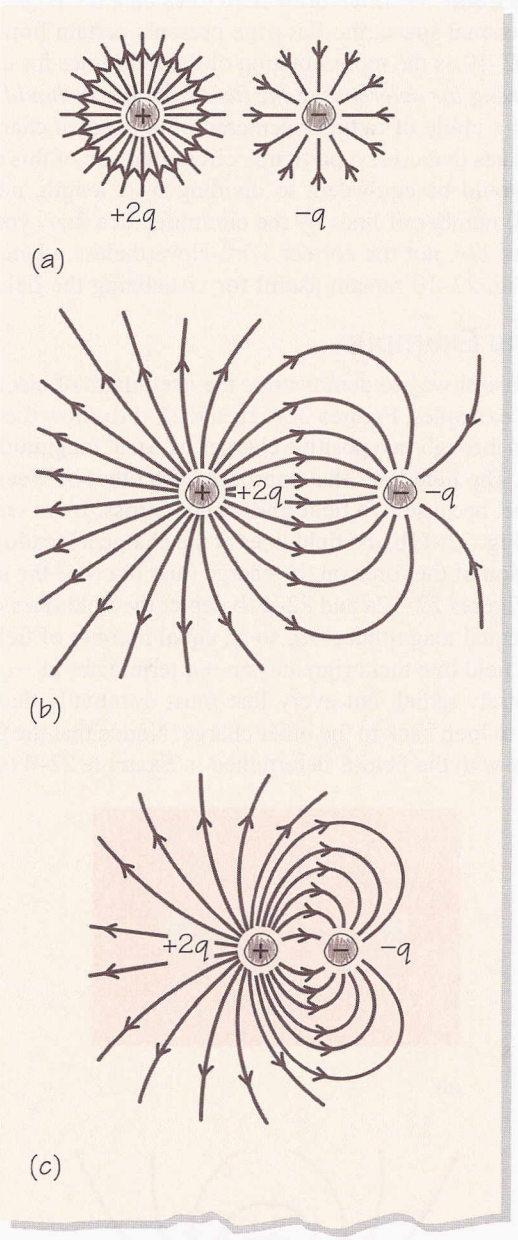
(a)

(b)

◀ **FIGURE 22–12** (a) The electric field lines due to point charges $+q$ and $-q$, a dipole, as indicated by threads in oil. (b) Schematic diagram of the field lines, all of which begin on $+q$ and end on $-q$; those that appear to head toward infinity do continue far from the charge, but eventually loop around and end on $-q$.

CONCEPTUAL EXAMPLE 22–5 The electric field lines of an isolated point charge go to infinity. How many field lines go to infinity for the electric dipole?

Answer Remember *Property Two:* Electric field lines always start on positive charges and terminate on negative charges. For an isolated point charge (say positive), the electric field lines go to infinity because there is no negative charge for them to end on. An electric dipole has one positive charge of a given magnitude and one negative charge of the same magnitude. Every line that starts on the positive charge will end on the negative charge, and so there will be none "left over" to go to infinity. We cannot see all the field lines doing this in Fig. 22–12, but if we made the figure large enough, we would see them all curve around and finally terminate on the negative charge!



EXAMPLE 22–6 Draw the electric field lines for a system of two charges, $+2q$ and $-q$, separated by a fixed distance.

Setting It Up We sketch a 2-dimensional representation of the field due to the two charges $+2q$ and $-q$ in Fig. 22–13a. Twice as many field lines leave the charge $+2q$ as end at the charge $-q$.

Strategy Arbitrarily close to each charge the field lines will be radial and uniformly spread over the area surrounding the charge. With twice as many lines coming from $+2q$ as go into charge $-q$, we can take half of the lines from the charge $+2q$ and connect them to the lines going into charge $-q$. The remaining lines go off to infinity.

Working It Out We choose, arbitrarily, to show 24 lines coming from $+2q$ so that 12 lines will go into $-q$ and 12 will go off to infinity. The final sketches are presented in Figs. 22–13b and 22–13c.

What Do You Think? What happens to the remaining 12 lines that emerge from $+2q$ that don't terminate on $-q$?

▶ **FIGURE 22–13** (a) The electric field lines close to the $+2q$ and $-q$ point charges are those of a point charge. (b) Half the electric field lines that emerge from $+2q$ end up on $-q$. (c) Far from the point charges, the electric field lines are those of a point charge $+q$. In this view you can begin to see the lines spread out to form a radial distribution.

22–3 The Field of a Continuous Distribution

We have thus far concentrated on electric fields due to point charges or collections of point charges. But *continuous* distributions of charge† also produce fields, and such distributions are very important in practice—for example, later we'll be interested in the

†Only point charges exist in nature; however, when we put many such charges together across a region, we will have a distribution that looks continuous to all but the sharpest measuring instrument.

field produced by charged capacitors. We will consider charges that are distributed *uniformly* throughout a region in space, whether a line, a surface, or a volume. We will also emphasize distributions where there is symmetry. For charge distributions that are not uniform or symmetrical, the problem of determining the resulting electric field can be more complex.

In considering forces on point charges due to charge distributions in Chapter 21, we have already set up a general framework for calculating electric fields due to line, surface, and volume distributions. Consider the calculation of the electric field at point P due to the charge distribution shown in Fig. 22–14. We divide the charge distribution into tiny elements, each of charge Δq. We first find the electric field $\Delta\vec{E}$ at point P that is due to a tiny charge element Δq, whose distance from P is r:

$$\Delta\vec{E} = \frac{\Delta q}{4\pi\varepsilon_0 r^2}\hat{r}. \tag{22–17}$$

Here, $\hat{r}$ is the unit vector pointing away from the charge element. Superposition applies, and the total electric field at P is found by summing the infinitesimal fields $\Delta\vec{E}$:

$$\vec{E} = \sum \Delta\vec{E}. \tag{22–18}$$

In the language of calculus, Eq. (22–17) becomes

$$d\vec{E} = \frac{dq}{4\pi\varepsilon_0 r^2}\hat{r}, \tag{22–19}$$

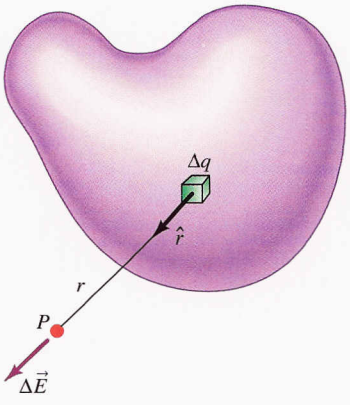
whereas the summation that gives the total electric field becomes an integral over the entire charge distribution:

$$\vec{E} = \sum_{\Delta q \to 0} \Delta\vec{E} = \int d\vec{E} = \frac{1}{4\pi\varepsilon_0}\int \hat{r}\frac{dq}{r^2}. \tag{22–20}$$

The formal expression of Eq. (22–20) is identical to the one we found for the force on a point charge q due to a charge distribution, Eq. (21–11), divided by q. This is exactly how we define the electric field.

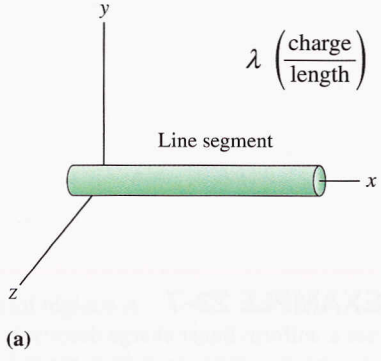
We can follow the development in Chapter 21 further to more specifically find the electric field due to a charge distribution along a line in terms of the linear charge density λ, the electric field due to a charge spread over a surface in terms of the surface charge density σ, and the electric field due to a charge distribution over a volume in terms of a volume charge density ρ (Fig. 22–15). In each case, the electric field is simply the expression for the force on the charge q divided by q; that is, Eqs. (21–13), (21–15), and (21–17) divided by q, respectively.

Constant Charge Densities



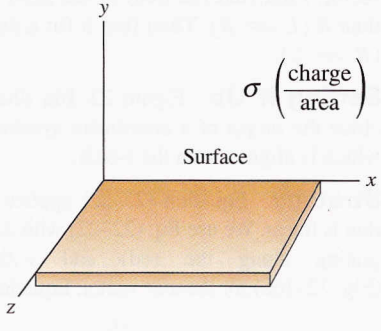
An important simplification for calculating the electric field due to a charge distribution occurs when the charge distribution, whether one-, two-, or three-dimensional, is *uniform*. This means that the charge densities are constants that can be removed from beneath the integrals expressing the electric field. Moreover, we can express the charge density in terms of the total charge Q contained in the distribution and the size of the distribution. In particular, if charge Q is distributed uniformly along a line segment of length L on a line, the linear charge density λ is

$$\lambda \equiv \frac{Q}{L}. \tag{22–21}$$

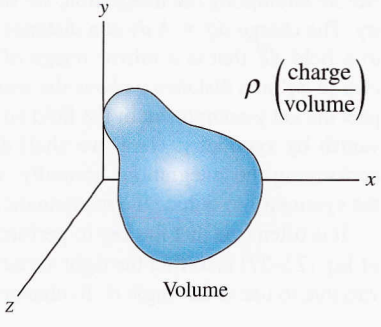


Dividing Eq. (21–13) by the test charge q, we have

$$\vec{E} = \frac{\lambda}{4\pi\varepsilon_0}\int \hat{r}\frac{dx}{r^2}. \tag{22–22}$$



Here, r is the distance to the point P at which the field is to be calculated, while $\hat{r}$ is a unit vector from the segment within the sum to point P. The integral is over a *one*-dimensional distribution.



▲ **FIGURE 22–14** To find the electric field due to a continuous charge distribution, add all the electric fields $\Delta\vec{E}$ due to the charge elements Δq.

(a)

(b)

(c)

▲ **FIGURE 22–15** (a) One-dimensional, (b) two-dimensional, and (c) three-dimensional charge distribution. The charge density is labeled λ, σ, and ρ, respectively.

For a charge Q distributed uniformly on a surface of area A, the surface charge density σ is

$$\sigma \equiv \frac{Q}{A}. \tag{22–23}$$

Then

$$\vec{E} = \frac{\sigma}{4\pi\varepsilon_0}\int_{\text{surface}} \hat{r}\frac{dS}{r^2}. \tag{22–24}$$

The integral in this case is over a *surface*.

Finally, if charge Q is distributed uniformly throughout a volume V, the volume charge density ρ is

$$\rho \equiv \frac{Q}{V} \tag{22–25}$$

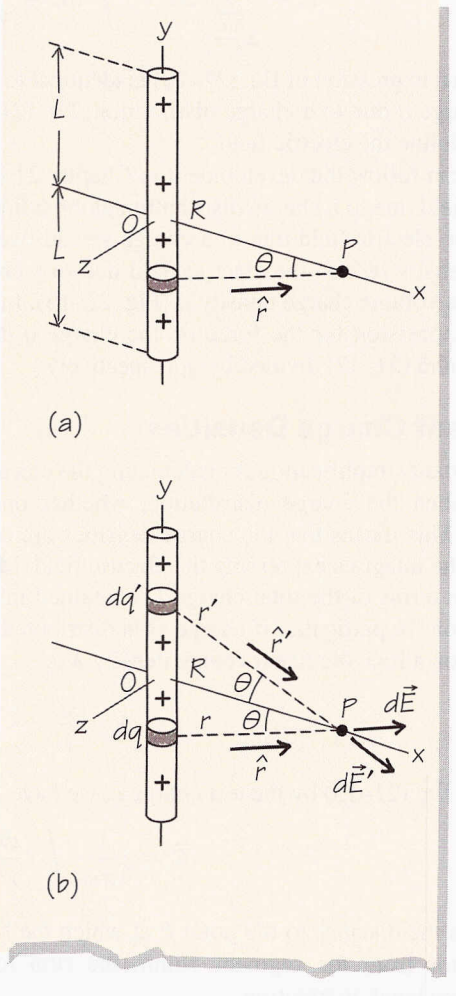
and the electric field is

$$\vec{E} = \frac{\rho}{4\pi\varepsilon_0}\int_{\text{volume}} \hat{r}\frac{dV}{r^2}. \tag{22–26}$$

This time the integral is over a *volume*.

The three integrals in Eqs (22–22), (22–24), and (22–26) are formal, and to understand how they work in practice, it is best to look at some examples.

EXAMPLE 22–7 A straight insulating rod of length $2L$ carries a uniform linear charge density λ. Determine the electric field at point P, a distance R from the rod along the perpendicular bisector. First find the field in the limit that the rod is much longer than R ($L \gg R$). Then find it for a distance very far from the rod ($R \gg L$).



Setting It Up Figure 22–16a illustrates the situation. We include the origin of a coordinate system at the midpoint of the rod, which is aligned with the y-axis.

Strategy Equation (22–22) applies because the charge distribution is linear. We use Eq. (22–22) with dx replaced by dy (we are integrating along the rod) and with $\hat{r} = (\cos\theta)\hat{i} + (\sin\theta)\hat{j}$ (Fig. 22–16a) for the unit vector. Equation (22–22) becomes

$$\vec{E} = \frac{\lambda}{4\pi\varepsilon_0}\int_{-L}^{L}[(\cos\theta)\hat{i} + (\sin\theta)\hat{j}]\frac{dy}{r^2}. \tag{22–27}$$

Before attempting the integration, we want to recognize any symmetry. The charge $dq = \lambda\, dy$ at a distance y *below* the x-axis gives rise to a field $d\vec{E}$ that is a mirror image of the field $d\vec{E}$ due to another charge dq' at a distance y *above* the axis (Fig. 22–16b). Thus we expect the net y-component of the field on the perpendicular bisector to vanish by symmetry. Here, we shall demonstrate this formally by performing the integration; normally, we would take advantage of the symmetry to reduce the mathematical calculation.

It is often true that the key to performing integrations such as that of Eq. (22–27) is to find the right variables. In this case, the simplest variable to use is the angle θ. To change from dy to $d\theta$, we recognize

▶ **FIGURE 22–16** (a) Geometry of the situation described. (b) The y-components of electric field due to matching pieces above and below the origin cancel, whereas the x-components add.

that y, r, and $\hat{r}$ depend on θ. We must find the dependence of both y and r on θ. We have

$$\tan\theta = \frac{y}{R} \tag{22–28}$$

and

$$\cos\theta = \frac{R}{r}. \tag{22–29}$$

From Eq. (22–28), we obtain

$$dy = Rd(\tan\theta) = R\sec^2\theta\, d\theta = \frac{R}{\cos^2\theta}\, d\theta.$$

With Eq. (22–29), the combination dy/r^2 that appears in Eq. (22–27) is

$$\frac{dy}{r^2} = \frac{1}{r^2}\frac{R}{\cos^2\theta}\, d\theta = \frac{1}{r^2}\frac{R}{(R/r)^2}\, d\theta = \frac{1}{R}\, d\theta.$$

Now we turn to the integral itself. We use the algebra above; the factor $1/R$ is a constant and comes out of the integral, leaving

$$\vec{E} = \frac{\lambda}{4\pi\varepsilon_0 R}\int_{-\theta_0}^{\theta_0}[(\cos\theta)\hat{i} + (\sin\theta)\hat{j}]\, d\theta.$$

The limits $-\theta_0$ and θ_0 are the maximum values of θ, corresponding to the two ends of the line of charge.

Working It Out In this case our strategy has helped us a great deal, because the integral over $d\theta$ is simple. Let's consider each of the two terms in turn. When we integrate the second term $(\sin\theta)$, we obtain a value proportional to $\cos\theta_0 - \cos(-\theta_0) = 0$. Therefore, the coefficient of $\hat{j}$, which is the y-component of the field, is zero, as we argued it must be by symmetry.

The coefficient of $\hat{i}$ is the x-component,

$$E_x = \frac{\lambda}{4\pi\varepsilon_0 R}\int_{-\theta_0}^{\theta_0}\cos\theta\, d\theta = \frac{\lambda}{4\pi\varepsilon_0 R}\sin\theta\Big|_{-\theta_0}^{\theta_0} = \frac{\lambda}{2\pi\varepsilon_0 R}\sin\theta_0. \tag{22–30}$$

We can use $\sin\theta_0 = L/\sqrt{L^2 + R^2}$ if desired.

We next take the requested limits. For a rod with length $L \gg R$, $\sin\theta_0 \cong 1$, and the component E_x given by Eq. (22–30) becomes in this limit

$$\text{for } L \gg R: \qquad E_x = \frac{\lambda}{2\pi\varepsilon_0 R}. \tag{22–31}$$

Equation (22–31) gives the electric field for an almost infinitely long rod (or for a point very close to a finite rod). The direction of the field is perpendicular to the rod.

For the case of $R \gg L$, $\sin\theta_0 \cong L/R$, and in this limit Eq. (22–30) becomes

$$\text{for } R \gg L: \qquad E_x = \frac{\lambda L}{2\pi\varepsilon_0 R^2} = \frac{Q}{4\pi\varepsilon_0 R^2}, \tag{22–32}$$

where $Q = 2\lambda L$ is the total charge on the rod. In this case $(R \gg L)$, we have obtained the point-charge result, because a rod of finite length looks like a point when it is viewed from large distances.

What Do You Think? The rod is a collection of point charges, and the field from a point charge falls off as $1/R^2$. So how can the field of the rod fall off as $1/R$, as in Eq. (22–31)?

EXAMPLE 22–8 Find the electric field at a distance L from an infinite plane sheet with a uniform surface charge density σ. (This situation relates to capacitors, which are important elements in electric circuits.)

Setting It Up We sketch the plane in Fig. 22–17a, where we place the sheet in the xz-plane. The point P where we want to find the field is on the y-axis.

Strategy Again, the main challenge is to find the simplest way to perform the integral of Eq. (22–24). For this we are going to use a technique that is useful in a variety of contexts. To integrate the effect of the entire plane, we break it up into pieces for each of which the field is easy to calculate. Here we break up the plane into a series of thin concentric circular regions centered around a point below P (Fig. 22–17a). These circles have a width Δr that is so small that the area of the circular regions is $2\pi r\,\Delta r$. To see why this is a good choice, take a look at Fig. 22–17b, which shows the contributions to the field at P from two segments on opposite sides of one of these concentric circles. You can see that their contributions to the field in the xz-plane *cancel* and that their contributions to the y-component of the field *add*. This is true all the way around the circle, so that we can first say that the field at P will have only a y-component. Moreover, the contribution dE_y to the y-component of the field of each of these segments is the same. Call the charge on a little segment of the ring dq. Then from Fig. 22–17b we have $dE_y = \dfrac{dq}{4\pi\varepsilon_0}\dfrac{1}{d^2}\cos\theta$. Every factor in this expression is the same all the way around the ring, so that when we sum the contributions around the ring, the net field y-component ΔE_y from the ring is

$$\Delta E_y = \frac{\Delta Q}{4\pi\varepsilon_0 d^2}\cos\theta = \frac{\sigma(2\pi r\,\Delta r)}{4\pi\varepsilon_0 d^2}\cos\theta.$$

Here, ΔQ is the total charge on the ring, which in the second term is expressed as the surface-charge density times the area of the ring. Finally, we note that $\cos\theta = L/d$, so that

$$\Delta E_y = \frac{\sigma(2\pi r\,\Delta r)}{4\pi\varepsilon_0 d^2}\frac{L}{d} = \frac{\sigma L}{2\varepsilon_0}\frac{r\,\Delta r}{(r^2 + L^2)^{3/2}}.$$

(We have used the fact that $d = \sqrt{r^2 + L^2}$.) In thinking about the direction of $\Delta\vec{E}$, symmetry has been an important guide. We have now found the field from a single ring. To find the net field, we must now sum over the rings, and this is a straightforward integration.

Working It Out The net field is the sum over the fields from the set of rings of all different radii r from 0 to ∞; these rings cover the entire plane. This sum is a single integral over the radii r. We have

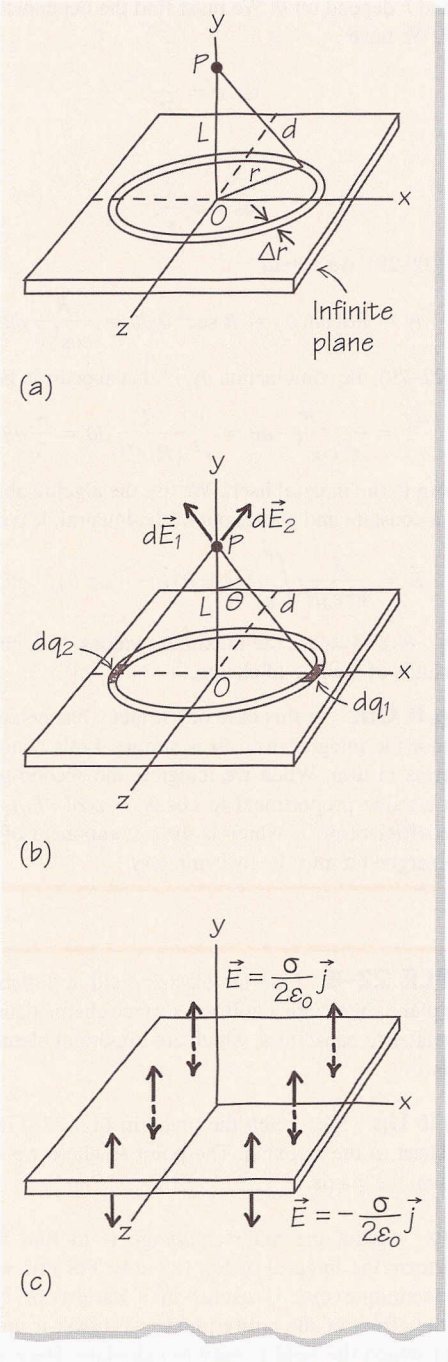
$$E_y = \sum \Delta E_y = \sum \frac{\sigma L}{2\varepsilon_0}\frac{r\,\Delta r}{(r^2 + L^2)^{3/2}} = \frac{\sigma L}{2\varepsilon_0}\int_0^\infty \frac{r\, dr}{(r^2 + L^2)^{3/2}}.$$

A table of integrals gives us

$$\int_0^\infty \frac{r\, dr}{(r^2 + L^2)^{3/2}} = \frac{-1}{(r^2 + L^2)^{1/2}}\Bigg|_{r=0}^{r=\infty} = \frac{1}{L}.$$

(continues on next page)

Thus the field due to the entire plane has magnitude $\sigma/2\varepsilon_0$ and is oriented in the y-direction:



$$\vec{E} = \frac{\sigma}{2\varepsilon_0}\hat{j}, \qquad (22\text{–}33)$$

FIELD OF AN INFINITE UNIFORMLY CHARGED PLANE

where more generally the direction is perpendicular to the plane. The electric field is *constant* in both magnitude and direction: The field $\vec{E}$ does not even depend on how far the point is from the plane (Fig. 22–17c).

In reality, we cannot have planes of infinite extent. The result above holds for finite planes when the point where the field is specified is at a distance from the finite plane that is much less than the distance to the edge of the plane.

What Do You Think? The field does not depend on how far the point is from a plane, because (a) all charged planes have the same field; (b) the infinite, uniformly charged plane looks the same from any distance; (c) this is only an approximation, and very close to the plane the field is actually larger. Which of the above statements is true?

▶ **FIGURE 22–17** (a) To find the electric field at a point P a distance L above an infinitely charged plane, break up the plane into concentric circles about the axis passing through P. (b) The field due to one such circle has no horizontal component at P because the horizontal contributions from opposite points on the circle cancel; moreover, the vertical component is easy to find because every point of the circle is equidistant from P. (c) The net field after summation from all circles is uniform and perpendicular to the plane.

The preceding instance illustrates how a formal two-dimensional integration can be reduced to a single integration. There are often several ways to approach this type of problem. For instance, we could have divided our plane into narrow straight strips. The field due to a strip was found in Example 22–7, and we could have used that result. The effect of the entire plane is then found by summing over all the strips that make up the plane. Once again, the final integral would have been a single integral, with the integration variable being the differing distances of the strips from point P.

CONCEPTUAL EXAMPLE 22–9 Suppose that a very large sheet with uniform positive charge density is placed on an insulating stand parallel to Earth's (horizontal) surface. What will a charged cork ball placed a small distance above the plate do?

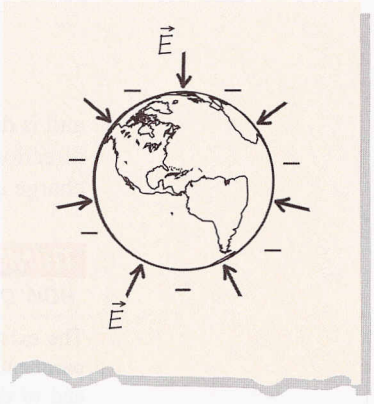
Answer We are told the sheet is very large and that the cork is only a small distance from the plate, so that to the cork the plate appears to be infinite and we can use the result of Example 22–6. We have a constant electric field, magnitude $E = \sigma/2\varepsilon_0$, that points

upward where the cork is. Accordingly, a vertically oriented force of magnitude qE will act on the cork, where q is the charge on the cork. If q is positive, the cork will be repelled from the sheet, and if q is negative, the cork will be attracted to the sheet. For q negative, the cork will be accelerated toward the sheet. However, if q is positive, which way the cork moves depends on whether the electrical force is larger than or smaller than its weight.

EXAMPLE 22–10 Table 22–1 indicates there is an electric field near Earth's surface of about 150 N/C that points vertically down. Assume this field is constant around Earth and that it is due to charge evenly spread on Earth's surface. What is the total charge on the Earth?

Setting It Up We draw a diagram in Fig. 22–18.

Strategy Because the electric field points toward the Earth's center, the responsible charge is negative. To find the value of the charge, we can treat Earth's surface as a plane (see Question 24) and use Eq. (22–33) for the electric field. Given the field's magnitude, we can find the charge density σ, and because we know Earth's surface area, we can then find the total charge Q.



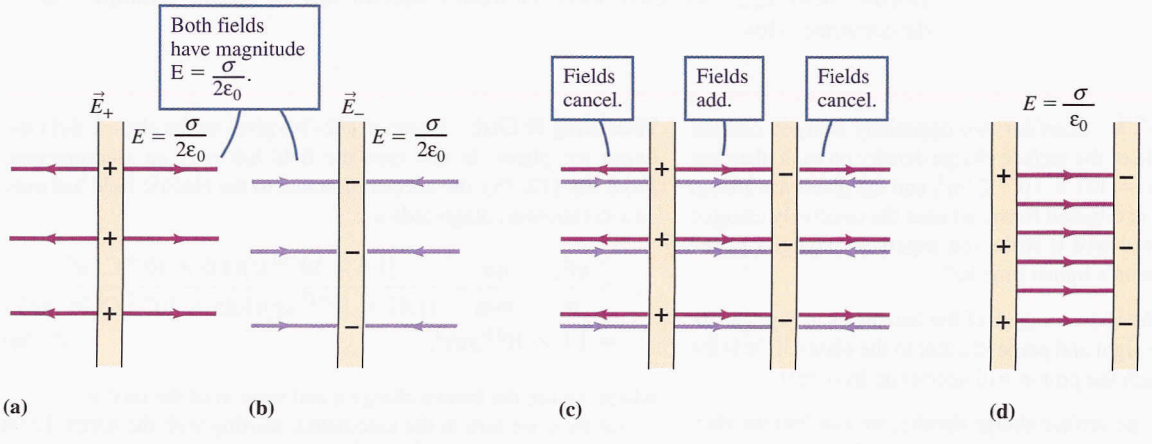
Working It Out From Eq. (22–33),

$$\sigma = 2\varepsilon_0 E = 2(8.85 \times 10^{-12}\,\text{C}^2/\text{N}\cdot\text{m}^2)(150\,\text{N/C})$$
$$= 2.7 \times 10^{-9}\,\text{C/m}^2.$$

The total charge Q is found by multiplying this charge density by Earth's surface area, $4\pi R^2$:

$$Q = \sigma 4\pi R^2 = (2.7 \times 10^{-9}\,\text{C/m}^2)(4\pi)(6.37 \times 10^6\,\text{m})^2$$
$$= 1.4 \times 10^6\,\text{C}.$$

While this may seem like a lot of charge, don't forget that it is spread out over Earth's entire surface. Washington, D.C., has an area of 68 square miles ($1.8 \times 10^8\,\text{m}^2$), which would mean that it contains only a half coulomb.



▲ **FIGURE 22–18**

What Do You Think? Suppose the Moon had a similar total charge on its surface. As a result, (a) the Moon and Earth would fly apart; (b) the Moon's surface charge density would be less than that of Earth's; (c) there would be very little effect on the Earth–Moon system; (d) the electric field at the Moon's surface would be the same as that of Earth's. Which of these statements are true?

The Electric Field Between Two Uniformly Charged Planes with Opposite Charge

Example 22–8 shows that the electric field for a positively charged plane of uniform surface charge density σ is uniform and perpendicularly directed away from the plane (Fig. 22–19a). If the plane were negatively charged, the field would be similar but would be directed *toward* the plane (Fig. 22–19b). What happens if we place the two planes, oppositely charged but with the same magnitude of charge density σ, parallel to each other? (This forms a capacitor.) As shown in Fig. 22–19c, the fields outside the

▲ **FIGURE 22–19** (a) The electric field due to a positively charged plane is directed away from the plane; (b) that due to a negatively charged plane is directed into the plane. (c) With two parallel planes carrying equal but opposite charge, the electric field cancels to zero outside the planes but is additive inside. (d) The field inside is σ/ε_0 and is directed from the positive plane to the negative plane.

parallel planes will exactly cancel each other, but the fields between the planes are additive. The resulting field is shown in Fig. 22–19d. For two parallel, oppositely charged planes, the electric field is zero everywhere except between the planes, where the field has magnitude

$$E = \frac{\sigma}{\varepsilon_0} \tag{22–34}$$

ELECTRIC FIELD BETWEEN PARALLEL PLANES OF OPPOSITE UNIFORM CHARGE DENSITY

and is directed from the positively to the negatively charged plane. (Remember that the direction of the electric field is always the direction of the force on our positive test charge q_0.)

THINK ABOUT THIS. . .

HOW DO WE KNOW THAT CHARGES COME IN MINIMUM SIZE UNITS?

The existence of a minimum charge is an experimental result. The determination of this fact and of the value of the minimum charge was carried out by Robert Millikan at the beginning of the twentieth century. The *electron* had been discovered in 1897 by the British physicist J. J. Thomson—the method of discovery will be explained in a later chapter—but all that was known about the electron at that time was the ratio q/m, the charge-to-mass ratio. Millikan's experiment of 1910, the result of several years of preparation, involves spraying of very small oil drops (size 0.1–1.0 μm) into a cavity. These oil drops fall with a very small constant velocity under the influence of gravity, the buoyancy of air, and the air's viscosity. The drops were allowed to fall through a hole into a region between two parallel horizontal plates, oppositely charged, so that there was a known, constant electric field pointing downward. In formation some of the drops acquired small electric charges, and any drops that were negatively charged were subject to a force qE that would arrest their fall, or lead to a constant upward velocity. By studying a large number of such drops, Millikan determined that the charges on the drops came in multiples of a charge $|e| = 1.6 \times 10^{-19}$ C. This smallest charge is the charge of the electron. See Problem 66 for a quantitative treatment of Millikan's experiments.

22–4 Motion of a Charge in a Field

We have been concerned thus far with finding the electric field of a given collection of charges. Let's turn now to the force that charged particles will experience in an external electric field. Newton's second law becomes

$$\vec{F} = q\vec{E}_{\text{ext}} = m\vec{a}, \tag{22–35}$$

where a particle of mass m and charge q has an acceleration $\vec{a}$ due to a given external electric field $\vec{E}_{\text{ext}}$. We then solve Newton's second law as usual. Example 22–11 demonstrates this.

EXAMPLE 22–11 Consider two oppositely charged parallel plates. The magnitude of the surface charge density on each plate has a constant value of $\sigma = 1.0 \times 10^{-6}\ \text{C/m}^2$, and the plates are 1.0 cm apart. (a) If a proton is released from rest near the positively charged plate, with what speed will it strike the negatively charged plate? (b) What will the proton's transit time be?

Setting It Up We show a sketch of the two plates in Fig. 22–20, with the x-axis to the right and perpendicular to the plates. This is the direction toward which the proton will accelerate from rest.

Strategy Given the surface charge density, we can find the electric field and hence the force on the proton; the force will be constant. This then becomes a problem in one-dimensional constant acceleration kinematics in which we determine the proton's speed and transit time.

Working It Out Equation (22–34) gives us the electric field between the plates. In this case the field has only an x-component. From Eq. (22–35), the acceleration due to the electric field has only an x-component, magnitude a_x:

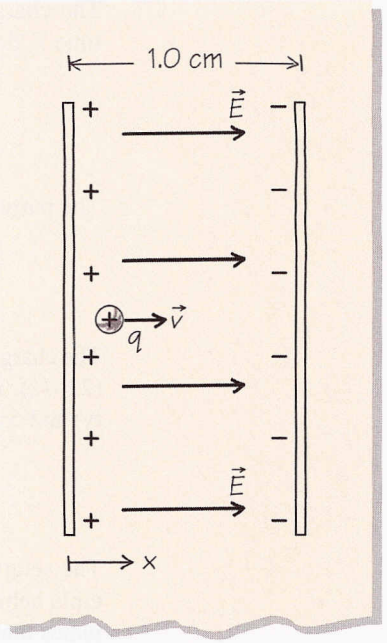
$$a_x = \frac{qE_x}{m} = \frac{q\sigma}{m\varepsilon_0} = \frac{(1.6 \times 10^{-19}\ \text{C})(1.0 \times 10^{-6}\ \text{C/m}^2)}{(1.67 \times 10^{-27}\ \text{kg})(8.85 \times 10^{-12}\ \text{C}^2/\text{N}\cdot\text{m}^2)} = 1.1 \times 10^{13}\ \text{m/s}^2, \tag{22–36}$$

where we use the known charge q and mass m of the proton.

(a) Now we turn to the kinematics, starting with the speed. From Section 2–5 we have $v^2 - v_0^2 = 2a_x x$. With the initial speed v_0 zero,

$$v^2 = 2a_x x. \tag{22–37}$$

Equation (22–36) gives us a_x, while the distance traveled between the plates is $x = 1.0$ cm. Thus



$$v^2 = 2(1.1 \times 10^{13}\ \text{m/s}^2)(1.0 \times 10^{-2}\ \text{m}) = 2.2 \times 10^{11}\ \text{m}^2/\text{s}^2;$$
$$v = 4.7 \times 10^5\ \text{m/s}.$$

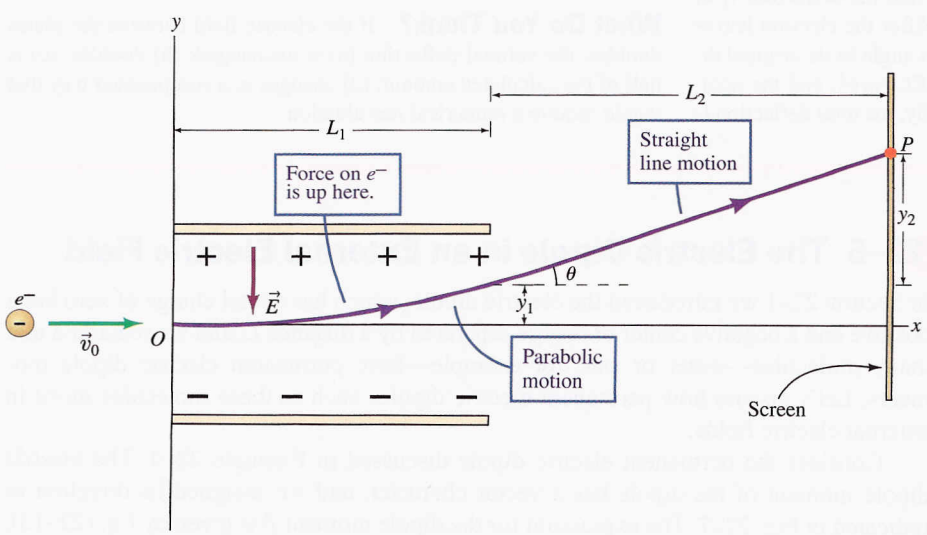
(b) The transit time is the final speed divided by the acceleration:

$$t = \frac{v}{a_x} = \frac{4.7 \times 10^5\ \text{m/s}}{1.1 \times 10^{13}\ \text{m/s}^2} = 4.3 \times 10^{-8}\ \text{s}.$$

The plates accelerate protons and thus represent a charged-particle accelerator.

What Do You Think? What would happen to an electron released from the same position as the proton?

▶ **FIGURE 22–20** A charge $+q$ moving between parallel plates.



Deflection of Moving Charged Particles

Let's consider what happens when we inject a negatively charged particle (an electron, for example) into a region of uniform $\vec{E}$ between two plates (Fig. 22–21; we ignore edge effects). The particle has initial velocity $\vec{v}_0$ perpendicular to $\vec{E}$, and since it carries negative charge, it will be deflected upward in Fig. 22–21. From Eq. (22–35) the acceleration vector is

$$\vec{a} = a_x\hat{i} + a_y\hat{j} = \frac{qE}{m}\hat{j}. \qquad (22\text{–}38)$$

Note that the x-component of the acceleration is zero. Because the initial velocity is only in the x-direction ($\vec{v}_0 = v_0\hat{i}$), the velocity vector becomes

$$\vec{v} = v_x\hat{i} + v_y\hat{j} = v_0\hat{i} + \left(\frac{qE}{m}t\right)\hat{j}. \qquad (22\text{–}39)$$

◀ **FIGURE 22–21** An electron passing between plates that deflect vertically.

The charged particle travels a horizontal length L_1 between the charged plates in the time T, determined by

$$x = v_0 T = L_1; \tag{22–40}$$

$$T = L_1/v_0. \tag{22–41}$$

The particle's deflection in the y-direction is then

$$y_1 = \frac{1}{2}a_y t^2 = \frac{1}{2}\frac{qE}{m}T^2 = \frac{1}{2}\frac{qE}{m}\frac{L_1^2}{v_0^2}. \tag{22–42}$$

The charged particle emerges from the plates at a position (x, y) given by Eqs. (22–40) and (22–42). The charged particle is then free from the influence of any force (ignoring gravity) and continues past the plates in a straight line at an angle θ from its initial direction:

$$\tan\theta = \frac{v_y}{v_x} = \frac{(qE/m)(L_1/v_0)}{v_0} = \frac{qEL_1}{mv_0^2}. \tag{22–43}$$

The setup described here allows control of a beam of charged particles and is the principle behind the picture tubes of televisions. In a television, there is also a second set of plates that controls deflection in the third direction, and a beam of electrons can then be directed anywhere on the screen.

EXAMPLE 22–12 An electron moving horizontally at a speed $v_0 = 3 \times 10^6$ m/s enters the region between two horizontally oriented plates of length $L_1 = 3$ cm. A fluorescent screen is located $L_2 = 12$ cm past these plates. Find the electron's total vertical deflection on the screen from its initial direction if the electric field between the plates points downward with a magnitude of $E = 10^3$ N/C.

Setting It Up Figure 22–21 again illustrates the situation, with the x-axis along the initial direction of the electron and the y-direction perpendicular. The electron will be deflected along the y-direction.

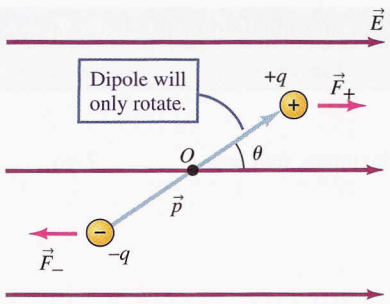
Strategy A constant electric field will lead to a constant acceleration, and we must apply the kinematic equations that describe constant acceleration. These equations are worked out above. Let us label as y_1 the vertical deflection of the electron between the plates, and as y_2 the additional vertical deflection of the electron after it has passed between the plates, where it continues in a straight path until it strikes the screen. We use Eq. (22–42) to find the deflection y_1 of the electron while it is between the plates. After the electron leaves the region between the plates, it travels at an angle to its original direction, given by Eq. (22–43) as $\tan\theta = qEL_1/mv_0^2$, and the additional deflection will be $y_2 = L_2 \tan\theta$. Finally, the total deflection is $y = y_1 + y_2$.

Working It Out We have from Eq. (22–42) $y_1 = \frac{1}{2}\frac{qE}{m}\frac{L_1^2}{v_0^2}$, and from Eq. (22–43) $y_2 = L_2 \tan\theta = \frac{qEL_1L_2}{mv_0^2}$. The net deflection is then

$$y = y_1 + y_2 = \frac{1}{2}\frac{qEL_1^2}{mv_0^2} + \frac{qEL_1L_2}{mv_0^2} = \frac{qEL_1}{mv_0^2}\left(\frac{1}{2}L_1 + L_2\right).$$

Numerical evaluation with a minus sign for E ($\vec{E}$ points downward) gives

$$y = \frac{(-1.6 \times 10^{-19}\text{ C})(-10^3\text{ N/C})(3 \times 10^{-2}\text{ m})}{(9.11 \times 10^{-31}\text{ kg})(3 \times 10^6\text{ m/s})^2} \times \left[\frac{1}{2}(3 \times 10^{-2}\text{ m}) + (12 \times 10^{-2}\text{ m})\right] = 8 \times 10^{-2}\text{ m}.$$



Of this 8 cm, the deflection $y_1 = 1$ cm, and the deflection $y_2 = 7$ cm.

What Do You Think? If the electric field between the plates doubles, the vertical deflection (a) is unchanged; (b) doubles; (c) is half of the calculated amount; (d) changes in a complicated way that would require a numerical reevaluation.

22–5 The Electric Dipole in an External Electric Field

In Section 22–1 we introduced the electric dipole, which has a total charge of zero but a positive and a negative center of charge separated by a distance L, and we remarked that many molecules—water or salt, for example—have permanent electric dipole moments. Let's discuss how permanent electric dipoles such as these molecules move in external electric fields.

Consider the permanent electric dipole discussed in Example 22–4. The electric dipole moment of the dipole has a vector character, and we assigned its direction as indicated in Fig. 22–7. The expression for the dipole moment $\vec{p}$ is given by Eq. (22–13).

◀ **FIGURE 22–22** A dipole placed in a uniform external electric field experiences no net force but will experience a torque.

If we place the electric dipole in a uniform external field (Fig. 22–22), then the forces on $+q$ and $-q$ are, respectively,

$$\vec{F}_+ = q\vec{E},$$
$$\vec{F}_- = -q\vec{E} = -\vec{F}_+.$$

We notice that the two forces are equal and opposite and therefore cancel. *There is no net force on the dipole.*

There is, however, a torque that tends to rotate the dipole. To calculate the torque and the corresponding rotation, we must choose a reference point, and it is convenient to choose this point to be the midpoint of the dipole, which is located at point O in Fig. 22–22. The actual motion will be independent of the choice of reference point. The torque, τ, about a point due to a force that acts on another point that is a displacement $\vec{r}$ away is given by Eq. (10–6):

$$\vec{\tau} = \vec{r} \times \vec{F}, \tag{22–44}$$

where $\vec{r}$ is measured from point O. The resulting torque from the force on each charge is then clockwise, with magnitudes

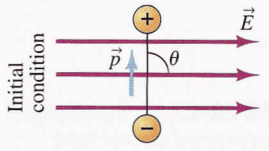
$$\tau_+ = \left(\frac{L}{2}\right)qE \sin\theta, \qquad \tau_- = \left(\frac{L}{2}\right)qE \sin\theta,$$

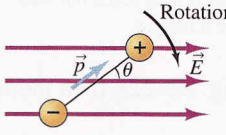
where the subscripts $+$ and $-$ refer to the charges. Because both τ_+ and τ_- are clockwise rotations, the total torque is also clockwise, with magnitude

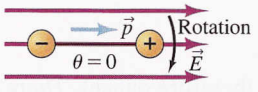
$$\tau = \tau_+ + \tau_- = qLE \sin\theta. \tag{22–45}$$

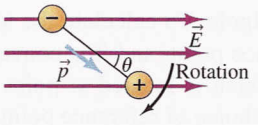
We can represent this expression for the torque on a dipole as the vector product of $\vec{p}$ and $\vec{E}$:

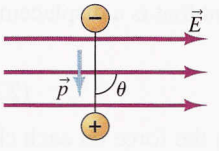
$$\vec{\tau} = \vec{p} \times \vec{E}, \tag{22–46}$$

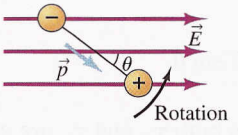












TORQUE ON A DIPOLE DUE TO A FIELD

which gives both the torque's magnitude ($pE \sin\theta$) and direction (into the page in Fig. 22–22).

The maximum torque ($\tau = pE$) occurs when $\vec{p}$ and $\vec{E}$ are perpendicular ($\theta = \pi/2$). The torque is zero when $\vec{p}$ and $\vec{E}$ are parallel ($\theta = 0$) or antiparallel ($\theta = \pi$). The torque tends to rotate the electric dipole until $\vec{p}$ is parallel to $\vec{E}$. The position $\theta = 0$ corresponds to a stable equilibrium, but the position $\theta = \pi$ is one of unstable equilibrium because a small deviation will cause the dipole to rotate toward $\theta = 0$.

Suppose the dipole is initially aligned along some angle $\theta \neq 0$ with respect to an electric field. What will the motion look like? This question is most easily answered when we look at the potential energy U of the dipole in the field (see the paragraph below). There we shall see that *for small angles, U* is a constant + a term proportional to θ^2. This corresponds to the behavior of an ordinary pendulum, or a spring, and the motion is oscillatory about $\theta = 0$. As the dipole rotates toward $\theta = 0$, it gains kinetic energy and passes through $\theta = 0$ to the other side. The torque, however, then becomes counterclockwise, and the dipole slows down, stops, returns to $\theta = 0$, and passes through it again to the original side. Table 22–2 illustrates a time sequence for a rotating dipole in an electric field. Without a mechanism to dissipate the dipole's energy, the oscillations will continue.

The Energy of a Dipole in an External Electric Field

When a dipole rotates under the influence of an external electric field, the field does work on it. From this work we can find the potential energy of the dipole in the field. To find the work done by the field as the dipole rotates from an initial angle θ_0 to a final angle θ, we use the form $W = \int_{\theta_0}^{\theta} \vec{\tau} \cdot d\vec{\theta}$. We refer to Fig. 22–22 to see that for a counterclockwise rotation, the infinitesimal angle change is out of the page, while the torque $\vec{\tau} = \vec{p} \times \vec{E}$ is into the page. Thus the scalar product $\vec{\tau} \cdot d\vec{\theta} = -\tau\, d\theta = -(pE \sin\theta)\, d\theta$, and the work done by the field is

$$W = \int_{\theta_0}^{\theta} (-pE \sin\theta)\, d\theta = -pE(\cos\theta_0 - \cos\theta). \tag{22–47}$$

Now, as we know from Chapter 7, the potential energy $U(\theta)$ at point θ minus its value $U(\theta_0) = U_0$ at some initial point θ_0 is the *negative* of the work done by the associated force as the object moves from θ_0 to θ. Thus we have

$$U - U_0 = pE(\cos\theta_0 - \cos\theta). \tag{22–48}$$

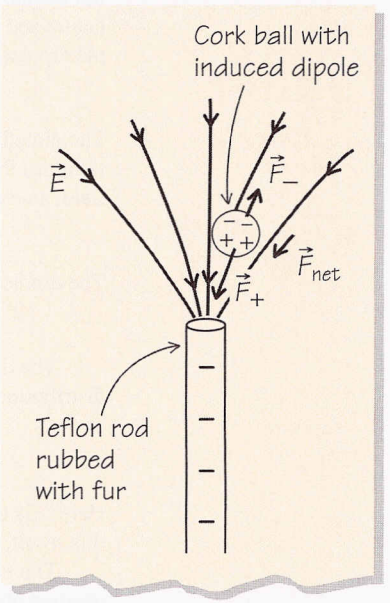
We are free to choose the constant U_0, and we choose it such that $U_0 = 0$ at $\theta_0 = \pi/2$. Thus the potential energy at angle θ is given by

$$U = -pE\cos\theta. \tag{22–49}$$

Notice that Eq. (22–49) is consistent with our choice for the zero of the potential energy, because $U_0 = -pE\cos\theta_0$, which is zero when $\theta_0 = \pi/2$.

Equation (22–49) can be written more compactly by using the scalar dot product of $\vec{p}$ and $\vec{E}$:

$$U = -\vec{p} \cdot \vec{E}. \tag{22–50}$$



POTENTIAL ENERGY OF A DIPOLE IN A FIELD

Above, we discussed the stability of the equilibrium of the dipole in an external field. We can see directly from Eq. (22–50) that the orientation in which $\vec{p}$ is aligned with $\vec{E}$ is a point of stable equilibrium because U has a minimum there. In contrast, U has a maximum when $\vec{p}$ is antiparallel to $\vec{E}$, and therefore this is a point of unstable equilibrium.

CONCEPTUAL EXAMPLE 22–13 What is the motion, if any, of an electric dipole placed in a *nonuniform* external electric field?

Answer A possible setup of this situation is sketched in Fig. 22–23. We have used a cork ball that has a dipole moment induced by the field itself. If the field is nonuniform, the forces on the two charges in the dipole will generally differ in magnitude. Then, in addition to a torque, there will be a net force on the dipole. The resulting motion would be a combination of linear acceleration and rotation. The details of the motion depend on the particular electric field. While we have used the tip of a charged rod in this figure, we could equally well have placed a dipole in the region of a point charge, as long as the point charge field lines "spread" significantly over the size of the dipole.

The effect of a nonuniform electric field on an induced dipole explains the attraction of a neutral cork ball coated with conducting paint to a Teflon rod rubbed against fur (Fig. 22–23). The charged Teflon rod induces an electric dipole on the cork ball, which is in the nonuniform electric field of the rod. Another example of the action of a nonuniform electric field on an induced dipole is the attraction between small bits of paper and a comb that has just been charged by passing it through hair. The bits of paper have induced dipole moments and are attracted to the comb in its nonuniform field.

▲ **FIGURE 22–23** A dipole placed in a nonuniform external electric field can experience a net force. In this case the external electric field induces a dipole in the cork ball, which then experiences a force due to the electric field. This effect can be understood by using Coulomb's law.

Summary

Charge distributions set up electric fields in the space around them. The electric field vectors can be mapped out by moving a small, positive test charge q_0 around in this field. The field $\vec{E}$ is defined as the force $\vec{F}$ on this test charge, divided by q_0:

$$\vec{E} \equiv \lim_{q_0 \to 0} \frac{\vec{F}}{q_0} \tag{22–2}$$

The electric field has units of N/C (or V/m). The force on a point charge q' in a given external electric field is

$$\vec{F} = q' \vec{E}_{\text{ext}}. \tag{22–7}$$

Electric field lines aid in the visualization of the direction and magnitude of the electric field produced by various charge configurations. We can summarize the rules for drawing them and their properties by saying that

- Electric field lines are drawn so that the tangent to the field line specifies the direction of the electric field itself.
- The density in field lines per unit area is proportional to the magnitude of the electric field.
- Electric field lines start and end on electric charges, never in empty space. In particular, they start on positive charges and terminate on negative charges.
- Electric field lines never cross.

From Coulomb's law, the electric field due to a point charge q is

$$\vec{E} = \frac{q}{4\pi\varepsilon_0 r^2}\hat{r}. \tag{22–5}$$

Electric fields obey the principle of superposition:

$$\vec{E}_{\text{net}} = \vec{E}_1 + \vec{E}_2 + \vec{E}_3 + \cdots = \sum_i \vec{E}_i, \tag{22–10}$$

where $\vec{E}_i$ labels the field of the components (normally point charges) that make up a charge distribution.

In its simplest form, an electric dipole consists of a positive charge q separated by a distance L from a negative charge $-q$. Such a configuration, or any configuration that is electrically neutral but has an imbalance of positive and negative charge from one side to another, occurs often in nature and produces an electric field. This field decreases with distance r as $1/r^3$ and, for the simple dipole, is proportional to the magnitude of the electric dipole moment $\vec{p}$, given by

$$\vec{p} = q\vec{L}. \tag{22–13}$$

The direction of $\vec{L}$ (and of $\vec{p}$) is from the negative charge to the positive charge. This direction determines the angular dependence of the electric dipole field. In addition to producing an electric field, an electric dipole experiences a torque in a uniform external electric field:

$$\vec{\tau} = \vec{p} \times \vec{E}. \tag{22–46}$$

The dipole in the external field has a potential energy of

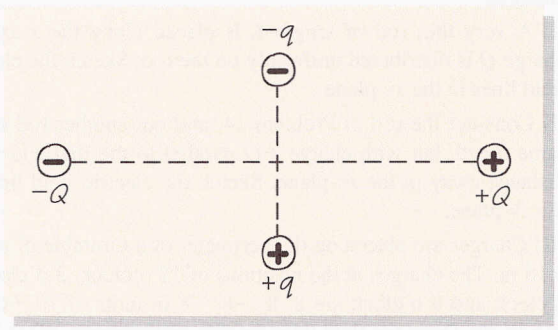
$$U = -\vec{p} \cdot \vec{E}. \tag{22–50}$$

The dipole is a configuration of two point charges, but we also deal with continuous charge distributions. The electric field due to a continuous charge distribution is

$$\vec{E} = \frac{1}{4\pi\varepsilon_0}\int \hat{r}\frac{dq}{r^2}. \tag{22–20}$$

Here, r is the distance of a charge element dq from the point where the field is measured. To use this result, it is necessary to know how dq varies throughout space.

The electric field due to an infinitely long wire is radial and perpendicular to the wire. A charged plane, infinite in area, with a charge per unit area of σ has an electric field that is uniform and directed perpendicular to the plane, with



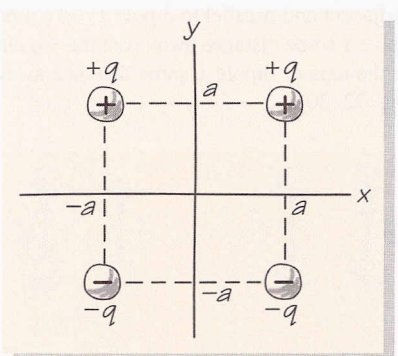
$$E = \frac{\sigma}{2\varepsilon_0}. \tag{22–33}$$

In later chapters we'll have ample opportunity to apply the electric field concept.

Understanding the Concepts

1. In older movies, you may see gasoline trucks dragging metal chains along the road. Why?
2. Why can't two electric field lines cross?
3. We have introduced the concept of an electric field. Why might it be useful to introduce an analogous gravitational field? In what ways would this field be like an electric field, and in what ways would it be different?
4. An inflated rubber balloon is charged by rubbing it with fur. Explain what happens when that balloon is placed against (a) a metal wall; (b) an insulating wall.
5. Two charges of opposite polarities are close together. Five times as many field lines leave one charge as end up on the other charge. What is the ratio of charges?
6. Electric field lines originate from positive charges and terminate at negative charges, as exemplified by the field lines due to a dipole. Does this statement contradict the depiction of field lines due to a single positive point charge?
7. If in Example 22–3 there were a point (or points) on the line connecting the three charges at which the electric field is zero, where, qualitatively, would it (or they) be?
8. A pair of equal and opposite charges forms a dipole, and the electric field of a dipole is not zero. But if we were to look at a dipole from very far away, the two charges would appear to be on top of one another and to cancel; that is, we would see no charge, and hence we should see no field. How do you reconcile these statements?
9. In Example 22–10, we asked how many electrons the charge on Earth represents. How do we know that the charge responsible for Earth's field is a negative one?
10. Can the electric dipole induced on a spherical conducting ball cause the ball to rotate? How about the electric dipole induced on a long rod?
11. After you comb your hair, the comb can often attract small pieces of paper. The act of combing may induce an electric charge on the comb, but the combing does not itself affect the paper. What accounts for the attraction?
12. Is it possible for electric field lines to go all the way to infinity?
13. Explain how the water molecule, H_2O, acts as an electric dipole (see Fig. 22–8), given that there are *two* spatial regions (around the H atoms) with negative charge.

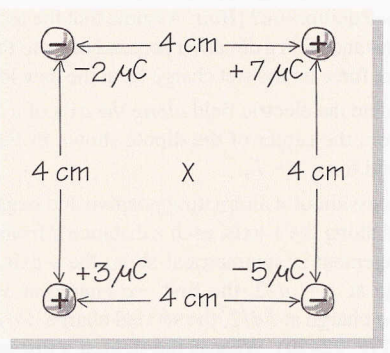
14. We called the arrangement in Example 22–11 an accelerator; how could we get the accelerated particle out in order to use it?
15. Explain why the electric-field-line technique would not be useful for a point charge if Coulomb's experiments had shown the electric force to decrease as $1/r$ or as $1/r^{2+\delta}$.
16. The internal motion of a liquid can be described by a velocity field, which is the velocity vector of the element of fluid at a given point. In what ways is this field like an electric field, and in what ways is it different?
17. Can you invent an arrangement of charges whose electric field would be radially directed into a point in some region of empty space? The correct answer has implications for the stability of charges placed in static electric fields.
18. Suppose that a small electric dipole ($+q$ and $-q$) is placed somewhere on a line that is perpendicular to, and bisects, a second (fixed) dipole ($+Q$ and $-Q$), as seen in Fig. 22–24. If the small dipole is free to pivot about its center, what will it do?



▲ **FIGURE 22–24** Question 18.

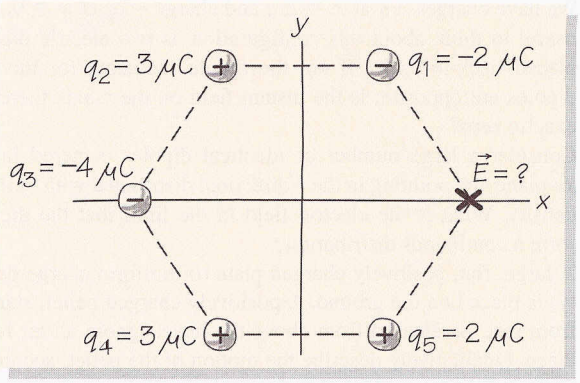
19. We have charges $+q$ at $x = \pm a$ and charge $-2q$ at $x = 0$. Is it useful to think about this configuration as two electric dipoles placed back-to-back? If so, the dipole moments for the two dipoles are opposite; is the distant field on the y-axis therefore exactly zero?
20. Consider a large number of identical dipoles centered in the xy-plane and pointing in the z-direction, distributed with uniform density. What is the electric field in the limit that the dipoles form a continuous distribution?
21. A large, flat, positively charged plate (of uniform charge density) is placed on the ground. A positively charged pellet, starting from rest, is released from above the plate. Ignore all air resistance. Qualitatively describe the motion of the pellet, according to the height from which it is dropped.
22. Suppose that a positively charged pellet is dropped from above onto the north pole of a large, positively charged sphere (of uniform charge density). Disregarding air resistance, and any small instabilities that would make the pellet move away from the vertical, describe the motion of the pellet.
23. Suppose in Example 22–3 q_1 were at $x_1 = -1$ mm rather than -1 cm. What useful approximation could you make to find the field at A?
24. In Example 22–10, we found Earth's charge by treating its surface as a plane rather than thinking of it as a sphere. Why is this a very good approximation?

Problems



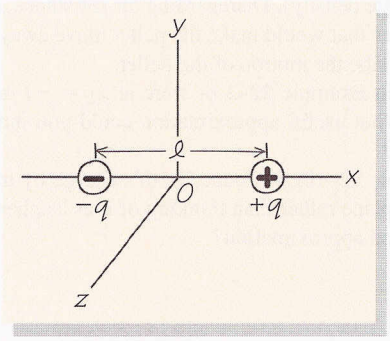
22–1 Electric Field

1. (I) A 5-μC charge is located at $(x, y) = (5\text{ cm}, 0\text{ cm})$. Determine the electric field at (2 cm, 4 cm).
2. (I) Calculate the electric field at the origin due to the following distribution of charges: $+q$ at $(x, y) = (a, a)$, $+q$ at $(-a, a)$, $-q$ at $(-a, -a)$, and $-q$ at $(a, -a)$ (Fig. 22–25).



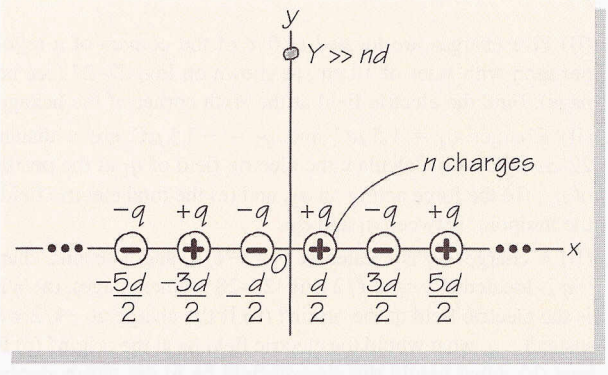
▲ **FIGURE 22–25** Problem 2.

3. (I) Find the electric field due to the nucleus of an atom of gold ($Z = 79$) at a point 1 nm from the nucleus. Treat the nucleus as a point. What is the force on an electron at that point?
4. (II) Charges of $+3$ μC, -5 μC, $+7$ μC, and -2 μC are located at the four corners of a square 4 cm on each side (Fig. 22–26). Calculate the electric field at the center of the square. [*Hint*: You may want to use a coordinate system with axes along the diagonals.]



▲ **FIGURE 22–26** Problem 4.

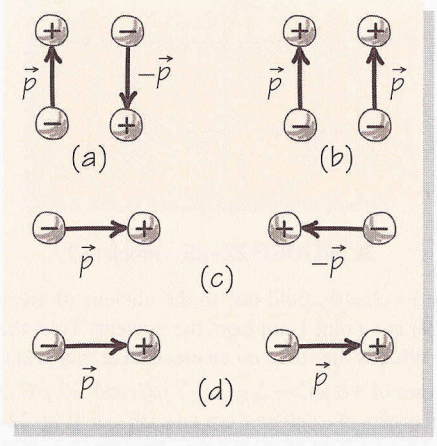
5. (II) Five charges are located at five of the corners of a regular hexagon with sides of 10 cm, as shown on Fig. 22–27 (see next page). Find the electric field at the sixth corner of the hexagon.
6. (II) Charges $q_1 = 1.5$ μC and $q_2 = -3.5$ μC are a distance 22 cm apart. (a) Calculate the electric field of q_1 at the position of q_2; (b) the force acting on q_2, and (c) the total electric field at the midpoint between q_1 and q_2.
7. (II) A charge $-q$ is located at $y = -\ell/2$, and a second charge $+q$ is located at $y = +\ell/2$ (Fig. 22–28 see next page). (a) What is the electric field at the origin? (b) If the charge at $-\ell/2$ were instead $+q$, what would the electric field be at the origin? (c) For part (b), what would the electric field be in the entire xz-plane specified by $y = 0$?



▲ **FIGURE 22–27** Problem 5.

▲ **FIGURE 22–28** Problem 7.

8. (II) Identical positive charges Q are placed at $x = a$ and $x = -a$, respectively. (a) What is the electric field at $x = 0$? (b) Suppose that a positive test charge q_0 is placed at $x = 0$. Will it be in stable or unstable equilibrium? [*Hint*: Assume that the test charge is displaced a distance δ in a direction perpendicular to the x-axis. What will the net force on the test charge be at the new location?]
9. (II) Calculate the electric field *along the axis* of a dipole at a distance r from the center of the dipole shown in Fig. 22–5. Work out the field for $r \gg L$.
10. (II) A succession of n alternating positive and negative charges q are placed along the x-axis, each a distance d from its neighbors. The arrangement is symmetrical about the y-axis, with the first $+q$ charge at $x = d/2$, the first $-q$ charge at $x = -d/2$, the second $-q$ charge at $3d/2$, the second charge $+q$ at $-3d/2$, and so forth (Fig. 22–29). What is the field at a distant point $y = Y$ (where $Y \gg nd$) on the y-axis?



▲ **FIGURE 22–29** Problem 10.

11. (III) Suppose that the positive test charge in Problem 8 is constrained to move along the x-axis only. Will $x = 0$ be a stable equilibrium position? If it is, then the test charge should oscillate about $x = 0$ for small enough displacements. If that were the case, what would the frequency of oscillation be for a test charge of mass m? [*Hint*: Assume that the charge is displaced to a point $x = \delta$, where $\delta \ll a$, and calculate the magnitude and the direction of the electric field there. Use the approximation $1/(a + \delta)^2 = (1/a^2) - (2\delta/a^3) + \cdots$, valid for $\delta \ll a$.]

22–2 Electric Field Lines

12. (I) Draw the electric field lines due to charges of $+0.6\,\mu C$ and $+1.8\,\mu C$ located 15 cm apart.
13. (I) A pair of parallel plates have equal and opposite uniform charge distributions. The field is represented by parallel lines drawn with a density N per m^2. The charge density on the plates is tripled. How should the density of electric field lines be changed?
14. (I) A very thin rod of length L is placed along the x-axis. A charge Q is distributed uniformly on the rod. Sketch the electric field lines in the xy-plane.
15. (I) Consider the rod in Problem 14, and put another rod of the same length but with charge $-Q$ parallel to the first and some distance away in the xy-plane. Sketch the electric field lines in the xy-plane.
16. (II) Charges are placed on the perimeter of a turntable of radius 0.15 m. The charges at the positions of 12 o'clock, 3 o'clock, 6 o'clock and 9 o'clock are 8, 8, -8, -8 in units of 10^{-5} C, respectively. Draw the field lines for this arrangement. What is the electric field at the center of the circle?
17. (II) Six equal charges of alternating opposite sign $(+, -, +, -, +, -)$ are aligned along the x-axis, each separated from its neighbor by a distance d. Draw the configurations of field lines.
18. (II) Consider charges q placed along the x-axis at $x = na$, with $n = 0, \pm 1, \pm 2, \pm 3, \ldots$. Sketch the electric field lines.
19. (II) The field lines due to an electric dipole $\vec{p}$ (dipole 1) are shown in Fig. 22–12b; by definition, the direction of $\vec{p}$ points from $-q$ to $+q$. Sketch the field lines for the combination of this dipole and (a) a dipole $-\vec{p}$ adjacent and parallel to dipole 1; (b) a dipole $\vec{p}$ adjacent and parallel to dipole 1; (c) a dipole $-\vec{p}$ on the axis of dipole 1 some distance away past the $+q$ charge; (d) a dipole $\vec{p}$ on the axis of dipole 1 some distance away past the $+q$ charge (Fig. 22–30).

▲ **FIGURE 22–30** Problem 19.

20. (II) Charges q, q, and $-q$ form an equilateral triangle whose sides each have length 12 cm, with the negative charge at the top. Sketch the electric field lines. What is the magnitude of the electric field 0.080 cm from and directly above $-q$; what is it at a distance of 35 m from and directly above $-q$?

22–3 The Field of a Continuous Distribution

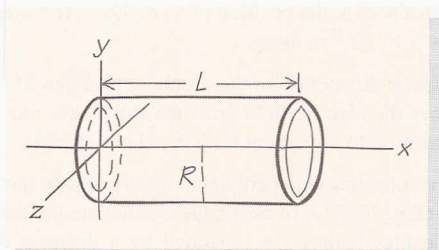
21. (I) Calculate the electric field due to an infinitely long, thin, uniformly charged rod with a charge density of 0.3 μC/m at a distance 20 cm from the rod. Assume that the rod is aligned with the x-axis.

22. (I) A thin, uniformly charged rod with a total charge of 6 μC and length 25 cm is placed along the z-axis, centered at the origin. Find the electric field at $(x, y, z) = (6\text{ cm}, 0\text{ cm}, 0\text{ cm})$ and $(0\text{ cm}, 6\text{ cm}, 0\text{ cm})$.

23. (I) Sketch the electric field lines between a point charge Q and a uniformly charged, flat square of area L^2 and total charge $-Q$. The point charge is located a distance L above the center of the plane.

24. (I) Consider two infinite plane sheets of insulator with uniform surface charge densities σ_1 and σ_2, respectively. The two sheets are parallel to each other and a distance L apart. What is the force on a point charge Q placed midway between the sheets?

25. (II) A negative charge is distributed uniformly on a long cylindrical shell. Sketch the field lines both inside and outside the shell. Do not include the ends of the cylinder.



26. (II) Consider positive charges distributed uniformly with a charge density λ on a circle of radius R. (a) Use symmetry arguments to deduce the direction of the electric field at a point in the plane of the circle but outside the circle. (b) What is the magnitude of the electric field at a distance L along the axis of the circle for $L \gg R$?

27. (II) A rod with a uniform negative charge is bent into a semicircle. Make a rough sketch of the electric field lines in the plane of the rod.

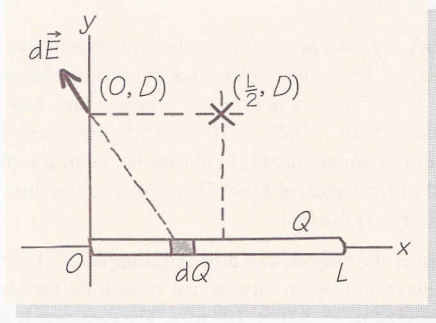
28. (II) Two infinite plates with a uniform charge density of 1.2 μC/m^2 are placed along the yz-plane with one plate passing through $x = 2$ cm and the other through $x = -2$ cm. Determine the electric field at $(x, y, z) =$ (a) (0 cm, 0 cm, 0 cm); (b) (8 cm, 0 cm, 0 cm); (c) (8 cm, 1 cm, 2 cm).

29. (II) Two large, flat, vertically oriented plates are parallel to each other, a distance d apart. Both have the same uniform positive charge density σ. What is the electric field in the space around and between them?

30. (II) The axis of a hollow tube of radius R and length L is aligned with the x-axis; the tube's left-hand edge is at $x = 0$, as shown in Fig. 22–31. It carries a total charge q distributed uniformly along its surface. By integrating the result for a field due to a hoop of charge along the axis of the hoop (see Example 22–8), find the electric field along the x-axis due to the tube as a function of x.

▲ FIGURE 22–31 Problem 30.

31. (II) A thin, circular disk of radius R is oriented in the xy-plane with its center at the origin. A charge Q on the disk is distributed uniformly over the surface. (a) Find the electric field due to the disk at the point $z = z_0$ along the z-axis. (b) Find the field in the limit $z_0 \to \infty$. (c) Find the field in the limit that $R \to \infty$. Are the limits of parts (b) and (c) the same?



32. (II) Consider a thin, uniformly charged rod 18 cm long that is bent into a semicircle. The total charge on the rod is 0.36 μC. What are the magnitude and direction of the electric field at the center of the semicircle?

33. (II) A rod 30 cm long is charged uniformly with a charge density of 15 μC/m. A charge of 3 μC is placed 30 cm from the midpoint of the rod along a line perpendicular to the rod. Calculate the electric field at a point halfway between the point charge and the center of the rod.

34. (II) Determine the electric field from the large plane in Example 22–8 by assuming the plane is made of a series of charged rods, using the results of Example 22–7.

35. (II) Consider a spherical shell of radius R uniformly charged with a total negative charge $-Q$. Starting at the surface of the shell going outward, there is a uniform distribution of positive charge in space such that the electric field at the radius $(R + h)$ vanishes, where $R \gg h$. What is the positive charge density? [*Hint*: With $R \gg h$ you can assume that $(R + r)^n \cong R^n + nrR^{n-1}$ for $0 \le r \le h$.]

36. (III) A total charge Q is distributed uniformly over a rod of length L. The rod is aligned on the x-axis, with one end at the origin and the other at the point $x = L$ (Fig. 22–32). Calculate the electric field at a point $(0, D)$, and compare this result with the field at the point $(L/2, D)$.

▲ FIGURE 22–32 Problem 36.

37. (III) Consider a point at a height z_0 directly above the midpoint of a square with sides of length $2L$. The (nonconducting) square carries a uniform charge density σ. (a) Use the method of Example 22–8 to write an integral for the electric field at z_0. (b) How does the integral simplify in the limit $L \to \infty$? (c) $z_0 \to 0$?

22–4 Motion of a Charge in a Field

38. (I) An infinite plate carries a uniform charge density $\sigma = 2.17 \times 10^{-6}$ C/m^2. A pellet of mass 0.555 g is placed at rest 0.175 m from the plate. The pellet carries a negative charge $q = -1.08 \times 10^{-6}$ C. What is its speed when it reaches the plate? Ignore all forces except the electrostatic attraction.

39. (I) A small object, mass 120 mg, is observed to undergo an acceleration of magnitude 4.6 m/s^2 when it is placed in a constant electric field of magnitude 850 N/C. What is the charge on the object?

40. (I) A sheet of uniform charge density 6.1×10^{-9} C/m^2 is placed at $z = 0$ in the xy-plane. An electron with zero initial velocity is placed at $z = 0.45$ m. What will be its velocity after 17.5 ns?

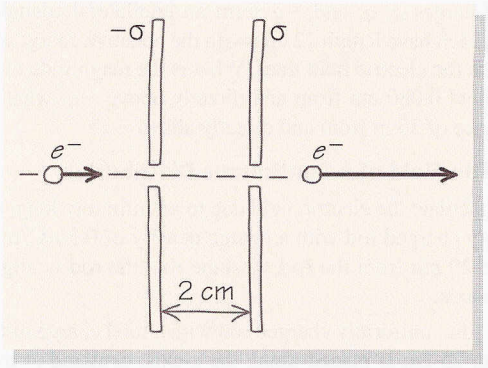
41. (I) A large, flat plate with unknown, uniform charge density σ is placed on a horizontal tabletop. A cork ball of mass 0.83 g, carrying a charge 8.5×10^{-7} C, is placed at rest above the plate and remains at rest. What is σ?

42. (I) An alpha particle approaches a gold atom head on, stops, and turns around at a distance of 10^{-11} m from the nucleus. What is the electric field due to the gold nucleus at this point? Ignore the effects of the gold atom's orbiting electrons. What is the acceleration of the alpha particle when it is stopped? An alpha particle is a helium nucleus, composed of two protons and two neutrons.

43. (II) Consider an infinite wire with uniform charge density λ along the z-axis. A negatively charged particle moves in a circle in the xy-plane centered on the wire. Calculate the particle's speed, and show that the speed is independent of the radius of the circle. Ignore all forces except those due to the wire.

44. (II) A negative charge $-q$ is restricted to move in a plane in which there is a continuous line of positive charge and a charge density λ. The negative charge, of mass m, can pass the line of positive charge freely. What is the equation of motion for the negative charge?

45. (II) A positive charge q can travel in a circular orbit about a negatively charged line with uniform charge density λ. Show that the period of the orbit is proportional to the radius of the orbit. Compare this to the dependence of the period of a circular orbit on the radius of the orbit for a point charge that interacts with another point charge.

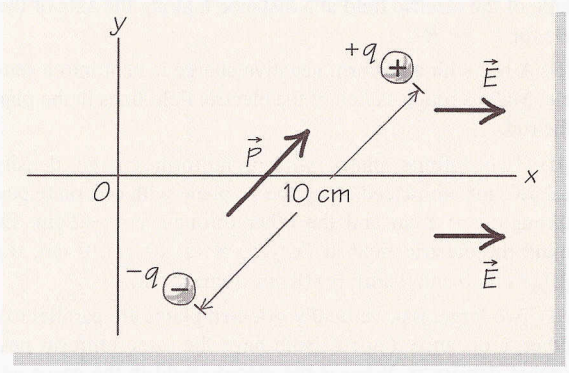


46. (II) A cork ball of mass 5.6 g is placed between two large horizontal plates. The bottom plate has a uniform charge density of $+1.6 \times 10^{-6}$ C/m^2, whereas the upper plate has a uniform charge density of -0.22×10^{-6} C/m^2. The cork ball, which carries an unknown charge, is placed between the plates and is observed to float motionlessly. What are the sign and magnitude of the charge on the ball?

47. (II) Consider the cathode-ray tube of Example 22–12. This time an electron enters the region between the vertical-deflection plates with a total speed of $v_0 = 5.0 \times 10^6$ m/s. The direction is such that the velocity has a vertical component $v_{0y} = +2.0 \times 10^5$ m/s. Find the total vertical deflection of the electron when it reaches the screen.

48. (II) A beam of electrons is accelerated by passing it through a region between two large charged parallel plates (Fig. 22–33). Calculate the charge density on the plates if the electrons accelerate from 1.4×10^6 m/s to 3.0×10^7 m/s between the plates.

49. (II) A cork ball of mass 5 g, carrying a charge of $-2\ \mu$C, is suspended from a string 1 m long above a horizontal, uniformly charged plate of charge density 1 μC/m^2. The ball is displaced from the vertical by a small angle and allowed to swing. Show that the ball moves in simple harmonic motion, and calculate the angular frequency of that motion.

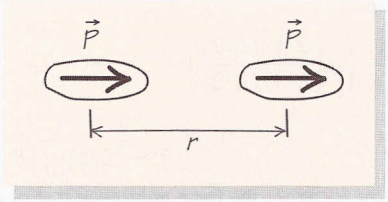


50. (III) A proton moves at speed $v = 5 \times 10^5$ m/s in the $+x$-direction and enters a certain region. An electric field in the region also is oriented in the $+x$-direction. The field's strength drops linearly with x: At the beginning of the region, $x = 0$ m, the field strength is 500 N/C; at $x = 3$ m, the field strength is zero. How much time does it take for the proton to traverse this region? [*Hint*: The equation of motion will be more familiar in terms of the variable $x' = x - 3$.]

▲ **FIGURE 22–33** Problem 48.

22–5 The Electric Dipole in an External Electric Field

51. (I) An electric dipole consists of two opposite charges of magnitude 2 μC placed 10 cm apart (Fig. 22–34). The dipole is placed in a uniform electric field of 10 N/C along the x-axis, with the direction of $\vec{p}$ at an angle of $+45°$ from the x-axis in the xy-plane. Determine the torque on the dipole.



▲ **FIGURE 22–34** Problem 51.

52. (I) The magnitude of the two opposite charges that form an electric dipole is increased by a factor of 5 while the separation between the charges is tripled. What is the change in magnitude of the torque on the dipole in a uniform electric field?

53. (I) A water molecule has a permanent electric dipole moment of magnitude 6×10^{-30} C · m. Estimate the size of the electric field it produces at the position of a neighboring water molecule, which is 3×10^{-9} m away.

54. (II) Describe the motion of the dipole in Problem 51. How much work does the electric field do when the dipole moves from its initial position to alignment with the electric field?

55. (II) Two molecules with permanent electric dipole moments $\vec{p}$ are aligned (Fig. 22–35, see next page). Calculate the force between the molecules if they are separated by a distance that is large compared with the dimension of the dipoles. [*Hint*: The relation $(1 + x)^{-2} \cong 1 - 2x + 3x^2 - \cdots$ for small x is useful.]

▲ **FIGURE 22–35** Problem 55.

56. (II) A molecule of lithium fluoride (LiF) has a permanent dipole moment. The molecule is placed in a uniform electric field of strength 10^4 N/C, and the difference between the maximum and minimum potential energies of the molecule in this field is 4.4×10^{-25} J. What is the electric dipole moment of the LiF molecule?

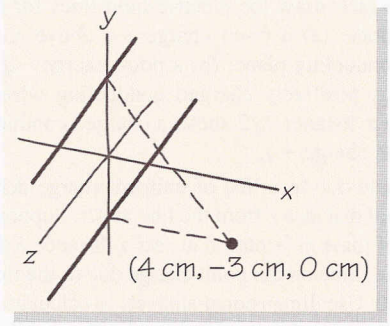
General Problems

57. (II) A point charge $-q$ is fixed at the center of a hollow spherical conductor of charge $+q$. Draw the electric field lines both inside and outside the sphere.

58. (II) A point charge $+q$ is fixed at the center of a hollow spherical conductor also of charge $+q$. Draw the electric field lines both inside and outside the sphere.

59. (II) Draw the electric field lines for a point charge $+q$ near an infinitely long, positively charged wire.

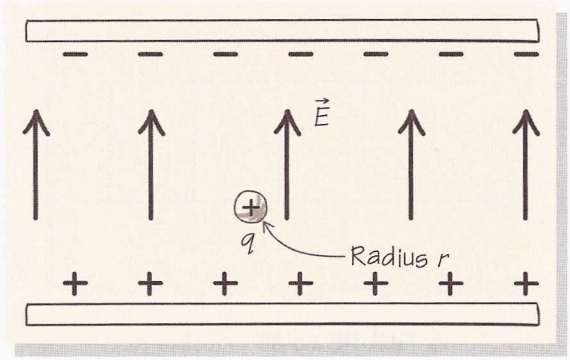
60. (II) A cork ball of radius 1.2 cm and a charge of +3.5 nC is covered with conducting paint. What is the electric field strength just outside the surface? A nickel nucleus, with a radius of 5×10^{-15} m, has a positive charge of $28e$. What is the electric field strength just outside the surface of the nucleus?



61. (II) Two infinitely long, uniformly charged rods, with charge densities of λ and $-\lambda$, respectively, are lined up parallel to each other and separated by a distance R. What are the magnitude and direction of the electric field due to the two rods at points that lie (a) on a line joining the two rods, and (b) along a perpendicular bisector of that line? Draw a figure to show the configuration, and use symmetry.

62. (II) What is the force per unit length that one of the two rods in Problem 61 exerts on the other?

63. (II) Two uniformly charged infinite plates with charge densities $-5\ \mu C/m^2$ and $3\ \mu C/m^2$ are placed at right angles, the first one along the xz-plane, the second along the yz-plane. A test particle of mass 1 g and charge 1×10^{-7} C is placed a distance of 1 m from both planes; that is, its initial position is $(x, y, z) = (1\text{ m}, 1\text{ m}, 0\text{ m})$. What is the location of the test particle after a short time t (before it hits a plate)?



64. (II) Two infinite lines of charge density $5\ \mu C/m$ are parallel to the z-axis. One line passes through $(x, y) = (0\text{ cm}, 1\text{ cm})$; the other, through $(x, y) = (0\text{ cm}, -1\text{ cm})$ (Fig. 22–36). Find (a) the electric field at the origin; (b) the force on a 0.5-μC charge at the origin; (c) the force on a 6-μC charge located at $(x, y, z) = (4\text{ cm}, -3\text{ cm}, 0\text{ cm})$.

65. (II) A proton with kinetic energy of 2×10^6 eV is fired perpendicular to the face of a large metal plate that has a uniform surface charge density of $\sigma = 8.0 \times 10^{-6}\ C/m^2$. (a) Calculate the magnitude and direction of the force on the proton. (b) How much work must the electric field do on the proton to bring it to rest? (c) From what distance should the proton be fired so that it stops right at the surface of the plate?

▲ **FIGURE 22–36** Problem 64.

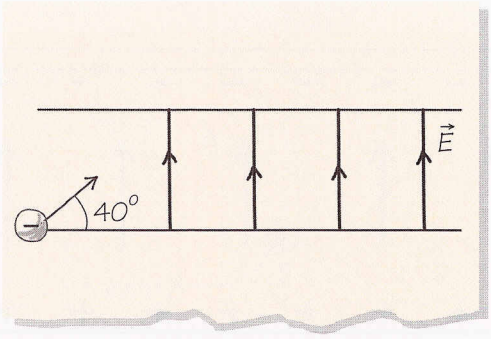
66. (II) The electric charge with the smallest magnitude that can be isolated is the charge on the electron or the proton. In 1909, Robert A. Millikan developed a classic method to measure this charge, known as the *oil drop experiment*. Millikan was able to place charges on tiny droplets of oil, which would fall at a given terminal velocity under the influence of gravity and air drag. By placing these droplets between parallel, horizontal charged plates, as in Fig. 22–37, the electric field between the plates produces a force on the charged droplet that is directed upward and can partly cancel the gravitational force. If the mass and size of the droplet are known, then, by seeing how fast droplets fall with and without the electric field, the charge can be measured.

▲ **FIGURE 22–37** Problem 66.

The drag force on a droplet of radius r that falls at a steady speed v through air is also directed upward and is given by *Stokes's law*, $F_{drag} = 6\pi\eta rv$, where η is the viscosity of air. (a) Show from Newton's second law that the terminal velocity v_0 of the *uncharged* drop is $v_0 = (2/9)r^2\rho g/\eta$, where ρ is the density of the oil and g is the acceleration due to gravity. (b) Suppose that the charge on the drop, q, is positive and that the field is directed vertically upward, as in the figure, so that the electric force points up. Show by using Newton's second law that the charge is given by

$$q = \frac{18\pi(v_0 - v_1)}{E}\sqrt{\frac{v_0\eta^3}{2\rho g}},$$

where v_1 is the terminal velocity when the electric field E is imposed. (c) Take the minimum charge as 1.6×10^{-19} C, the oil's density as $0.85\ g/cm^3$, and the radius of the droplet as 2.0×10^{-4} cm. The droplet has the minimum charge. Find the value of E that will hold the droplet stationary between the plates.



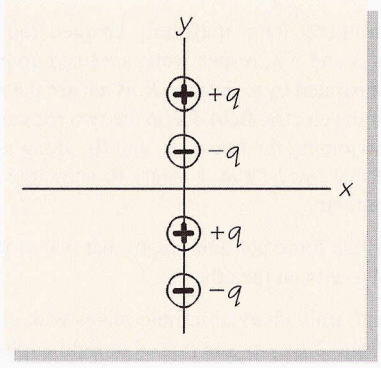
67. (II) We will learn in Chapter 23 that the electric field near a conductor *must be perpendicular to the conducting surface.*

Using this fact, draw the electric field lines for the following configurations: (a) a point charge $+q$ above an infinite, uncharged conducting plane; (b) a point charge $-q$ near an infinitely long, positively charged conducting wire; (c) a point charge $+q$ a distance $L/2$ above a charged conducting plane of area L^2 and charge $+q$.

68. (II) The field due to a line of uniform charge density λ varies with a radial distance r from the line as $1/r$. Suppose that a point charge q of mass m is placed at rest a distance R from the line, and that the force on the point charge due to the field of the line is attractive. Use dimensional analysis to calculate how the time it will take for the charge to drop to the charged line depends on λ, q, m, R, and ε_0.

69. (II) Consider two thin insulating rods of equal length (0.20 m) placed parallel to each other, and 0.18 m apart. Each of the rods has a charge 2.2×10^{-4} C and -2.2×10^{-4} C placed at opposite ends, with the positive charges on the two rods nearest to each other. What is the force that one of the rods experiences due to the presence of the other rod? What torque about an axis through its midpoint is experienced by one of the rods due to the presence of the other?

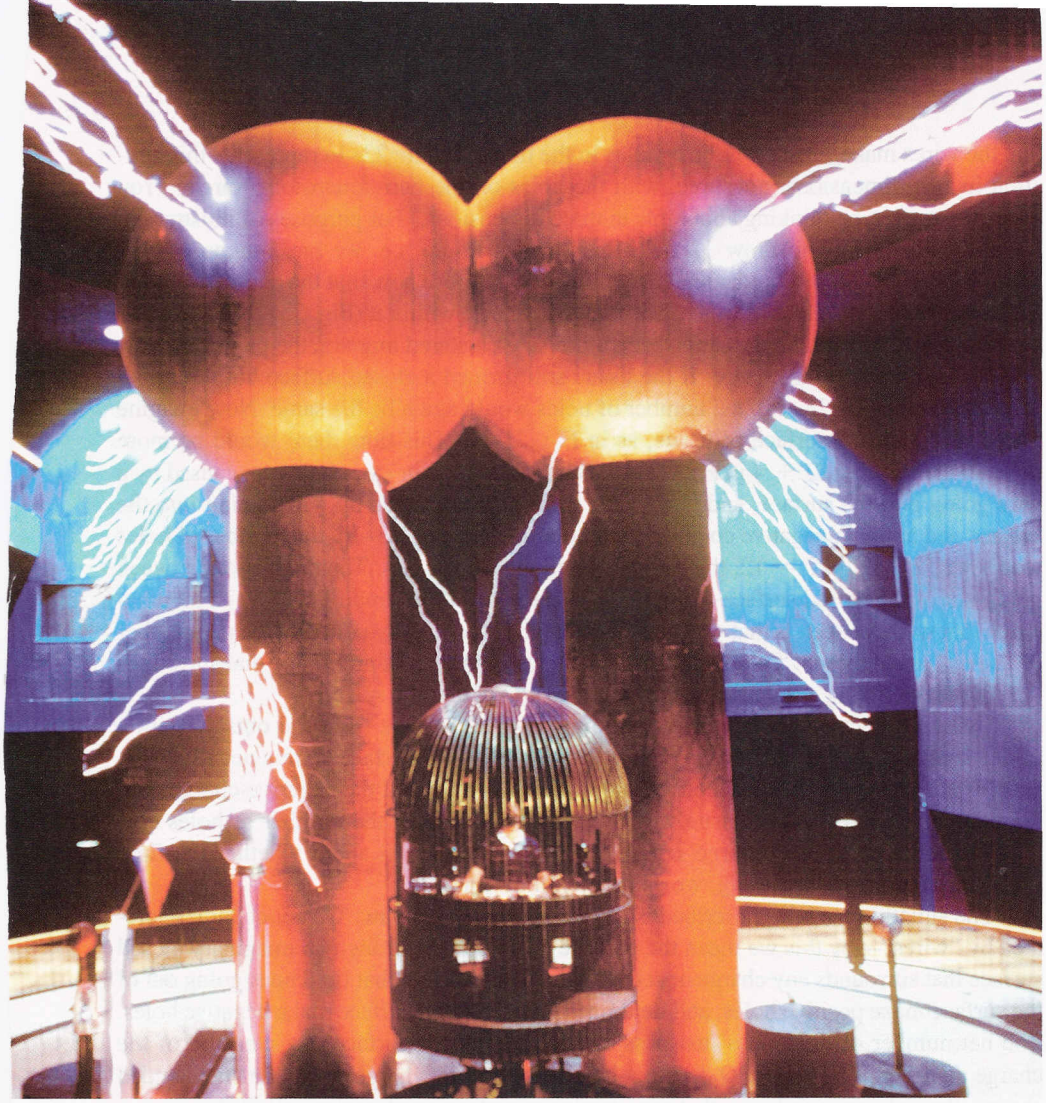
70. (II) An electron of speed 3×10^6 m/s enters a region of constant electric field at an angle of 40° as shown in Fig. 22–38. How far away from where the electron enters will it strike the bottom plate?



▲ **FIGURE 22–38** Problem 70.

71. (III) Consider the straight, nonuniformly charged rod of length L aligned along the x-axis, with the ends at $x = \pm L/2$, in Example 21–11. We showed there that the force on a charge q located at a point $x = R$ on the x-axis, to the right of the right-hand end of the rod, is

$$\vec{F} = \frac{q\lambda_0}{2\pi\varepsilon_0 L}\left\{\ln\left[\frac{R-(L/2)}{R+(L/2)}\right] + R\left[\frac{1}{R-(L/2)} - \frac{1}{R+(L/2)}\right]\right\}\hat{i}.$$



Show that for $R \gg L$, the force reduces to that of a dipole acting on q, $\vec{F} \cong (q\lambda_0 L^2/12\pi\varepsilon_0 R^3)\hat{i}$. What is the dipole moment? [*Hint*: Use the approximate forms $(1-x)^{-1} \cong 1 + x + x^2 + \cdots$ and $\ln(1+x) \cong x - (x^2/2) + (x^3/3) - \cdots$, both appropriate for $x \ll 1$.]

72. (III) The field of an electric dipole decreases as $1/r^3$ when the distance of a given point to the dipole, r, is much larger than the separation between the charges. The only way to arrange two charges with a total charge of zero is to form a dipole. There are, however, many ways to arrange four charges with a total charge of zero in a compact pattern. An arrangement with an electric field that behaves at great distances as $1/r^4$ is an *electric quadrupole*. (a) For four charges aligned with alternating sign (such as $(+\,-\,-\,+)$ so that the combination acts like dipoles of opposite orientation) along an axis, show that the field on the axis perpendicular to the line of charges decreases as $1/r^4$, where r is much larger than any separation distance within the quadrupole. [*Hint*: Use the approximation $(r^2+\delta^2)^{-3/2} \cong \frac{1}{r^3} - \frac{3\delta^2}{2r^5} + \cdots$ (good when $\delta \ll r$) for each of the four charges; do not forget the sign of the charge in determining the field.] (b) Sketch the field for the arrangement shown in Fig. 22–39, using the field-line technique.

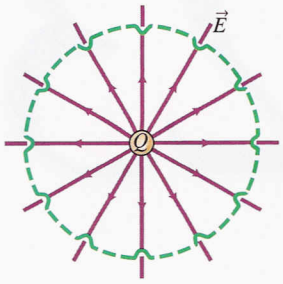
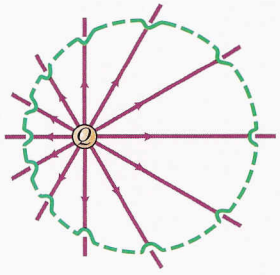
Chapter 23

◀ Sparks from a high-voltage electrostatic generator at the Boston Museum of Science do not harm the operator who is sitting inside a grounded Faraday cage.



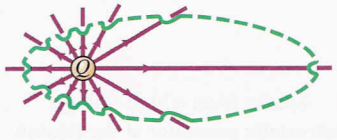
Gauss' Law

The concept of the electric field allows us to study the interaction between two charges as a two-step process: one involving the interaction of a charge with an electric field, the other involving the determination of the electric field due to electric charges. We saw in Chapter 22 that this division simplifies the problem of calculating interactions between charges. Gauss' law, the subject of this chapter and one of the fundamental laws of electromagnetism[†], gives us a new way to think about the electric field due to charge distributions. This law contains all the information in Coulomb's law and will allow us to go further. When there is symmetry in the charge distribution, Gauss' law is a powerful tool for the direct evaluation of the electric field. Gauss' law also gives us valuable insight into the behavior of conductors.



23–1 What Does Gauss' Law Do?

For a simple insight into Gauss' law, consider the electric field lines associated with a charge Q. We suppose that the charge gives rise to N electric field lines. (The choice is arbitrary, although once it is made we must use it as a normalizing factor—for example, a charge $2Q$ will give rise to $2N$ lines.) We can think of the field lines as a collection of N rigid wires that emerge radially from a point—the location of the charge—and extend to infinity. One way of finding the value of Q would be to imagine that we could somehow make a sphere of tissue appear at any fixed radius around the charge and count the holes



[†]Karl Friedrich Gauss, a great mathematician of the nineteenth century, worked on celestial mechanics, electromagnetism, optics, and the theory of errors.

(c)

(d)

▲ **FIGURE 23–1** (a) Twelve wires representing field lines pass through this two-dimensional representation of a three-dimensional tissue forming a sphere with a charge Q at its center. (b) If the sphere is displaced the number of wires (field lines) passing through it remains 12, at least as long as the charge is somewhere within. (c) The tissue does not have to form a sphere; it can be another shape that still encloses the charge, and the count of wires that pass through it is the same. (d) If the surface enclosing the charge has folds, the counting looks as though it fails. But if one counts the number of times a line enters the surface from the outside, and assigns this number a minus sign, the algebraic total of the number of wires through the closed surface surrounding the charge is the same whatever the shape, including the case illustrated here, in which the surface has a fold.

that the wires make. There will be N holes in the tissue. Figure 23–1a represents this situation in two dimensions, not three, with the holes on the two-dimensional circle. (You should, however, be thinking about this in three dimensions.) For purposes of illustration, we have also chosen to draw 12 field lines in this figure, i.e. we have supposed that $N = 12$, but this has no fundamental significance. Suppose now that the charge were not at the center of the sphere of tissue, but somewhere else within it (Fig. 23–1b). The number of holes would still be the same, even if they are clustered more on the part of the surface that is closer to the charge. If the tissue still formed a closed surface but no longer made a sphere (Fig. 23–1c), the number of holes would again be the same. Now imagine a fold in the closed surface of tissue, as in Fig. 23–1d. This time there would be more holes in the surface, $12 + 4$ in Fig. 23–1d. But two of the four extra holes are caused by a wire going *into* the surface, and if we keep track of holes made by wires going *into* the surface and assign a negative count to such holes then in Fig. 23–1d, the number of holes would be $12 - 2 + 2 = 12$, the same as in all the other cases. The distinction between going out of the closed surface and into the surface will be an important one. To summarize, what we have seen is that we can determine the charge Q by counting the net number of "holes" made by the "field lines" through a closed surface of any shape that surrounds the charge, including a minus sign for field lines going into the surface.

Using the fact that we count lines going into the surface from the outside with a minus sign, then we see that if the charge inside our closed surface were a negative one, $-Q$ instead of $+Q$, then the electric field lines will go toward the negative charge, and the number of holes in our tissue would be -12, the sign of the number of holes correctly accounting for the charge's sign. Without a distinction about whether the field lines were ingoing or outgoing, we cannot tell the sign of Q.

The situation we have described is the essence of Gauss' law: We count "holes" created by "wires"—by this we mean the passage of field lines through an imaginary closed surface that surrounds any charge or set of charges, with a rule that field lines going out of the surface make positive holes, and field lines going into the surface make negative holes. The net number of field lines that pass through the closed surface is a measure of the charge enclosed. The charge Q does not have to be a point charge. It can be an extended charge, the only proviso being that the imaginary surface must enclose all of the charge. This is really all there is to Gauss' law, which as we'll see in the next section expresses a relation between the charge contained within a closed surface and an appropriate generalization to the number of "holes" made in the surface by the electric field.

Drawing field lines and literally counting the passage of the lines through a surface is not a practical possibility, and we now need to provide a mathematical expression for this process. We will do this by replacing the idea of holes made by rigid wires with a calculation of what is known as the *flux* of electric field, or, more simply, electric flux.

Electric Flux

We'll stay for a moment with the idea of electric field lines as represented by rigid wires, but this time we'll consider a sheet of tissue that is not closed. Rather than the field of a point charge, consider the electric field due to an infinite plane of uniformly distributed charge. As we showed in Example 22–8, the field lines are uniformly distributed (let's say with N lines per unit area of the plane) and are perpendicular to the infinite sheet of charge (aligned with the field *direction* $\hat{E}$, where the hat indicates that this is a unit vector that specifies the direction, but not the size, of the electric field). Suppose we now somehow place a flat piece of tissue, area A, above the plane and parallel to it. The wires are perpendicular to the piece of tissue, and we'll take the charge density on the plane such that there will be NA holes in the tissue (Fig. 23–2a). Now, if instead of the tissue aligning parallel to the charge plane, we could make it appear in a tilted position (Fig. 23–2b), there would be fewer holes—think of fewer field line crossings—for the simple reason that the *perpendicular* area presented to the wires by the square of tissue is smaller. We can in fact give a mathematical description to the idea that our surface makes an angle to the sheet of charge by defining the *normal* to the surface. More precisely, the normal vector $\hat{n}$ will be a unit vector *perpendicular* to the surface. In Fig. 23–2b we draw it in the direction away from the sheet of charge. Suppose now $\hat{n}$ and $\vec{E}$ make an angle θ (Fig. 23–2b). Then you can see from the figure that the area presented to the wires coming from the surface is the

original area A multiplied by $\cos\theta$. A compact way of stating this is that the number of holes will be given by $NA\cos\theta = NA(\hat{n}\cdot\hat{E})$. When the tissue is aligned parallel to the plane, then $\hat{n}$ and $\vec{E}$ are parallel, and the expression for the number of holes—again, the number of field lines that cross the surface—reduces correctly to NA.

At this point, we can say that the number of field lines crossing the surface is proportional to the surface area, the orientation of the surface, and the field strength. The orientation factor is in the scalar product $\hat{n}\cdot\hat{E}$. The field strength factor is in the number of lines N, which you will recall is an arbitrary normalization of the field strength. We can take care of the factor N and remove any arbitrariness by replacing N with the magnitude of the field itself, E. Thus we replace the factor $(\hat{n}\cdot\hat{E})N$ with $\hat{n}\cdot\vec{E}$. Finally, the area A remains. But we have chosen in this discussion a large flat area—the flatness makes the normal the same. For a more general surface, there will be various curvatures, and the normal will vary from point to point. Thus, rather than A, we work with an area dA that is sufficiently tiny so that we can treat it as flat and there is no ambiguity in the value of $\vec{E}$ over it.

We have now found our equivalent to the number of holes through a piece of tissue of area dA: It is the **electric flux** $d\Phi$ through the area dA,

$$d\Phi \equiv (\hat{n}\cdot\vec{E})\,dA.$$

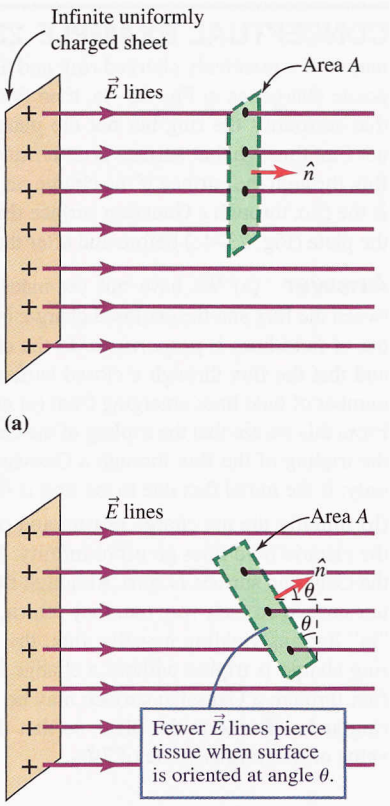
We have written this expression in differential form as a reminder that the area to which it refers is small; the field $\vec{E}$ is the field at the location of the surface element. Now just as the total number of holes in our tissue is the sum of the number of holes through the entire surface, we will want to define the electric flux Φ_S across a surface S as the sum over the fluxes through the elements that make it up:

$$\Phi_S = \int_S (\hat{n}\cdot\vec{E})\,dA. \tag{23–1}$$

Finally, we noted above that Gauss' law will concern *closed* surfaces. We indicate that the surface being summed over is closed with a circle on the integral sign,

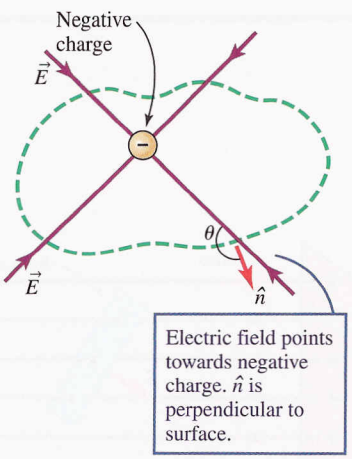
$$\Phi = \oint_S \hat{n}\cdot\vec{E}\,dA. \tag{23–2}$$

There is another item to deal with: For an open surface, it is not clear from which side of the surface the normal $\hat{n}$ points. In Fig. 23–2b we chose to draw it in one of two possible directions, but this choice was in no way compelled by anything in the situation; for an open surface, the direction of $\hat{n}$ is inherently ambiguous. For a closed surface, we can decide this in a completely unambiguous way: The direction of $\hat{n}$ is defined as pointing toward the *outside* of the closed surface. With this choice, the flux through a closed surface containing a positive charge is positive because $\vec{E}$ points outward as $\hat{n}$ does, and $\hat{n}\cdot\vec{E}$ is positive. For a negative charge, $\vec{E}$ points inward and $\hat{n}\cdot\vec{E}$ is negative (Fig. 23–3).



We simplify the notation by combining the magnitude of the infinitesimal area dA with the associated normal direction, writing $\hat{n}\,dA = d\vec{A}$. Thus

$$\Phi = \oint_S \vec{E}\cdot d\vec{A}. \tag{23–3}$$

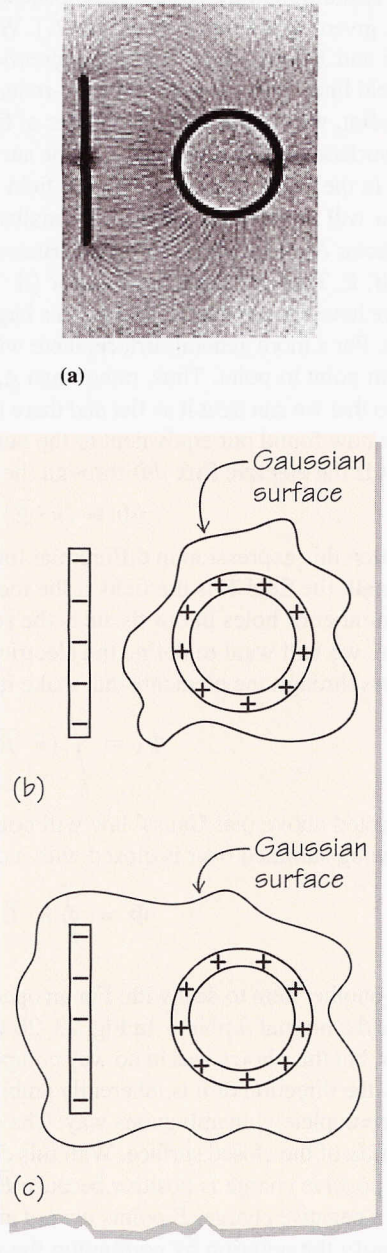


This, then, is the mathematical generalization of counting the number of field lines crossing a closed surface.

We have now established that when electric flux through a closed surface is not zero, there is a net charge within the surface. The surface, which can be picked at will just as long as it encloses the charge, is an imaginary construct generally known as a **Gaussian surface**. We are going to use such surfaces to help us calculate values for the electric field, and we shall see that surfaces that have a special symmetry in relation to the charge distribution are especially useful. For example, for spherically symmetric charge distributions, a concentric spherical Gaussian surface is particularly useful, and for charges uniformly distributed along a straight line, a Gaussian surface in the shape of a cylinder, with the line charge forming the axis, is useful.

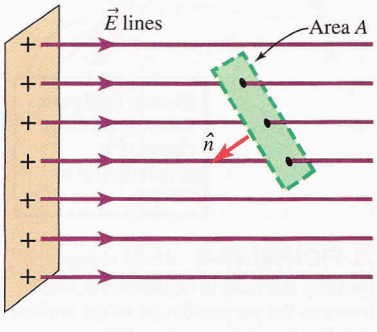
We note in passing that the use of the term *electric flux* comes from an analogy with the flow of water through a surface, a concept we met in Chapter 16, and an analogy between electric flux and the flux of water can be made.

▲ **FIGURE 23–2** A plane of area A is placed in a uniform electric field. In (a) the plane is aligned perpendicular to the field. (b) The perpendicular to the plane makes an angle θ with respect to the field.



▲ **FIGURE 23–3** If the charge forming the field is negative, the angle between the perpendicular to the surface and the field is larger than 90°.

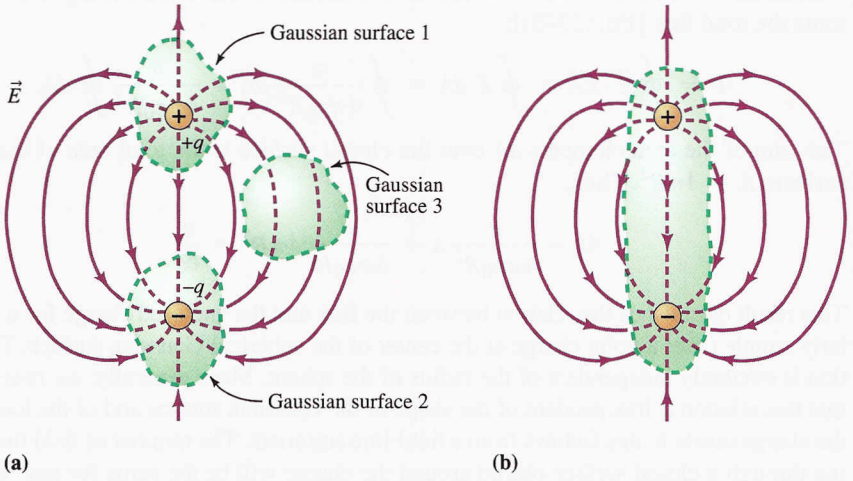
CONCEPTUAL EXAMPLE 23–1 Consider the combination of a positively charged ring and a plate with an equal and opposite charge, as in Fig. 23–4a, then think about a Gaussian surface that surrounds the ring but not the plate (Fig. 23–4b). Suppose the net flux through that surface is determined to be Φ_0. (a) What is the flux through the surface if the charge on the ring is tripled? (b) What is the flux through a Gaussian surface that encloses both the ring and the plate (Fig. 23–4c) before and after the tripling of the ring charge?



Answer (a) We have not yet made an explicit connection between the flux and the enclosed charge, but we do know that the number of field lines is *proportional* to the charge that gives rise to them and that the flux through a closed surface is also proportional to the number of field lines emerging from (or entering) the enclosed charge. From this we see that the tripling of the charge on the ring will result in the tripling of the flux through a Gaussian surface enclosing the ring only: If the initial flux due to the ring is Φ_0, the final flux is $3\Phi_0$.

(b) Initially the net charge of ring and plate is zero, so that none of the electric field lines go off to infinity. The total charge enclosed by the Gaussian surface is zero. Although field lines may cross a Gaussian surface on their way out, they return, and by our rule of counting "in" lines as yielding negative flux, the total flux is zero. When the ring charge is tripled without a change in the plate charge, the total flux through a Gaussian surface may be calculated as 3Φ due to the ring and $-\Phi$ due to the plate, so that the flux goes from an initial value of 0 to a final value of $2\Phi_0$.

▶ **FIGURE 23–4** (a) The electric field lines due to a charged conducting cylinder placed close to an oppositely charged conducting plate, as shown by threads in a shallow dish of oil. (b) A Gaussian surface surrounds the cylinder. (c) A Gaussian surface surrounds both the cylinder and the plate.



Let us look at a calculation of electric flux through an *open* surface, where there is an ambiguity: Whereas for a closed surface there is a clear distinction between a normal to the surface $\hat{n}$ pointing out and pointing in, for an open surface this is subject to definition. The choice, once made, must be consistently preserved throughout the calculation. To take an example, we can look again at the large uniformly charged plane, with a flat square surface of area A oriented as in Fig. 23–2b. With the unit vector oriented as in that figure and a positive charge on the plane, the factor $\vec{E} \cdot \hat{n}$ in the flux is $+E \cos\theta$. This is constant over the surface, so that the flux is just $(E \cos\theta)A$. On the other hand, if we had initially chosen the normal in the opposite direction, as in Fig. 23–5, then the sign of the flux would be reversed. For an open surface such as this planar one, there is no way to decide what the "right" direction for the normal is. For a closed surface, the use of the word "outside" is unambiguous, as is the choice of direction for the normal.

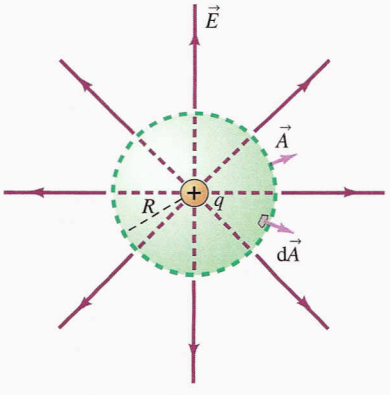
◀ **FIGURE 23–5** The perpendicular to an open Gaussian surface has an ambiguous orientation. Here we have placed it in the opposite direction to that chosen for Fig. 23–2b. This means the flux has an ambiguous sign for an open surface. This is not the case for a closed surface.

CONCEPTUAL EXAMPLE 23–2 You have a plane sheet of charge, infinite in extent, with a uniform positive charge density. You want to consider the flux through a flat, open surface. Are there circumstances in which the flux through the surface is zero?

Answer Yes. Aside from the possibility that the charge on the plane is zero, so that $E = 0$, the surface could be aligned so that the electric field is parallel to the surface. In other words, $\hat{n}$ is perpendicular to the direction of E, and therefore $\hat{n} \cdot \vec{E} = 0$.

◀ **FIGURE 23–6** (a) Three Gaussian surfaces (shown dashed to remind you that they are imaginary) in the electric field of a dipole. For surface 1, which surrounds the $+q$ charge, the electric flux is positive; for surface 2, which surrounds the $-q$ charge, the flux is negative; and for surface 3, which surrounds no charge, the flux is zero. (b) A Gaussian surface surrounding both charges. The flux through this surface is proportional to the net charge and is therefore zero.

23–2 Gauss' Law



Gauss' law describes the relation between a charge and the electric flux through a closed surface—a Gaussian surface—that surrounds that charge. To start, we can most easily show that the flux through a Gaussian surface is zero if no *net* charge is enclosed by the surface by using a field-line argument. No matter how many field lines we employ, it will be true that if the enclosed charge adds to zero, then as many field lines go back into the surface as leave it. This follows by virtue of the fact that outgoing lines contribute a positive sign and ingoing lines a negative sign. For example, Fig. 23–6 shows the electric field due to a dipole as described in Chapter 22. Imagine a series of Gaussian surfaces of any convenient shape placed wherever we choose. For example (Fig. 23–6a), if we place an imaginary Gaussian surface (surface 1) around charge $+Q$ of a dipole, all the electric field lines exit the Gaussian surface, and the total electric flux is positive. If we place a second Gaussian surface (surface 2) around charge $-Q$, all the electric field lines enter the Gaussian surface, and the electric flux is negative. Any Gaussian surface, such as surface 3, that surrounds *neither* charge has no net electric flux through it because the same number of electric field lines enter and exit such a surface. If the Gaussian surface surrounds *both* charges (Fig. 23–6b), then the number of field lines that enter and exit the surface is again equal, and the total flux is zero. We conclude that

The electric flux through a closed surface that encloses no net charge is zero.

To go further, we must find the relation between the electric flux Φ and the enclosed charge. We can do so by thinking about a point charge, then using superposition. Figure 23–7 shows an (imaginary) Gaussian sphere of radius R centered on a point charge q. The centered sphere is chosen because the electric field has constant magnitude at a fixed distance from a charge, and it will be easy to find the flux through the sphere. We use Eq. (23–3) to find the electric flux that passes through the Gaussian surface. The electric field due to a point charge q was found to be [Eq. (22–5)]

$$\vec{E} = \left(\frac{q}{4\pi\varepsilon_0 r^2}\right)\hat{r}.$$

The electric field points in the radial direction and is directed outward for positive q. Because the direction of the infinitesimal area $\hat{n} \cdot dA = d\vec{A}$ for a small area on the sphere also points outward in the radial direction, $\vec{E} \cdot d\vec{A} = E\, dA$. Because the electric

▲ **FIGURE 23–7** A simple choice for a Gaussian surface for a point charge q is a sphere of radius R.

field has the constant value $q/(4\pi\varepsilon_0 R^2)$ everywhere on our sphere, the infinitesimal electric flux through the infinitesimal area dA is

$$d\Phi = E\,dA = \frac{q}{4\pi\varepsilon_0 R^2}\,dA.$$

We can now move the field E (constant on the surface A) outside the integral that represents the total flux [Eq. (23–3)]:

$$\Phi = \oint \vec{E}\cdot d\vec{A} = \oint E\,dA = \oint \frac{q}{4\pi\varepsilon_0 R^2}\,dA = \frac{q}{4\pi\varepsilon_0 R^2}\oint dA.$$

The sum of the area elements dA over the closed surface is the total area of the closed surface, $A = 4\pi R^2$. Thus,

$$\Phi = \frac{q}{4\pi\varepsilon_0 R^2}A = \frac{q}{4\pi\varepsilon_0 R^2}4\pi R^2 = \frac{q}{\varepsilon_0}. \tag{23–4}$$

This result establishes the relation between the flux and the enclosed charge for a particularly simple case: a point charge at the center of the spherical Gaussian surface. The relation is evidently independent of the radius of the sphere. More generally, we have argued that this relation is independent of the shape of the Gaussian surface and of the location of the charge inside it; this follows from a field-line argument. The number of field lines passing through a closed surface placed around the charge will be the same for any form and any location as long as it encloses the charge. Then it must also be true that the electric flux through any Gaussian surface around the charge is the same for a surface of any form and any location as long as it encloses the charge, and *that value is given by Eq. (23–4).*

Using superposition, we can easily generalize Eq. (23–4) to the case of multiple point charges and then continuous charge distributions. Start with an assembly of point charges q_i that add up to a net charge Q. From the superposition principle, we know that the total electric field $\vec{E}$ is the sum of the fields $\vec{E}_i$, due to point charges q_i. The total flux Φ through a Gaussian surface S enclosing a net charge is the sum of the fluxes Φ_i due to the charges q_i:

$$\Phi = \sum_i \Phi_i = \oint_S \sum_i \vec{E}_i\cdot d\vec{A} = \frac{1}{\varepsilon_0}\sum_i q_i = \frac{Q}{\varepsilon_0}.$$

It is clear from the way we derived this result that it also holds for a continuous distribution of charge—the only difference is that the sum over point charges is replaced with an integral, but that integral remains the net charge Q.

The general statement of **Gauss' law** is therefore

$$\oint_S \vec{E}\cdot d\vec{A} = \frac{Q}{\varepsilon_0}. \tag{23–5}$$

GAUSS' LAW

The closed surface is *any* Gaussian surface that surrounds the *net* charge Q. The case in which the net charge is zero is included here—either because no charge whatsoever is enclosed by S or because there is an equal amount of positive and negative charge.

Coulomb's Law and Gauss' Law

In Chapter 22 we used Coulomb's law to determine the electric field of a point charge, and this in turn has led us to Gauss' law. Actually, the statement of Gauss' law is more general, and we may reverse the procedure to show that Gauss' law implies Coulomb's law. To do so, we center a Gaussian sphere on a point charge q (Fig. 23–7). The electric field $\vec{E}$ of the charge is assumed to be unknown. Gauss' law tells us only that the electric flux integrated over the surface of the sphere is q/ε_0. This is insufficient to determine the field, because the flux through any tiny surface element of the sphere depends on the value of the field in that region. We can, however, use a symmetry argument. There is no preferred direction for the field of a point charge. The only configuration of

field around a charge that does not favor some particular direction is a radial field. The surface element $d\vec{A}$ of a Gaussian sphere is also radial. Let's assume that $\vec{E}$ is parallel to $d\vec{A}$ at all locations (the other option is antiparallel). It then follows that

$$\vec{E} \cdot d\vec{A} = E\, dA.$$

Moreover, symmetry—that is, the absence of a preferred direction—also implies that $\vec{E}$ will have the same magnitude E everywhere on the centered sphere. We can then remove E from the integral that expresses the total flux through the sphere:

$$\oint \vec{E} \cdot d\vec{A} = \oint E\, dA = E \oint dA = EA = E(4\pi r^2) = \frac{q}{\varepsilon_0},$$

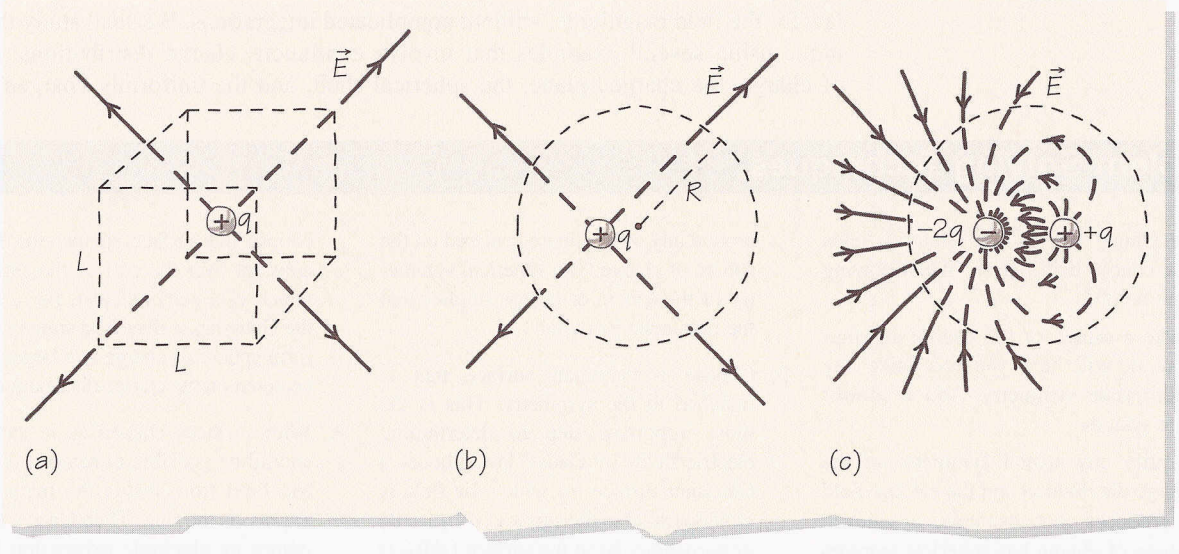
where r is the radius of the Gaussian sphere. The last term in this equality is just Gauss' law. The equation can be solved for the magnitude of the electric field:

$$E = \frac{q}{4\pi\varepsilon_0 r^2}.$$

This result is consistent with Eq. (22–5). Because E is positive, we correctly chose the direction of $\vec{E}$ to be radially outward for a positive charge. The symmetry of the situation tells us only that the electric field must be radial: either outward or inward. Gauss' law determines the orientation of $\vec{E}$ to be radially outward. Coulomb's law follows directly from our result for the electric field: We put another charge, q', in the electric field and use the relation $\vec{F} = q'\vec{E}$.

Gauss' law does not require us to use any particular surface. This has practical importance, because the flux through one surface may be much easier to calculate than the flux through another.

CONCEPTUAL EXAMPLE 23–3 Find the electric flux through the Gaussian surfaces in Fig. 23–8: (a) a cube of sides L that surrounds the point charge q; (b) a sphere of radius R that surrounds the charge q, which is off center; (c) a sphere of radius b that surrounds the charges $-2q$ and $+q$.



Answer We are asking for quantitative answers, yet this is in fact a conceptual example; this illustrates the power of Gauss' law. Although the expression for the flux looks as if it involves a formidable integral, Gauss' law tells us that it is just equal to the net charge inside the surface, divided by ε_0. We can therefore immediately answer the questions.

(a) We use Gauss' law here, rather than doing a direct integration of the electric field over the cube. The total electric flux is simply q/ε_0.

(b) It does not matter that the Gaussian sphere is off center. The total electric flux is still q/ε_0.

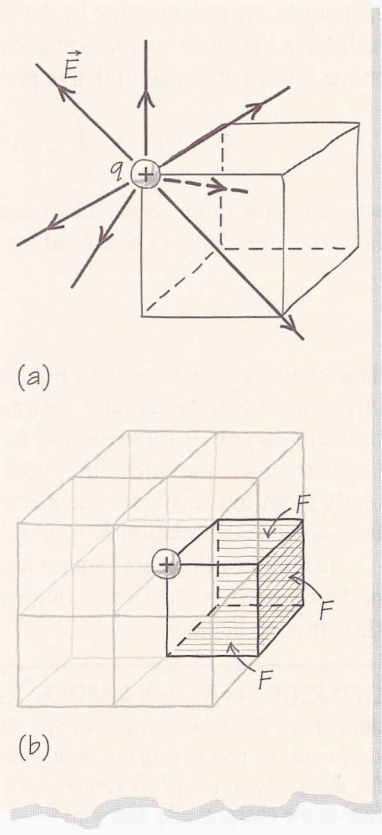
(c) The total net charge Q enclosed by the Gaussian surface is $-2q + q = -q$, and the total electric flux through the Gaussian surface is $-q/\varepsilon_0$. We do not need to concern ourselves with the positions of the two charges within the cube.

What Do You Think? Suppose the cube in Fig. 23–8a contained three more point charges of magnitude $2q$, $-7q$ and $4q$. What would the flux through the sides of the cube be? *Answers to **What Do You Think?** questions are given in the back of the book.*

▲ FIGURE 23–8

EXAMPLE 23–4 Consider a point charge $q = 1\ mC$ placed at a corner of a cube of sides 10 cm. Determine the electric flux through each face of the cube.

Setting It Up The situation is sketched in Fig. 23–9a.



Strategy We spoke about the utility of symmetry in solving problems with the help of Gauss' law. Here we'll use the symmetry of the situation, which involves the sides joining at the corner at which the charge resides. You can see from Fig. 23–9a that for these sides, $\vec{E} \cdot \hat{n} = 0$, since the normal is perpendicular to the surfaces while the electric field goes off in a spherically symmetric pattern and lies in the sides. In other words, the electric field that originates at the charge is tangential to the surface of these three sides. This means there is no flux through these sides. The electric flux through each of the remaining three faces of the cube must be equal by symmetry. We'll refer to these sides with the label F.

To find the flux through each of the sides F, we can use a technique that puts the single charge in the middle of a larger cube. It takes seven other similarly placed cubes to surround the point charge q completely (Fig. 23–9b). The charge is at the dead center of the new, larger cube, so the flux through each of the six sides of the large cube will now have an electric flux of one sixth of the total flux. The large sides of the cube consist of four smaller squares, one of which is in fact one of the sides F, so given that the total structure is completely symmetric, the flux through a side F is one fourth of the flux through the large side.

Working It Out The total flux is q/ε_0, so that the flux through each of the sides of the large cube is $q/6\varepsilon_0$, and one quarter of that, $q/24\varepsilon_0$, goes through each of the far sides of the small cube. Numerical evaluation gives

$$\Phi_F = \frac{q}{24\varepsilon_0} = \frac{1 \times 10^{-3}\ \text{C}}{24(8.85 \times 10^{-12}\ \text{C}^2/\text{N} \cdot \text{m}^2)} = 5 \times 10^6\ \text{N} \cdot \text{m}^2/\text{C}.$$

What Do You Think? Could you use this technique to determine the flux through each of the sides if a charge q were placed at each corner of the original cube?

▶ **FIGURE 23–9**
(a) A charge q is placed at the corner of a cube. (b) By surrounding the charge with a series of cubes such that the charge is at the center of a larger cube, we have created an arrangement sufficiently symmetric to be able to solve for desired flux values.

23–3 Using Gauss' Law to Determine Electric Fields

Gauss' law is a fundamental law in its own right. It is also a powerful tool for the determination of electric fields in situations where there is a high degree of symmetry. With enough symmetry the electric field will be constant over a simple surface, and this can then be removed from the integral that expresses the flux. We can then solve Gauss' law for the field magnitude, without complicated integrations. We shall study this technique using several examples that involve continuous charge distributions: the line of charge, the charged plane, the spherical shell, and the uniformly charged sphere.

Problem-Solving Techniques

To use Gauss' law to find electric fields given a charge distribution, the following steps are helpful:

1. Make a sketch of the charge distribution—it will help you recognize any appropriate symmetry. Add a coordinate system.
2. Identify any spatial symmetry of the charge distribution and the electric field it produces. For example, a uniform sphere of charge has spherical symmetry because it looks the same from all around any other sphere centered on the sphere of charge. The spherical symmetry of the sphere of charge implies that the field must be radial.
3. Choose a Gaussian surface that is matched to the symmetry. This is the most important step in determining electric fields by Gauss' law. Choose a Gaussian surface for which the field is either parallel to the surface ($d\Phi_E = 0$) or perpendicular to the surface ($d\Phi_E = E\,dA$) at various locations; further, choose the surface so that the field is constant over the part of the surface to which it is perpendicular. For example, the Gaussian surface best suited to a uniform sphere of charge is a larger sphere centered on the charge distribution.
4. With surfaces chosen as in step 3, it should be possible to remove the electric field from inside the integral that expresses the flux. Then Gauss' law becomes an algebraic expression for the magnitude of the field.

These cases were discussed in Chapter 22 and (for gravitation) in Chapter 12. We shall see that Gauss' law determines the fields briefly and simply. In Section 23–4 the real power of solution by Gauss' law is revealed when we discuss conductors and their electric fields, thereby learning about fields in situations that are entirely new.

In Examples 23–5 through 23–8, we use these techniques together with Gauss' law, Eq. (23–5), to determine the field. The method of solution that will be used in all of these examples involves adjusting the Gaussian surface to the charge distribution.

EXAMPLE 23–5 *Line of charge.* Determine the electric field due to an infinitely long, straight charged rod with positive, constant charge density λ.

Setting It Up Figure 23–10a illustrates the situation. We have oriented the rod along the z-axis.

Strategy To find the appropriate Gaussian surface, we want to see what symmetry tells us about the direction and magnitude of the electric field lines. These lines must leave the positively charged rod and, to be symmetric, the electric field lines must extend away from the rod radially in the xy-plane (Fig. 23–10b). The electric field lines cannot have a component along the z-direction (the direction along which the rod lies), because the symmetry prevents a choice between the $+z$- or $-z$-direction. Moreover, again by symmetry, the magnitude of the field must be the same on every point of a circle centered on the rod. Thus the field magnitude can depend only on the radial distance from the rod. The Gaussian surface that takes advantage of the symmetry is a closed cylinder whose axis coincides with the line charge. We choose it to be of radius r and height h (Fig. 23–10c). We apply Gauss' law for this surface and use the symmetry to extract the value of the field. Note that for application of Gauss' law we'll need to know that the total charge inside the cylinder is $q = \lambda h$, where λ is the charge per unit length.

Working It Out The flux through the cylinder is

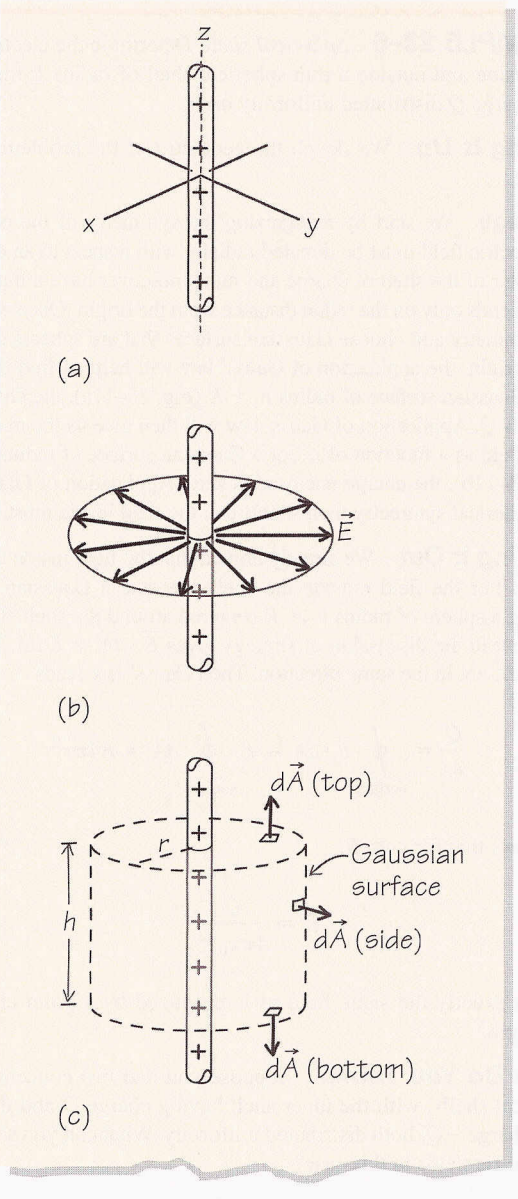
$$\Phi = \int_{\text{top surface}} \vec{E}\cdot d\vec{A} + \int_{\text{bottom surface}} \vec{E}\cdot d\vec{A} + \int_{\text{side surface}} \vec{E}\cdot d\vec{A}.$$

The flux through the top and bottom surfaces is zero. That is because the electric field is parallel to these surfaces, so the surface element $d\vec{A}$ is perpendicular to the field. As for the cylindrical side surface, the electric field is perpendicular to that surface, so that $\vec{E}\cdot d\vec{A} = E\,dA$. This expression must be integrated over the curved surface of the cylinder to find the flux through the side of the cylinder. But we have chosen the cylindrical surface so that the electric field has constant magnitude over the surface. The field magnitude can therefore be removed from the integral. Thus

$$\Phi = \int_{\text{side surface}} \vec{E}\cdot d\vec{A} = E\int_{\text{side surface}} dA = E(2\pi rh).$$

Here we use the fact that the surface area of the curved part of the cylinder is the circumference $2\pi r$ multiplied by the height.

The enclosed charge is λh, so Gauss' law reads



$$E(2\pi rh) = \frac{\lambda h}{\varepsilon_0},$$

or

$$E = \frac{\lambda}{2\pi\varepsilon_0 r}. \tag{23–6}$$

The arbitrary height h has canceled. In SI units, the charge density is in coulombs per meter. We can thus check that $\varepsilon_0 E$ has the units of coulombs per square meter. Compare the ease with which we obtained Eq. (23–6) with the direct integration technique [Eq. (22–31)].

What Do You Think? What can you say about the external field due to an infinitely long cylinder whose surface is uniformly charged?

▲ **FIGURE 23–10** (a) A line of charge is oriented along the z-axis. (b) By symmetry, the direction of the electric field $\vec{E}$ is radial in the xy-plane. (c) The best Gaussian surface to use to determine the electric field of a line charge is a cylinder. The directions of the areas $d\vec{A}$ for the various surfaces of the cylinder are shown.

THINK ABOUT THIS. . .

COULD WE USE GAUSS' LAW TO FIND THE FIELD OF A FINITE LINE OF CHARGE?

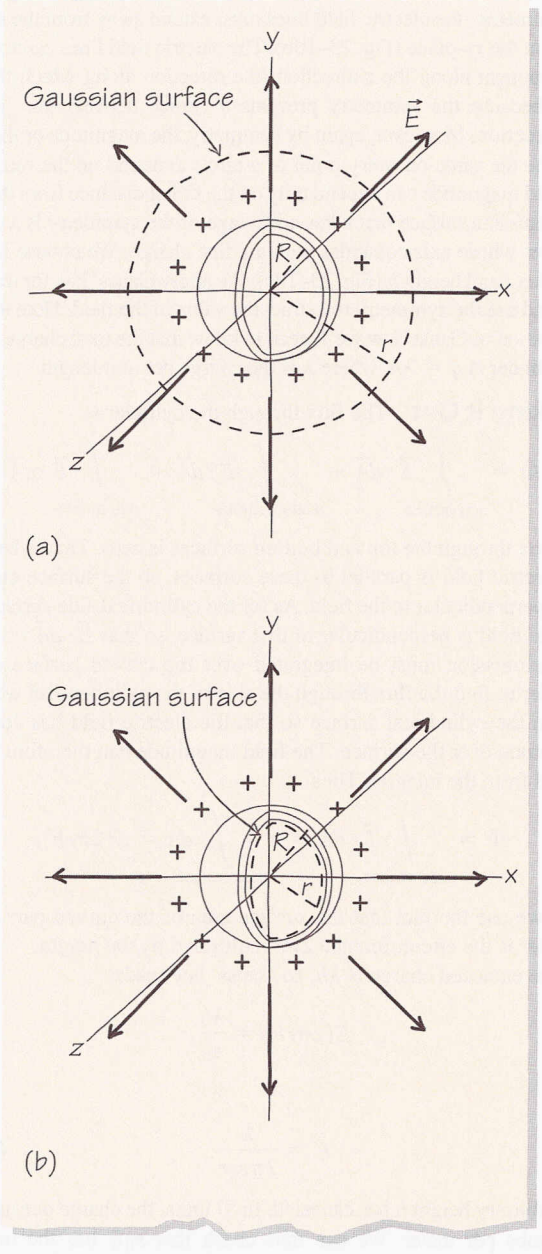
Gauss' law holds for *any* distribution of charge, but for a line of charge of finite length the symmetry that allows us to determine the direction of $\vec{E}$ and remove it from the flux integration is not present. If the ends of the line are in view, they provide a guide to tell us where we are along the wire—for example, we can look to see that we are close to one end or the other. The symmetry along the wire is lost. This loss of symmetry has two consequences: First, the electric field will have a component along the wire; and second, the magnitude of the field will vary *along* the line. In fact, from far enough away, a finite charged line is indistinguishable from a point charge, and the electric field will point in a direction normal to a Gaussian sphere centered on the line charge whose radius is much larger than the line length. Gauss' law is always true but not always useful.

EXAMPLE 23–6 *Spherical shell.* Determine the electric field both inside and outside a thin spherical shell of radius R that has a total charge Q distributed uniformly on it.

Setting It Up We sketch the geometry of the problem in Fig. 23–11a.

Strategy We start by recognizing the symmetry of the problem: Any electric field must be directed radially with respect to an origin at the center of the shell of charge and must moreover have a magnitude that depends only on the radial distance from the origin. Once we know this symmetry and choose Gaussian surfaces that are spheres centered at the origin, the application of Gauss' law will help us find the field. For a Gaussian surface of radius $r > R$ (Fig. 23–11a), the charge enclosed is Q. Application of Gauss' law will then give us the magnitude of the field as a function of r. For a Gaussian surface of radius $r < R$ (Fig. 23–11b), the charge enclosed is zero. Application of Gauss' law with spherical symmetry then shows that the field inside must be zero.

Working It Out We already argued that the field inside the shell is zero. For the field outside the shell, we take a Gaussian surface forming a sphere of radius $r > R$ centered around the shell. Then the argument in the discussion of strategy gives $\vec{E} \cdot d\vec{A} = E\, dA$, because $\vec{E}$ and $d\vec{A}$ are in the same direction. Then Gauss' law reads



$$\frac{Q}{\varepsilon_0} = \oint_{\text{surface}} \vec{E} \cdot d\vec{A} = E \oint_{\text{surface}} dA = E4\pi r^2. \qquad (23\text{–}7)$$

It follows that for $r \geq R$,

$$E = \frac{Q}{4\pi\varepsilon_0 r^2}. \qquad (23\text{–}8)$$

This is exactly the same field as is produced by a point charge at the origin.

What Do You Think? Suppose you had *two* concentric thin spherical shells, with the inner shell having charge Q and the outer shell charge $-Q$, both distributed uniformly. What can you say about the electric fields in this case?

▶ **FIGURE 23–11** (a) The best Gaussian surface to determine the electric field outside a uniformly charged spherical shell is a sphere, because the symmetry is spherical. (b) The best Gaussian surface to determine the electric field inside a uniformly charged spherical shell is a sphere inside the shell.

EXAMPLE 23–7 *Solid sphere.* Find the electric field outside and inside a solid, nonconducting sphere of radius R that contains a total charge Q uniformly distributed throughout its volume.

Setting It Up The charge distribution is sketched in Fig. 23–12a.

Strategy We again make use of the symmetry of the problem and take for our Gaussian surface a concentric sphere of radius r. By symmetry, the electric field is radial and uniform over the surface of the sphere, so that we can again use Gauss' law,

$$\frac{Q_{\text{enclosed}}}{\varepsilon_0} = \oint_{\text{sphere}} \vec{E}\cdot d\vec{A} = E \oint_{\text{sphere}} dA = E4\pi r^2.$$

Here, E is the field at a distance r from the center. The quantity Q_{enclosed} requires a little thought. In working it out, we note that if our Gaussian surface is outside the sphere (Fig. 23–12a), with $r > R$, the enclosed charge is the total charge. But if our Gaussian surface is inside the sphere (Fig. 23–12b), with $r < R$, we must *calculate* the charge included within the sphere of radius r, and this is done by using the fact that the charge density is given.

Working It Out We have for this case the general result

$$E = \frac{Q_{\text{enclosed}}}{4\pi\varepsilon_0 r^2}.$$

For the field *outside* the solid sphere, the charge enclosed by a Gaussian sphere at $r > R$ is just Q and, just as for the field for a point charge or for the region outside a spherical shell,

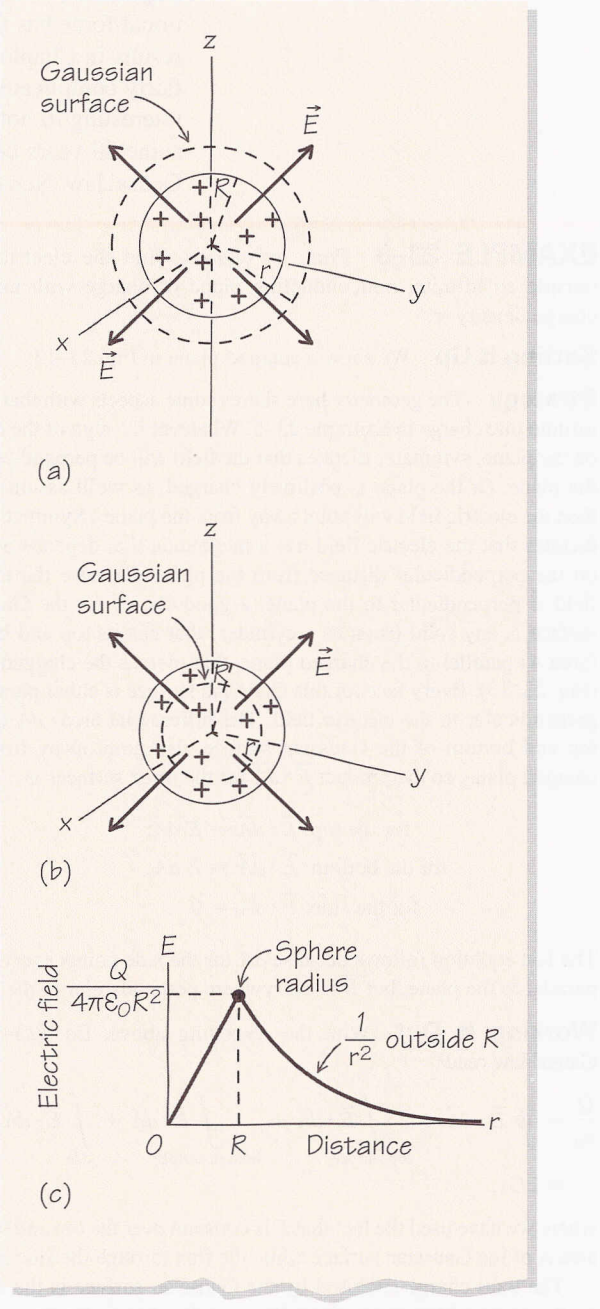
$$E = \frac{Q}{4\pi\varepsilon_0 r^2}. \tag{23–9}$$

Inside the solid sphere, however, the situation is different (Fig. 23–12b). The enclosed charge can be calculated in terms of the *uniform* charge density, which we denote by ρ:

$$Q_{\text{enclosed}} = (\text{volume of sphere}) \times \rho = \frac{4\pi r^3}{3}\rho.$$

The density is determined by the condition that the charge Q is uniformly distributed throughout a sphere of radius R. This means that

$$\rho = \frac{Q}{(\text{volume})} = \frac{Q}{(4\pi/3)R^3}.$$



Putting all this together, we get within the sphere

$$E = \frac{Q_{\text{enclosed}}}{4\pi\varepsilon_0 r^2} = \frac{1}{4\pi\varepsilon_0 r^2} \times \frac{4\pi r^3}{3}\rho = \frac{1}{4\pi\varepsilon_0 r^2} \times \frac{4\pi r^3}{3} \times \frac{Q}{(4\pi/3)R^3}$$

$$= \frac{Q}{4\pi\varepsilon_0}\frac{r}{R^3}. \tag{23–10}$$

The electric field due to a solid sphere has the radial dependence displayed in Fig. 23–12c. As symmetry demands, the field is zero at the center of the sphere. The field increases linearly with r up to the radius of the sphere and then decreases inversely as the square of r. The fields in Eqs. (23–9) and (23–10) match at the point $r = R$, as the field is continuous.

What Do You Think? Suppose a point negative charge $-q$ is inserted at rest inside the uniformly charged sphere, a distance r from the center. How do you expect it to move?

▲ **FIGURE 23–12** (a) The best Gaussian surface to determine the electric field outside a uniformly charged, nonconducting sphere is a concentric spherical surface. The symmetry is spherical. (b) The best Gaussian surface to determine the electric field inside a uniformly charged, nonconducting sphere is a Gaussian sphere inside the solid sphere. Only the charge inside the Gaussian sphere contributes to the electric field at r. (c) The electric field due to a uniformly charged, nonconducting sphere as a function of the distance from the center of the sphere.

From the two previous examples, we can draw the general conclusion that for a spherically symmetric charge distribution, the field at a radius r outside the charge distribution is that of a point charge at the center whose magnitude is the total charge within the sphere of radius r. We have seen that this is easy to prove by using Gauss' law. It holds not only for thin shells and solid spheres but indeed for *any* distribution of charge whose charge density varies only with the radius and is therefore spherically symmetric.

We noted in Chapter 12 that these same results hold for the force of gravity due to a spherical shell of matter. The mathematical problem is identical because the gravitational force has the same inverse-square form as the Coulomb force. We gave only the results in Chapter 12—without derivation—because the direct integration technique is fairly complicated. The Gauss' law derivation provided here is a very simple one. It is interesting to note that Newton delayed the publication of his theory of gravitation by some 20 years because of his lack of a simple proof of these results. If he had known Gauss' law, Newton would have saved a lot of time!

EXAMPLE 23–8 *Plane of charge.* Find the electric field outside an infinite, nonconducting plane of charge with uniform charge density σ.

Setting It Up We show a charged plane in Fig. 23–13.

Strategy The geometry here shares some aspects with that of the infinite line charge in Example 23–5. Whatever the sign of the charge on the plane, symmetry dictates that the field will be perpendicular to the plane. (If the plane is positively charged, as we'll assume here, then the electric field will point away from the plane.) Symmetry also dictates that the electric field has a magnitude that depends at most on the perpendicular distance from the plane. Because the electric field is perpendicular to the plane, a good choice for the Gaussian surface is any solid (such as a cylinder) that has its top and bottom (area A) parallel to the charged plane, that pierces the charged plane (Fig. 23–13). Every facet of this Gaussian surface is either parallel or perpendicular to the electric field. The differential areas $d\vec{A}$ for the top and bottom of the Gaussian surface also point away from the charged plane, so the product $\vec{E} \cdot d\vec{A}$ for the three surfaces is

$$\text{for the top: } \vec{E} \cdot d\vec{A} = E\, dA;$$
$$\text{for the bottom: } \vec{E} \cdot d\vec{A} = E\, dA;$$
$$\text{for the side: } \vec{E} \cdot d\vec{A} = 0.$$

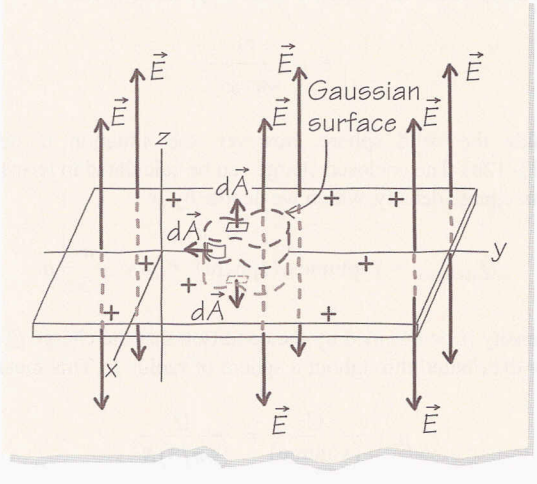
The last equation follows because $d\vec{A}$ for the side points everywhere parallel to the plane, but $\vec{E}$ is everywhere perpendicular to the plane.

Working It Out With the reasoning above, Eq. (23–5) for Gauss' law reads

$$\frac{Q}{\varepsilon_0} = \oint \vec{E} \cdot d\vec{A} = \underbrace{\int \vec{E} \cdot d\vec{A}}_{\text{top surface}} + \underbrace{\int \vec{E} \cdot d\vec{A}}_{\text{bottom surface}} + \underbrace{\int \vec{E} \cdot d\vec{A}}_{\text{side}}$$
$$= 2EA,$$

where we have used the fact that E is constant over the top and bottom area A of the Gaussian surface while the flux through the side is zero.

The total charge enclosed by the Gaussian surface is the charge on the plane within the surface. Because the charge density is σ and the area enclosed is A, we must have $Q = \sigma A$. The previous equation becomes



$$\frac{Q}{\varepsilon_0} = \frac{\sigma A}{\varepsilon_0} = 2EA,$$

from which we get the result

$$E = \frac{\sigma}{2\varepsilon_0}. \qquad (23\text{–}11)$$

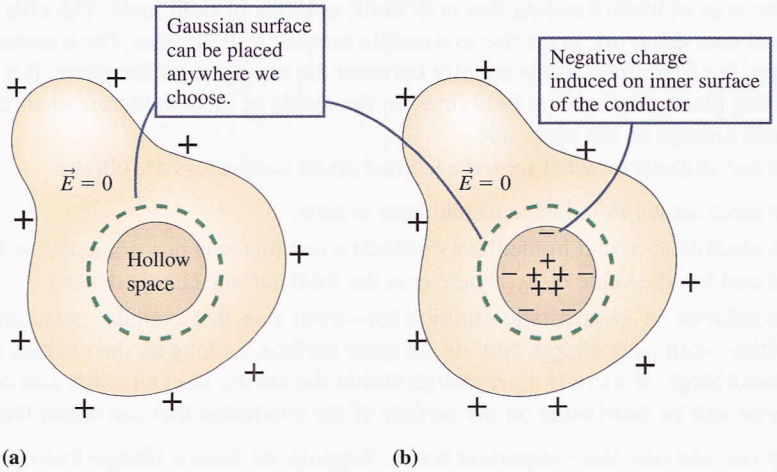
Equation (23–11) is the same result that we found with much more difficulty by direct integration in Chapter 22 [Eq. (22–33)]. Note that E is independent of the distance from the plane.

What Do You Think? Does your result tell you anything about the field outside a *finite* uniformly charged plane?

▲ **FIGURE 23–13** A convenient Gaussian surface for a uniformly charged infinite plane can be any shape whose sides are perpendicular to the plane and whose top and bottom are parallel to the plane.

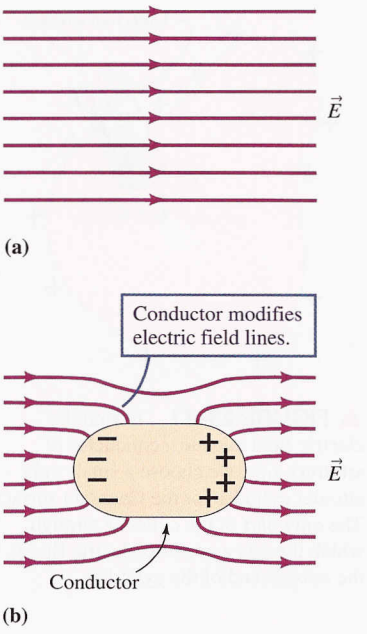
23–4 Conductors and Electric Fields

A good conductor, such as silver, copper, or aluminum, has a large number of "free" electrons, which can move within the (electrically neutral) material. Any electric field that may appear inside the metal due to the presence of an external electric field will cause these electrons to move. In less than a microsecond, they rearrange themselves into a configuration that cancels the electric field inside the material. If any field whatsoever remained inside the



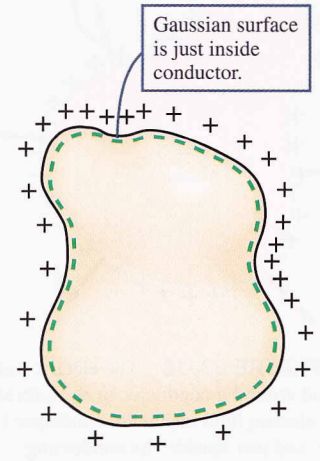
material, it would cause the electrons of the conductor to move until they reached equilibrium. *Conductors in electrostatic equilibrium have no internal static electric field.*

The mechanism for the field cancellation within conductors (think of metals) is illustrated in Fig. 23–14. A metal is placed in a spatially constant and static external field that points to the right (Fig. 23–14a). Some electrons in the metal move to the left side of the conductor, which leaves a deficiency of electrons on the right side of the conductor. The arrangement of excess electrons on the left and a deficiency of electrons on the right forms a new, internal electric field that points to the left. This internal field will precisely cancel the external field, with the result that there is no net field within the conductor (Fig. 23–14b).

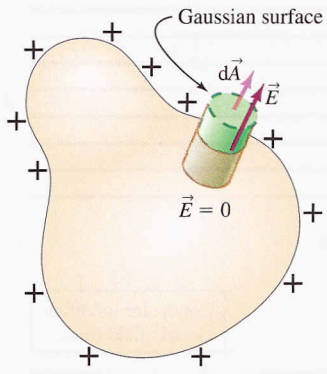


The fact that there are no static electric fields within conductors has implications for the behavior of conductors when charges are put on or near them, or when they are placed in external electric fields, and this behavior can be determined using Gauss' law. Let's consider what happens when an excess charge is added to a conductor. We might guess that because the components of this excess charge repel each other, and because they can move freely within the conductor, they move as far apart as possible. Figure 23–15 shows such a conductor as well as a Gaussian surface just inside the metal surface. If we apply Gauss' law to this surface, we find that because there is no field, there is no flux, and hence there is no net charge inside the metal. Where is the excess charge? *In electrostatic equilibrium, all excess charge is on the outside surface of a conductor.*

We can establish that the remark above is true even if our conductor has one or more cavities within it. Imagine such a cavity, filled with a nonconducting medium such as air or even a vacuum (Fig. 23–16a). Suppose that there is no excess charge within the cavity. Could charge accumulate on the surface of the cavity—an *interior* surface of the conductor? A Gaussian surface surrounding the cavity, but drawn within the conductor, has no electric flux through it because there is no static field within any conductor. Thus there is no net charge within that Gaussian surface. We have thereby shown that there can be no net charge on the interior surface of the conductor. *Any excess charge placed on a conductor, even if the conductor contains nonconducting cavities, moves to the outside surface of the conductor*, provided there is no charge within the nonconducting cavities.



We must modify our reasoning when there is charge within nonconducting cavities in the conductor. Suppose that such a cavity contains a charge $+Q$ (Fig. 23–16b). Again, draw a Gaussian surface within the metal to surround the cavity. Because there is no field inside the metal, the net charge enclosed must be zero. In this case, a charge of $-Q$ will be induced on the *inner* surface of the metal, that is, on the cavity surface. This induced negative charge keeps the electric field zero *inside the conductor*.

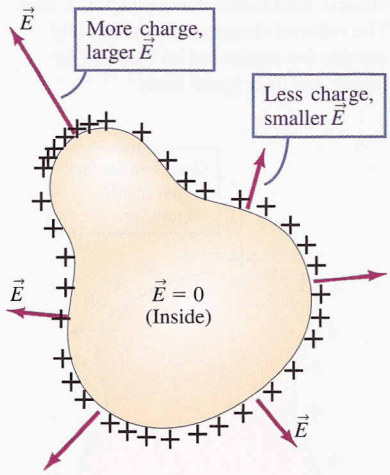


▲ **FIGURE 23–16** (a) A nonconducting cavity inside a conductor; the cavity contains no charge. Any net charge on the conductor must be on the outer surface of the conductor. (b) If we place a charge inside the hollow space, an induced charge will appear on the inside surface of the conductor, such that the electric field within the conducting material is zero. A Gaussian surface drawn just outside the cavity illustrates these results.

▲ **FIGURE 23–14** An uncharged conductor in an external electric field. (a) The electric field before a conductor is introduced. (b) Charges are induced on the surface of the conductor such that the electric field inside the conductor is zero. The induced charges modify the field outside the conductor, so the field no longer has its original form.

▲ **FIGURE 23–15** To find where excess charge placed on a conductor of arbitrary size and shape goes, choose a Gaussian surface just inside the surface. There is no field within the conductor, hence no flux through our surface, so all the excess charge is on the outside surface of the conductor.

▲ **FIGURE 23–17** To find the electric field outside a conductor of arbitrary size, we choose a small right circular cylinder for the Gaussian surface. The only part of the cylinder through which there is a nonzero electric flux is the outside end of the cylinder.



Electrostatic Fields Near Conductors

We can draw two important conclusions about electrostatic fields around metals or other conductors from this discussion. First, *the electric field immediately outside a conductor must be perpendicular to the conductor's surface.* If there were a parallel component, then there would be a force on charges resting on the surface; the charges would react and move along the surface and we would not have the static situation we assumed. The charges would readjust themselves until there was no parallel component. Second, by using Gauss' law, we can find the value of this perpendicular electric field at a point near the surface in terms of the charge density at that point on the surface. Consider the conductor shown in Fig. 23–17, with a tiny Gaussian surface whose side is perpendicular and whose top is parallel to the conductor's surface. We take the Gaussian surface small enough so that the surface charge density σ is constant within it, even though σ may vary over the conductor. We refer to σ only at the point where the Gaussian surface is erected. The electric field is zero inside the metal surface and outside it is parallel to the side of the Gaussian surface. Thus, the only contribution to the flux comes from the top of the Gaussian surface. If the Gaussian surface is small enough, $\vec{E}$, which is perpendicular to the top surface, can be regarded as constant over it, and

$$\frac{Q}{\varepsilon_0} = \oint \vec{E} \cdot d\vec{A} = EA,$$

where A is the area of the top of the Gaussian surface. The total charge Q enclosed by the Gaussian surface is σA, so that in the previous equation we set $Q = \sigma A$. We see that the area cancels and we get, *just outside the surface*,

$$\vec{E} = \frac{\sigma}{\varepsilon_0}. \tag{23–12}$$

▲ **FIGURE 23–18** The electric field in and around a conductor in equilibrium. The electric field inside the conductor is zero, and just outside the conducting surface it must be perpendicular to the surface. The magnitude of the electric field varies according to the surface charge density σ, which may not be constant everywhere on the surface.

From the way we found it, we see that this result holds only near the conductor's surface. The magnitude of the field will vary around the surface of the conductor as σ does, and the field direction will always be perpendicular to the conductor near its surface (Fig. 23–18). Whether this result is useful or not depends on whether we know the charge density. We can check our result by considering a conductor that is a sphere of radius R and total charge Q. In this case, symmetry demands that the charge is spread evenly over the surface, and

$$\sigma = \frac{Q}{\text{area}} = \frac{Q}{4\pi R^2}.$$

For the field just outside the sphere, Eq. (23–12) would then give $E = Q/4\pi\varepsilon_0 R^2$, which agrees with our earlier result, Eq. (23–9).

The field just outside a conductor ($E = \sigma/\varepsilon_0$) is twice as large as the field of a nonconducting charged plane with the same charge density ($E = \sigma/2\varepsilon_0$), Eq. (23–11). A simple way of understanding this is to think in terms of field lines. The charge on a surface of area dA, $\sigma\, dA$, gives rise to a certain number of field lines. For a nonconducting plane, the field lines divide equally between the two sides of the plane. For a thick conducting plane, there are no field lines on the inside of the conductor, so all the field lines must emerge on the open side.

We can summarize what we have learned about conductors as follows:

1. The electrostatic field inside a conductor is zero.
2. The electrostatic field immediately outside a conductor is perpendicular to the surface and has the value σ/ε_0, where σ is the local surface charge density.
3. A conductor in electrostatic equilibrium—even one that contains nonconducting cavities—can have charge only on its outer surface, as long as the cavities contain no net charge. If there is a net charge within the cavity, then an equal and opposite charge will be distributed on the surface of the conductor that surrounds the cavity.

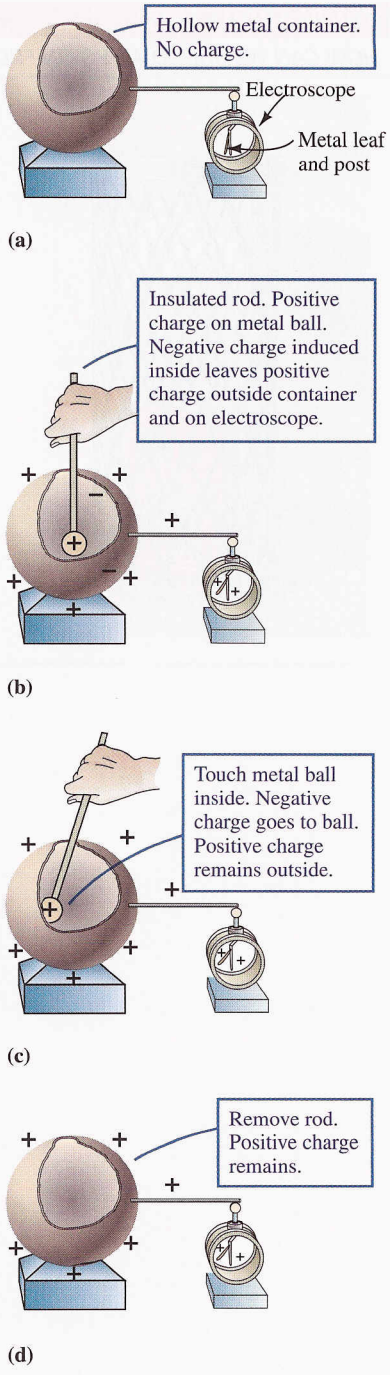
We can add one more important result. Suppose we have a charge-free cavity in a metal. We know that there is no field within the metal and, moreover, no *net* charge on the inner surface of the metal surrounding the cavity. But even for nonsymmetric situations, it can be shown that as long as there is no charge within the cavity, *the electric field is zero everywhere within the cavity.*

We'll discuss fields around conductors further in Chapter 24.

23–5 Are Gauss' and Coulomb's Laws Correct?

It is one of the characteristics of science to be eternally skeptical of yesterday's experiment. It is not so much that yesterday's experiment is wrong, although that certainly can happen; rather, a more accurate experiment can be done with more modern apparatus.

The equivalence of Gauss' and Coulomb's law makes it clear that testing one tests the other. Gauss' law is one of the cornerstones of our understanding of electricity and magnetism, and we must therefore ask just how well it is known and how it can be tested as precisely as possible. Many such tests rely on measurements of the $1/r^2$ behavior of Coulomb's law—you will recall that the equivalence of the two laws rests on this precise dependence. In this way, the errors implicit in measurements of Coulomb's law set limits on our knowledge of Gauss' law; these limits have been continually improved up to the present time. There are also more direct ways to look at Gauss' law, and we'll study a particularly sensitive technique for testing Gauss' law in this section.



Testing Gauss' Law with a Null Experiment

In 1773 Henry Cavendish, who you will recall from Chapter 12 measured the gravitational constant, made an early test of what later became known as Gauss' law. He placed one conducting sphere inside another and connected the two by a wire. After placing a charge on the apparatus, he disconnected the wire and looked for any charge that remained on the inner sphere. To the accuracy of his experiment, he found none. Cavendish's experiment now goes under the general name of the *Faraday "ice-pail" experiment*, after Michael Faraday, who presumably literally used an ice pail (as a conducting container) in a version of the experiment that he performed. This experiment is the basis for many of the modern high-precision tests of Gauss' law and—because Gauss' law is equivalent to Coulomb's law—of Coulomb's law.

For a simple version of the Faraday ice-pail experiment we require an electroscope (the free-charge detector introduced in Chapter 21). We also need a hollow metal container with a hole in the top, as in Fig. 23–19a, and a small metal ball on the end of an insulated rod that can be used to introduce charge to the inside of the container. The electroscope is attached to the outside of the container and thus indicates whether there is charge on the outside.

Next a positive charge, $+Q$, is placed on the small metal ball, and the ball is inserted through the small hole into the hollow container without touching it (Fig. 23–19b). Gauss' law states that there is no net charge *inside* the nearly closed metal container; therefore, a charge of $-Q$ is induced on the inside surface of the container. (The hole can be made smaller and smaller until its presence does not matter.) Because the metal container is neutral, a charge of $+Q$ must then be induced on its outside surface, and the electroscope indicates this charge. If the ball is moved around, there is no change whatsoever in the electroscope, consistent with Gauss' law—it makes no difference where in the cavity the charge is. The metal ball is subsequently touched to the interior of the hollow container (Fig. 23–19c). If Gauss' law is correct, the charge on the ball neutralizes the $-Q$ charge induced on the inside surface, leaving the $+Q$ charge on the outside surface. The electroscope indicates this result by not changing at all. When the metal ball is removed from the container, the container's outer surface remains charged (Fig. 23–19d). By touching the metal ball to another electroscope, we can verify that it carries no charge.

The description of this experiment shows why it is potentially so precise: If Gauss' law is correct, there is *no change* in the position of the gold leaf when the inner surface is touched. Equivalently, Cavendish's experiment tests for the *absence* of charge on the inner of two spheres. Experiments such as Coulomb's, the ones that try to measure departures from a $1/r^2$ fall-off of the force between two charges, look for small changes in comparison with larger effects. Such experiments are inherently less precise than experiments such as Cavendish's, which look for small changes in comparison with *no* effect. Experiments that test for small change versus no change are called **null experiments**. It is far easier to make a precise test of Gauss' law than of Coulomb's law because a null experiment can be done.

▲ **FIGURE 23–19** An electroscope is attached to the outside surface of a hollow conducting sphere to show the presence of charge. (a) No charge is present, and the gold leaf hangs down. (b) A charged metal ball on the end of an insulated rod is placed inside the sphere, and charge is induced. (c) If the metal ball touches the inside surface of the hollow conductor, all the charge passes to the outside surface. The electroscope's gold leaf indicates no change in the charge on the outside of the hollow conductor. (d) When the insulated metal ball is removed, the charge remains on the outside of the hollow conducting sphere, with no charge remaining on the metal ball.

THINK ABOUT THIS. . .

HOW CAN WE SHIELD A REGION FROM ALL ELECTRIC FIELDS?

Shielded regions or rooms in laboratories are often necessary so that electronic measurements are unaffected by outside electrical interference (Fig. 23–20). Such shielded rooms, known as *Faraday cages* and formed by enclosing a region with copper screens or sheets, rely on the fact that there are no electric fields within charge-free cavities. The enclosure is simply a cavity within a metal—in this case the conducting material is the copper that forms the screens. As long as there is no net charge inside of the enclosure, there is no electric field within it due to any external effects. If there were a net charge inside, charge would be induced on the inside of the copper screens, forcing the electric field in the copper to be zero, and there would be an electric field inside the enclosure.

Faraday cages occur beyond the laboratory. The interior of your car is a safe place in the event of nearby lightning, as any charge on the vehicle will go to the metal outer surface, but for the same reason, your car radio does not work as well when the car is located within the "cage" formed by a metal bridge.

◀ **FIGURE 23–20** By Gauss' law, there is no static electric field in an empty cavity in a metal. To the extent that this radio receives signals with only relatively slowly varying electric fields, it will not work very well within its cage. (*Copyright Jim Krider/Arizona State University.*)

*Coulomb's Law Holds over Small and Large Distances

Table 23–1 gives a summary of the accuracy to which Coulomb's law is known through experiments of the ice-pail type. It is characterized by expressing a *deviation* from Coulomb's law in the form

$$F \propto \frac{1}{r^{2\pm\delta}}.$$

When $\delta = 0$, the inverse-square law is exact; the smaller the limit on δ, the closer the law is known to be an inverse-square law. Table 23–1 expresses what is known experimentally about the possible value of δ. The limits on δ that are placed by the most recent experiments are astonishing.

TABLE 23–1 • Experimental Measurements of Deviation from an Inverse-Square Force Law†: Force $\propto 1/r^{2\pm\delta}$

Investigators	Date	Maximum δ
Robison	1769	0.06
Cavendish	1773	0.02
Coulomb	1785	0.10
Maxwell	1873	5×10^{-5}
Plimpton and Lawton	1936	2×10^{-9}
Williams, Faller, and Hill	1971	3×10^{-16}

†For more information on this subject, see A. S. Goldhaber and M. M. Nieto, "The Mass of the Photon," *Scientific American*, p. 86, May 1976.

This is not the end of the story, however. First, the experiments that we have listed in Table 23–1 test the laws only over a distance of about 1 m. Yet the laws of electrodynamics are supposed to hold in atomic systems and over galactic distances. Second, other evidence about the framework of the laws of physics suggests strongly that *a deviation from Coulomb's law of the form* $1/r^{2+\delta}$ *is not possible*. Instead, a way

to characterize a deviation from Coulomb's law is with the *approximate* form

$$F \propto \frac{e^{-\mu r}}{r^2},$$

where e is the exponential constant 2.78... and μ is a constant. If Coulomb's law is correct, the parameter $\mu = 0$. The exponential function decreases with r over a distance that depends on μ. The larger μ is, the faster the exponential decreases, and the larger the violation of Coulomb's law. Any violation is, we now know, more properly expressed by limits on μ. We can determine limits on μ, and hence tests of the accuracy of Coulomb's law, from the previously reported experiments. The experiment of Williams, Faller, and Hill, for example, implies that μ is smaller than 6×10^{-8} m^{-1}. These limits can be extended by observing the space dependence of Earth's magnetic field and also of Jupiter's magnetic field, as measured by the spacecraft *Pioneer 10*. Although we have not yet studied magnetism, we can say that the limits on μ found thereby are indeed those associated with Gauss' law. In addition to being direct, the planetary measurements give values of μ that are smaller by an order of magnitude or more than those given by the laboratory experiments; they have the further advantage of testing Gauss' law out to large distances.

Finally, how well do we know Gauss' law at short distances? The colors of light given off by excited hydrogen atoms are very sensitive indicators of the Coulomb force at distances on the atomic scale, about 10^{-10} m. The accuracy with which Gauss' (and therefore Coulomb's) law is known is comparable to the accuracy of the experiments of Plimpton and Lawton (see Table 23–1); that is, to about one part in 1 billion. Even down to nuclear distances—about 10^{-15} m—experiments indicate consistency with the basic theory that leads to Coulomb's law.

Summary

The electric flux due to the electric field $\vec{E}$ that intersects a surface S is

$$\Phi_S = \int_S (\hat{n} \cdot \vec{E})\, dA \qquad (23\text{–}1)$$

where we must find the normal to the surface at each point to carry out the integration. Gauss' law relates the electric flux through a Gaussian surface—an imaginary *closed* surface—to the total charge enclosed by the surface, Q:

$$\oint_S \vec{E} \cdot d\vec{A} = \frac{Q}{\varepsilon_0}. \qquad (23\text{–}5)$$

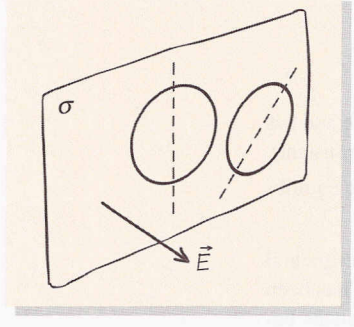
Gauss' law is equivalent to Coulomb's law for static situations; it is indeed one of the fundamental equations of electromagnetism.

Gauss' law is a powerful tool for determining electric fields due to charge distributions with a high degree of symmetry. It can be used to derive in simple fashion the electric fields due to a straight-line charge or due to a conducting plane. For a general spherically symmetric charge distribution centered at the origin of a coordinate system, Gauss' law gives a simple derivation of the field at a distance r from the origin. If q is the total charge contained within a Gaussian sphere of radius r, then the electric field at r is the same as that of the field of a point charge q at the origin, $E = q/(4\pi\varepsilon_0 r^2)$.

Using Gauss' laws, we learned that conductors have the following properties:

1. The electrostatic field inside a conductor is zero.
2. The electrostatic field immediately outside a conductor is perpendicular to the surface and has the value σ/ε_0, where σ is the local surface charge density (which is not necessarily constant).
3. If there are no nonconducting cavities containing charge, a conductor in electrostatic equilibrium can have charge only on its outer surface.

Gauss' law (and its equivalent, Coulomb's law) has been subjected to many experimental tests since the mid-eighteenth century. The inverse-square law dependence on distance has been verified to a precision that ranges from one part in 10^9 to one part in 10^{16} over distances between 10^{-10} m and 10^9 m.



Understanding the Concepts

1. A temperature field is defined when the temperature of every point of a region of space is specified. Is it possible to compute a flux associated with this field?
2. In the text we refer to the Faraday ice-pail experiment and discuss one version of it in detail. The discussion concerns a sphere with a hole cut in it, and we speak of the inside and outside of this open sphere (Fig. 23–19). Yet an open sphere does not have a clear inside and outside because, unlike a closed, hollow sphere, it can be deformed continuously to a plane. Why is it possible to talk of the inside and outside of an open sphere, and why does the open sphere behave like a closed, hollow sphere (a cavity) in the experiment?
3. Consider a surface enclosing no electric flux. Discuss whether the electric field is zero everywhere on the surface.
4. Use Gauss' law to show that electric field lines must be continuous and must originate from and end on charges.
5. Describe the way in which Gauss' law would fail if the field of a point charge were to decrease as $1/r$ rather than as $1/r^2$.
6. Suppose the charge in Example 23–4 were located in the middle of the face of a cube. What symmetric arrangement would you set up, if any, to calculate the flux through the remaining sides of the cube?
7. If a large, thin, flat plate is positively charged, the field extends in both directions from the plate and has a magnitude of $\sigma/2\varepsilon_0$. If a second plate of equal but opposite charge is placed parallel to the first plate, the field around the first plate extends only toward the second plate and has a magnitude of σ/ε_0, where σ is exactly the same as before. How do you reconcile this second case with Gauss' law?
8. Consider an electric field $\vec{E}$ that is zero at every point on a closed surface S. Does this mean that there are no charges within this surface? Give an example for which there are charges inside a surface while $\vec{E} = 0$ on the surface.
9. What is the force on a charge Q that is just inside a shell of uniformly distributed charge?
10. Analyze Gauss' law as it applies to the flow of fluids. How would you formulate it? Suppose that in a certain region there are no sources of fluid, only sinks. What would you learn from Gauss' law? How does the possibility of evaporation of a fluid affect Gauss' law? What would be its counterpart in the electric Gauss' law?
11. You are sitting in your spaceship, inside an interior cubicle made entirely of aluminum. Your arch enemy shoots a trillion coulombs of charge at you with his coulomb gun. Do you survive?
12. What would Gauss' law look like for the gravitational field, which is defined by force/unit mass of a test body?
13. Charge is distributed uniformly on a wire forming a circle that is surrounded by a torus (doughnut) for which the wire serves as an axis. Does the symmetry allow us to say anything about the electric field due to the charge on the circular wire?
14. A positive point charge and a negative point charge of equal magnitude are fixed on the surface of a conductor of arbitrary shape. What, if anything, can be said about the resulting electric field lines?
15. A region in space has a uniform electric field. What can we say about whether or not any charges are inside the region?
16. You have a charge at the origin of some coordinate system, and a hemispherical surface whose center of curvature is located at the origin. The charge is tripled. How does the flux through the hemispherical surface change?
17. To derive the electric field of an infinitely long line of charge, we used a Gaussian surface in the form of a right cylinder centered on the line. Why does the use of such a surface not allow us to find the field of a line of charge of *finite* length?
18. What would be the flux if both the charge and the length of the sides were doubled in Example 23–4?
19. Suppose that the electric field in some region is known to have only x- and y-components and that the components depend only on x and y, not on z. What can you deduce about the charge distribution that gives rise to this field?
20. You have a probe that measures the electric field at any point in space. For a region in which you know independently that the charge density is constant, how can you use the probe to measure that charge density?
21. Would the result of Example 23–6, which finds the field of a thin spherical shell of uniformly distributed charge, be the same if the distribution of charge weren't spherically symmetric?

Problems

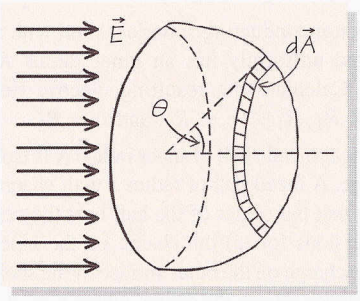
23–1 What Does Gauss' Law Do?

1. (I) An infinitely large, nonconducting, thin plate carries a uniform charge density σ. (a) What is the electric flux through a circle of radius R placed parallel to the plane? (b) What is the flux through that circle if the plane of the circle is tilted at a 30° angle with respect to its original orientation (Fig. 23–21)?

▲ FIGURE 23–21 Problem 1.

2. (I) A region of space contains a constant electric field of magnitude 1325 N/C. A wire frame forming a square 0.27 m on a side is placed in the region, oriented so that the perpendicular to the plane of the square makes an angle of 48° with the field. What is the magnitude of the electric flux through the frame?

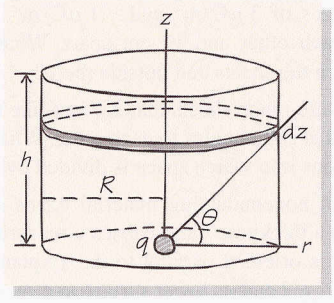
3. (I) The electric field due to an infinitely long, straight line of charge with uniform charge density λ points straight away from the line and has magnitude $E = \lambda/(2\pi\varepsilon_0 r)$, where r is the distance from the wire. Calculate the flux of this electric field through a right cylinder of height h and radius R, concentric with the charged line. Repeat the calculation for a cylinder of radius $2R$.



4. (I) The electric field in a certain region of space points in the z-direction and has magnitude $E = 5xz$, where x and z are measured from some origin. Calculate the flux of that field through a square perpendicular to the z-axis; the corners of the square are at $(x, y, z) = (-1, -1, 1)$, $(-1, 2, 1)$, $(2, 2, 1)$, and $(2, -1, 1)$. (All fields are measured in N/C, all distances in m.)

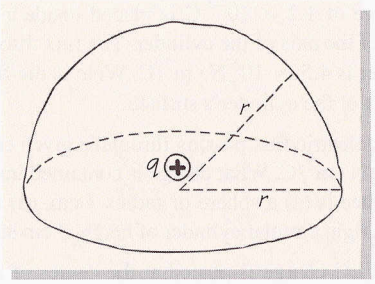
5. (I) An electric field has the components $E_x = 5x$, $E_y = -3y$, and $E_z = 4z$. Calculate the electric flux through the sides of a unit cube, whose corners are $(x, y, z) = (0, 0, 0)$, $(1, 0, 0)$, $(1, 1, 0)$, $(0, 1, 0)$, $(0, 0, 1)$, $(1, 0, 1)$, $(1, 1, 1)$, and $(0, 1, 1)$. (All fields are measured in N/C, all distances in m.)

6. (I) An electric field of 150 N/C points in the x-direction. A wire loop that is 4 cm^2 in area is placed so that its plane is perpendicular to the x-axis. (a) What is the electric flux through the loop? (b) If the loop is rotated about the y-axis so that the normal to the loop makes an angle of 25° with the x-axis, what is the flux through the loop now? (c) How does the flux change if the angle is increased to 335°?



7. (II) An electric field that is constant in direction is perpendicular to the plane of a circle of radius R. This electric field has a magnitude of $E_0(1 - r/R)$ at a distance r from the center of the circle. Calculate the electric flux through the plane of the circle.

8. (II) By direct calculation (that is, without using Gauss' law), find the flux of a constant electric field $\vec{E}$ through a hemispherical surface of radius R whose circular base is perpendicular to the direction of the field. Your result should be the same as the flux through the top surface of a cylinder whose circular base, of radius R, is oriented perpendicular to the field direction (Fig. 23–22). [*Hint*: The area of an infinitesimal strip at a latitude θ and a thickness $R\,d\theta$ is $2\pi R^2 \sin\theta\,d\theta$; θ varies from 0 at the North Pole to $\pi/2$ at the equator.]

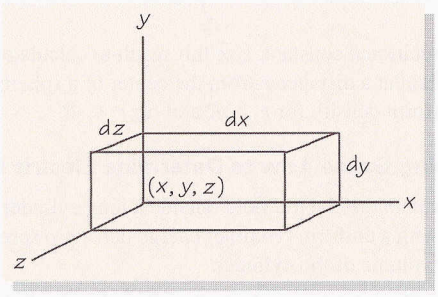


▲ **FIGURE 23–22** Problem 8.

9. (II) A point charge q is placed in the middle of a cylindrical surface of radius R, height $2h$. Find the electric flux through the surface by direct integration. [*Hint*: Use the angle θ in Fig. 23–23 as your variable of integration. Only the upper half of the cylinder is shown in the figure.]

▲ **FIGURE 23–23** Problem 9.

10. (II) A charge q is placed just above the center of a horizontal circle of radius r, and a hemisphere of this radius is erected about the charge. Compute the electric flux through the closed surface that consists of the hemisphere and the planar circle (Fig. 23–24). Do not use Gauss' law.



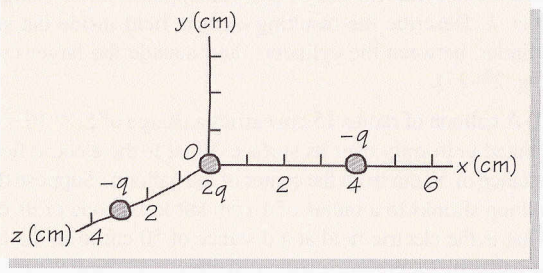
▲ **FIGURE 23–24** Problem 10.

11. (III) Consider an infinitesimal parallelepiped located at the point (x, y, z) with sides dx, dy, and dz along the x-, y-, and z-axes (Fig. 23–25). Show that the electric flux of the electric field given by $\vec{E} = E_x\hat{i} + E_y\hat{j} + E_z\hat{k}$ through the surface that bounds this volume is given by

$$\Phi = \left(\frac{\partial E_x}{\partial x} + \frac{\partial E_y}{\partial y} + \frac{\partial E_z}{\partial z}\right) dx\,dy\,dz.$$

The quantity in parentheses (the coefficient of $dx\,dy\,dz$) is called the *divergence* of the vector field $\vec{E}$.

▲ **FIGURE 23–25** Problem 11.



23–2 Gauss' Law

12. (I) The flux through a closed surface surrounding a single charge is $-5.7 \times 10^{-5}\ N \cdot m^2/C$. What is the value of the charge?

13. (I) A charge of 10^{-3} C is distributed uniformly on the surface of a sphere of radius 1 cm. Calculate the total electric flux through a concentric sphere (a) just within the charged surface, and (b) just outside the charged surface.

14. (I) A 120-nC point charge is placed just inside the center of one face of an imaginary Gaussian cube. What is the flux that passes through all six faces of the cube?

15. (I) Consider the charge distribution shown in Fig. 23–26, where $q = 1\ \mu C$. Draw a spherical Gaussian surface centered on the origin with a radius of 5 cm. (a) What is the electric flux through the Gaussian sphere? (b) Do any of the electric field lines from the three charges pierce the Gaussian surface?

▲ **FIGURE 23–26** Problem 15.

16. (I) A charge of 1.2×10^{-4} C is placed inside a cylinder at the midpoint of the axis of the cylinder. The flux through one end of the cylinder is 4.5×10^6 N · m^2/C. What is the flux through the curved part of the cylinder's surface?

17. (I) The net electric flux passing through a given closed surface is -4×10^2 N · m^2/C. What charge is contained inside the surface if that surface is (a) a sphere of radius 3 cm, (b) a cube of sides 3 cm, (c) a right circular cylinder of height 3 cm and radius 1 cm?

18. (II) A 420-μC charge is placed at the center of a cube of sides 8 cm. Determine the electric flux through each of the sides.

19. (II) A given region has an electric field that is a sum of two contributions: a field due to a charge $q = 5 \times 10^{-8}$ C at the origin, plus a uniform field of strength $E_0 = 3000$ N/C in the $-x$-direction. Calculate the flux through each side of a cube with sides of length 20 cm that are parallel to the x-, y-, and z-directions; the cube is centered at the origin.

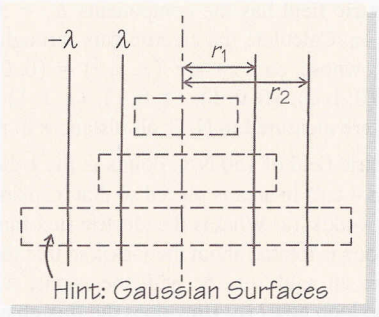
20. (II) The *gravitational field* $\vec{g}$ due to a point mass M may be obtained by analogy with the electric field by writing an expression for the gravitational force on a test mass, and dividing by the magnitude of the test mass, m. Show that Gauss' law for the gravitational field reads $\Phi = \oint_S \vec{g} \cdot d\vec{A} = -4\pi GM$, where G is the gravitational constant. Use this result to calculate the gravitational field at a distance r from the center of a sphere of radius R and uniform density for $r > R$ and for $r < R$.

23–3 Using Gauss' Law to Determine Electric Fields

21. (I) Calculate the electric field outside a long cylinder of finite radius R with a uniform (volume) charge density ρ spread throughout the volume of the cylinder.

22. (I) Use Gauss' law to show that the electric field outside a large, thin, nonconducting plate with uniform charge density σ is given by $E = \sigma/2\varepsilon_0$.

23. (I) Charge is distributed on a long, straight rod with uniform density $\lambda = 6.5 \times 10^{-8}$ C/m. Compare the magnitude of the field 1 cm from the rod to the field 1 cm from a point charge $q = 6.5 \times 10^{-8}$ C.



24. (II) An infinitely long cylinder of radius R carries a uniform (volume) charge density ρ. Calculate the field everywhere inside the cylinder.

25. (II) On a clear day in Nebraska, the electric field just above the ground is 110 N/C and points toward the ground. Our planet Earth is a reasonable conductor and contains no electric field. How much net charge is contained on the surface of a 60-acre corn field (1 acre $\cong$ 4000 m^2)?

26. (II) Two long, thin cylindrical shells of radii r_1 and r_2, respectively, are oriented coaxially (one cylinder is centered inside the other). The cylinders carry equal and opposite linear charge densities λ. Describe the resulting electric field inside the smaller cylinder, between the cylinders, and outside the larger cylinder (Fig. 23–27).

27. (II) A balloon of radius 15 cm carries a charge of 5×10^{-7} C distributed uniformly over its surface. What is the electric field at a distance of 50 cm from the center of the balloon? Suppose that the balloon shrinks to a radius of 10 cm but loses none of its charge. What is the electric field at a distance of 50 cm from the center?

28. (II) A thin, cylindrical copper shell of diameter 6.0 cm has a thin metal wire of diameter 0.10 mm along its axis. The wire and the shell carry equal and opposite charges of 8.5×10^{-9} C/cm, distributed uniformly. Calculate the electric field in the region between the wire and the cylinder, and the magnitude of the electric field at the surface of the wire and at the inner surface of the cylinder.

▲ **FIGURE 23–27** Problem 26.

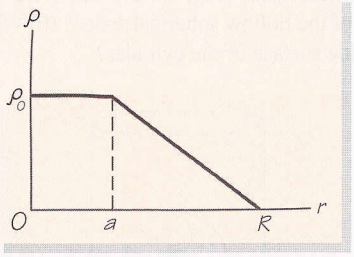
29. (II) A long, cylindrical shell of inner radius r_1 and outer radius r_2 carries a uniform volume charge density ρ. Find the electric field due to this distribution of charge everywhere in space.

30. (II) A Teflon rod of radius 4.0 mm and height 7.0 cm is being charged uniformly over its cylindrical surface. How much charge can the rod hold before the surrounding air breaks down electrically, which happens when the electric field in air is 2.0×10^6 N/C? Ignore the likelihood of breakdown at the sharp edges.

31. (II) A thick, nonconducting spherical shell with a total charge of Q distributed uniformly has an inner radius R_1 and an outer radius R_2. Calculate the resulting electric field in the three regions $r < R_1$, $R_1 < r < R_2$, and $r > R_2$.

32. (II) A spherical metal shell of inner radius R is isolated and carries no net charge. A metal ball of radius r with charge q is suspended inside it, so that the center of the ball is at the center of the shell. Write expressions for (a) the charge on the inner surface of the shell; (b) the charge on the outer surface of the shell, (c) the electric field at a distance d from the center, where $r < d < R$.

33. (II) Consider two infinite parallel charged plates with surface charge densities of σ_1 and σ_2 respectively. (a) What is the electric field in the three regions on the far sides of the plates and between the plates? (b) What are the fields if an infinite uncharged metallic plate is inserted between and parallel to the two charged plates? Is it enough to just use Gauss' law? What else is needed?



34. (II) Two infinite-plane nonconducting, thin sheets with uniform surface charges of 3 μC/m^2 and -1 μC/m^2, respectively, are parallel to each other and 12 cm apart. What are the electric fields between the sheets and outside them?

35. (II) Two infinite-plane sheets that are just like those of Problem 34 are placed at right angles to each other. What are the fields in the four regions into which space is divided by the planes?

36. (II) A slab of nonconducting material forms an infinite plane. The slab has a thickness t and carries a uniform positive charge density ρ. It is oriented parallel to the xy-plane, with its upper surface at $z = t/2$ and its lower surface at $z = -t/2$. Use Gauss' law to find the electric field both above and below the surface, as well as at an arbitrary value of z in the interior of the slab.

37. (II) Consider a solid sphere of radius 3 cm that carries a negative charge of 2 μC distributed uniformly. The sphere is placed concentrically in a spherical shell of radius 8 cm that has a positive charge of 5 μC distributed uniformly over it. Calculate the electric field as a function of radius r for $0 < r < 15$ cm.

38. (III) Charge is distributed throughout a sphere with the charge density given by $\rho = \rho_0$ for $r < a$, $\rho = \rho_0(r - R)/(a - R)$ for $a < r < R$, and $\rho = 0$ for $R < r$ (Fig. 23–28). Calculate the flux through the spherical surfaces at $r = a$, $r = R$, and $r = 10R$, and calculate the corresponding electric fields at these radii.

▲ FIGURE 23–28 Problem 38.

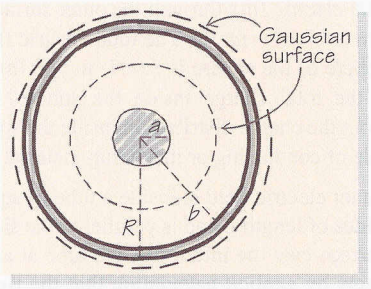
39. (III) Consider the charge distribution given in Problem 38. Plot the charge density, the flux through a concentric shell of radius r, and the electric field as a function of r. Use $R = 3a$.

23–4 Conductors and Electric Fields

40. (I) Two large, thin, metallic plates are placed parallel to each other, separated by 11 cm. The top plate carries a uniform charge density of 6.5 μC/m^2, while the bottom plate carries a uniform charge density of -4.8 μC/m^2. What is the electric field halfway between the plates?

41. (I) Two concentric metallic shells—conductors—have radii of R and $2R$, respectively. A charge q is placed on the inner shell, and a charge $-2q$ is placed on the outer shell. What are the electric fields in all of space due to the two shells?

42. (I) Two oppositely charged, parallel metal plates give rise to a field of 3×10^6 N/C between them. The plates are square and have dimensions 0.1 m $\times$ 0.1 m. How much charge must there be on each plate? Assume that the charge distribution and electric field are uniform, as if the plates were infinite in size. This will be a good approximation if the distance between the plates is much smaller than 0.1 m.



43. (I) Charge is placed on a large spherical surface. What is the maximum surface charge density that avoids electrical breakdown in air ($E_{max} = 3 \times 10^6$ N/C)?

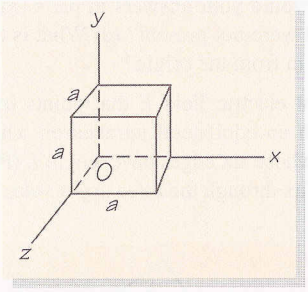
44. (I) A metal sphere of radius 15 cm is concentrically surrounded by a thin spherical metal shell whose inner radius is 25 cm. The electric flux through a concentric spherical Gaussian surface at a radius of 40 cm is 1.6×10^7 N $\cdot$ m^2/C, and that through a concentric spherical Gaussian surface at a radius of 18 cm is 0.80×10^7 N $\cdot$ m^2/C. What is the ratio of the charges on the inner and outer spheres?

45. (I) What is the ratio of the charge densities on the inner and outer spheres in Problem 44?

46. (I) A solid copper cube is placed in a constant electric field that points in the $+x$-direction. The faces of the cube are parallel to the xy-, yz-, and xz-planes, and one corner is at the origin. Draw the field lines as they would be observed looking down on the cube toward the xy-plane. Show at least two electric field lines starting or stopping on each of the four sides of the cube perpendicular to the xy-plane.

47. (II) A metal sphere of radius a is surrounded by a metal shell of inner radius b and outer radius R. The flux through a spherical Gaussian surface located between a and b is Q/ε_0, and the flux through a spherical Gaussian surface just outside radius R is $2Q/\varepsilon_0$ (Fig. 23–29). What are the total charges on the inner sphere and on the shell? Where are the charges located, and what are the charge densities?

▲ FIGURE 23–29 Problem 47.



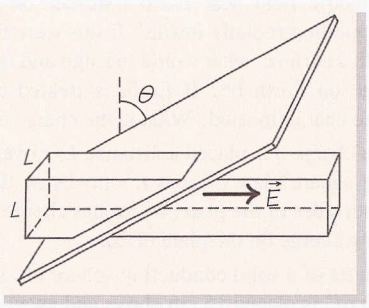
48. (II) The electric field near Earth's surface on a given day is 100 N/C, pointing radially inward. If this were true everywhere on the Earth's surface, what would the sign and magnitude of the total charge on Earth be? If Earth is treated as a conductor, where is the charge located? What is the charge density?

49. (II) A point charge q is placed a distance $L/2$ over the center of a conducting square plate of area L^2. (a) Draw the electric field lines on both sides of the plate, which has charge $-q$. (b) Repeat part (a) for a charge on the plate of $2q$.

50. (II) The center of a solid conducting sphere of radius 18 cm and charge 380 μC is placed 15 cm above and away from the center of a flat, horizontal conducting square plate of area 1000 cm^2 and charge 15 μC. Draw the electric field lines.

General Problems

51. (II) Consider a cube of sides a located at the origin (Fig. 23–30). Suppose that an electric field is present and given by $\vec{E} = bx^2\hat{i}$, where b is a constant. Calculate the flux through each side of the cube, and use this to find the charge within the cube.

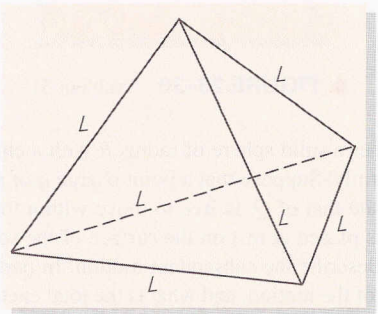


▲ FIGURE 23–30 Problem 51.

52. (II) Consider a solid sphere of radius R with a charge Q distributed uniformly. Suppose that a point charge q of mass m, with a sign opposite that of Q, is free to move within the solid sphere. Charge q is placed at rest on the surface of the solid sphere and released. Describe the subsequent motion. In particular, what is the period of the motion, and what is the total energy of the point charge? [*Hint*: Recall the properties of the motion for which the force varies linearly with the distance from a fixed point and is a restoring force.]

53. (II) Consider a point charge Q at the center of a Gaussian sphere of radius R. The sphere has a cap "sliced off," with the area of the cap forming a fraction of 0.067 of the total area of the sphere. (This corresponds to making the slice at a latitude of 60°, measured from the equatorial plane). The cap is replaced by a flat surface. (a) What is the total flux through the flat surface? (b) What is the magnitude of the electric field at the boundary of the flat surface?

54. (II) The total electric flux through the outer surface of a uniform solid sphere is 17.1 $N \cdot m^2/C$. The total electric flux through the top hemisphere of the sphere is 8.9 $N \cdot m^2/C$. (a) What can you say about the total charge inside the sphere? (b) What can you say about the charge distribution inside the sphere? (c) Is the sphere made of conducting or insulating material?



55. (II) A constant electric field is inside a tube of square cross section with sides of length L and is parallel to the sides of the tube. A plane surface cuts the interior of the tube at an angle θ (Fig. 23–31). Show by explicit calculation that the flux through this surface is independent of the angle θ. How would you show this without explicitly calculating the flux through the surface?

▲ FIGURE 23–31 Problem 55.

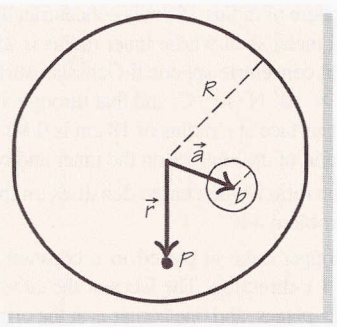
56. (II) A conducting sphere of radius 25 cm is centered at the origin of a coordinate system, as is a surrounding conducting shell of radius 75 cm. The inner sphere has a charge density of 16 $\mu C/m^2$ over its surface, and the outer sphere has a uniform charge density half that large. (a) Find the electric field at a distance 50 cm from the origin; (b) at a distance 70 cm from the origin. (c) How would your answers to parts (a) and (b) change if the outer shell were not present? (d) What is the electric field at a distance 1.5 m from the origin?

57. (II) A constant electric field E that points in the $+z$-direction passes through an equilateral tetrahedron whose base is in the xy-plane and whose six edges have length L (Fig. 23–32). Calculate the total flux through the three upper sides of the tetrahedron.

▲ FIGURE 23–32 Problem 57.

58. (II) How should the charge density of a sphere of radius R vary with the distance from the center of the sphere to give a radial field of constant magnitude within the sphere? What happens at the origin, and why?

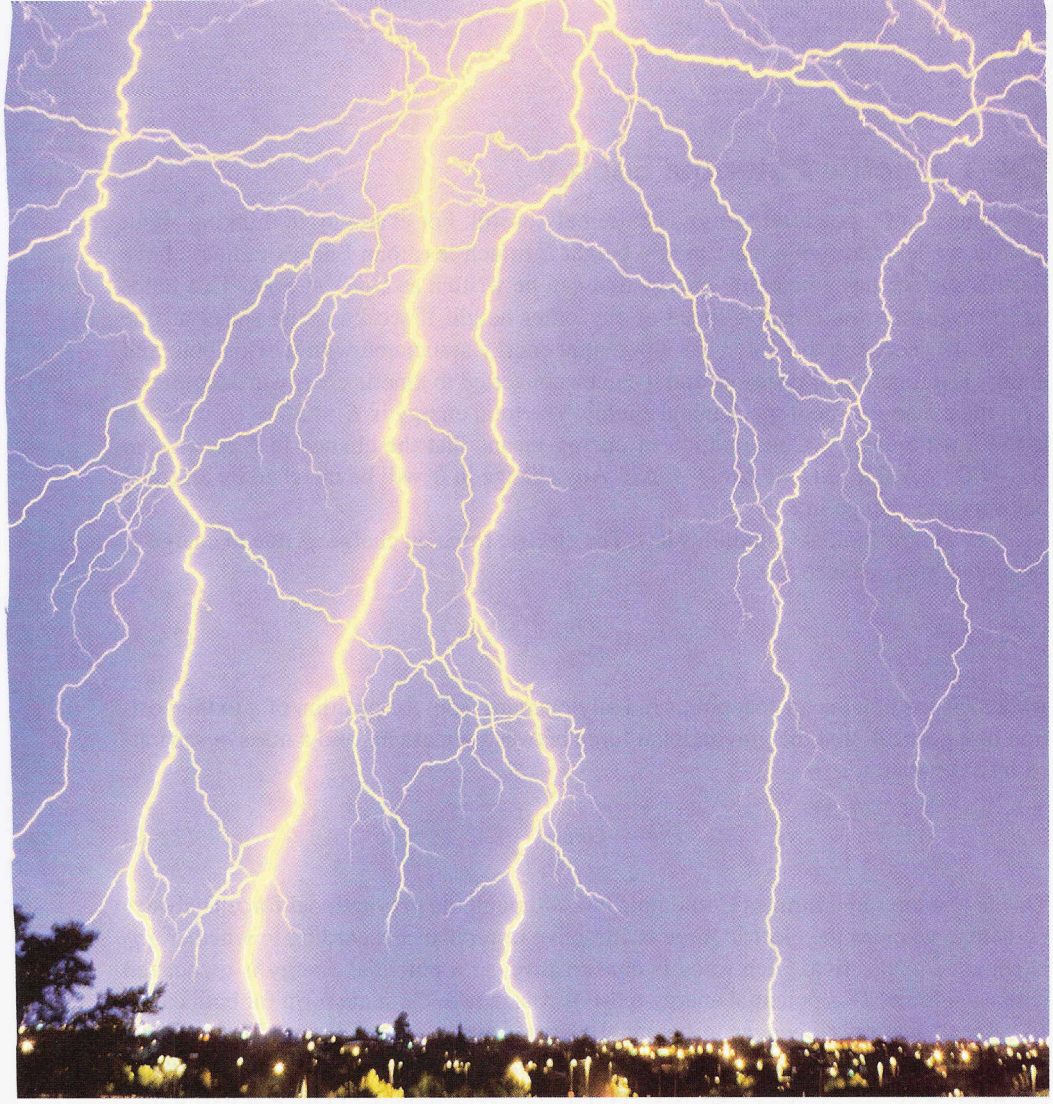
59. (II) A certain experiment requires an electric field that points symmetrically away from an axis and has a constant magnitude. Describe the charge distribution capable of creating such a field.



60. (II) A right solid conducting cylinder has a charge of −0.55 mC. Inside the cylinder a +0.12-mC charge rests at the center of a hollow spherical space (Fig. 23–33). (a) What is the charge on the surface of the hollow spherical space? (b) What is the charge on the outside surface of the cylinder?

▲ FIGURE 23–33 Problem 60.

61. (II) A conductor has a surface oriented in the yz-plane that marks the boundary of a region in which there is an electric field oriented in the $+x$-direction. The strength of this field increases linearly as x increases from $x = 0$ m to $x = 0.5$ m. At the beginning of the region, at $x = 0$ m, the field strength is 0; at $x = 0.5$ m, the field strength has increased to 3000 N/C. Describe the distribution in the x-direction of the charge that produces this field.



62. (III) A nonconducting sphere of radius R is charged uniformly with charge density ρ. Use Gauss' law to show that the electric field inside the sphere at a point P whose displacement vector from the sphere's center is $\vec{r}$ is given by $\vec{E} = (\rho/3\varepsilon_0)\vec{r}$. A small sphere centered at the point whose displacement from the origin is $\vec{a}$ is cut out of the sphere (Fig. 23–34). Use the superposition principle to calculate the electric field inside the cavity. [*Hint*: The cavity can be created by inserting in the original sphere a sphere of opposite charge density, $-\rho$, and radius b, centered at $\vec{a}$.]

▲ FIGURE 23–34 Problem 62.

63. (III) Use Gauss' law to show that a test charge in the electric field due to any given static charge distribution cannot be in stable equilibrium. [*Hint*: At an equilibrium point, the net electric field must be zero. What must the fields in the vicinity of that point be so that the equilibrium is stable?]

Chapter 24

◀ The discharge of lightning bolts provides an impressive demonstration that there is energy in electric fields. Lightning forms when a significant electric potential difference exists between Earth and the clouds or between different clouds.

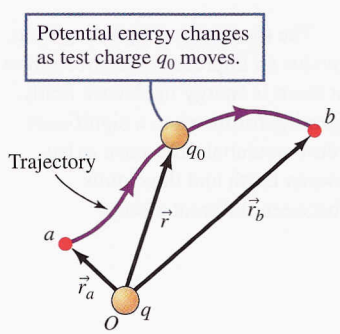
Electric Potential

We know that there is a potential energy associated with conservative forces, that this potential energy is a term in the total energy of systems, and that the conservation of energy is a powerful tool for solving problems. The electric, or Coulomb, force is a conservative force. Thus we expect a collection of charges to have a potential energy, the subject of this chapter. Many of the results we develop here are similar to those for gravitation (Chapter 12) because the gravitational force and Coulomb's law have the same form.

Electric force concerns the interaction of a charge distribution and a second charge and is the product of the second charge and the electric field due to the distribution. Similarly, the electrical potential energy is the potential energy of the system made up of the charge distribution interacting with a second charge. And just as it is useful to remove the second charge from the electric force and deal with the electric field due to the distribution, it is useful to remove the second charge from the electrical potential energy and deal with the *electric potential*, or just potential, a property of the charge distribution alone.

There is one more important point to keep in mind. One of the advantages of using the potential energy rather than the force is that the potential energy is a scalar quantity, while force is a vector. If we know the potential energy, we may find the force by appropriate derivatives. Similarly, the potential is a scalar quantity, easier to handle in many respects than the electric field, which is a vector quantity, and if we know the electric potential of a charge distribution, we can derive the electric field due to that distribution from it.

24–1 Electric Potential Energy



The concept of a potential energy is extremely useful. For example, in thinking about gravity we learned that a mass m at a height h (much less than Earth's radius) above Earth's surface has a potential energy that can be written as $U(h) = mgh$. This helps us to determine the object's speed at any other height if we know its speed at one height. *Any* conservative force has a potential energy associated with it. This potential energy is a function of position, and it can be converted to kinetic energy in accordance with the conservation of mechanical energy. The total energy is $E = K + U$, where K is the kinetic energy. Conservation of energy means that the change in E is zero, so $\Delta E = 0 = \Delta K + \Delta U$, or $\Delta K = -\Delta U$. Any change in U will be matched by an equal but opposite change in K.

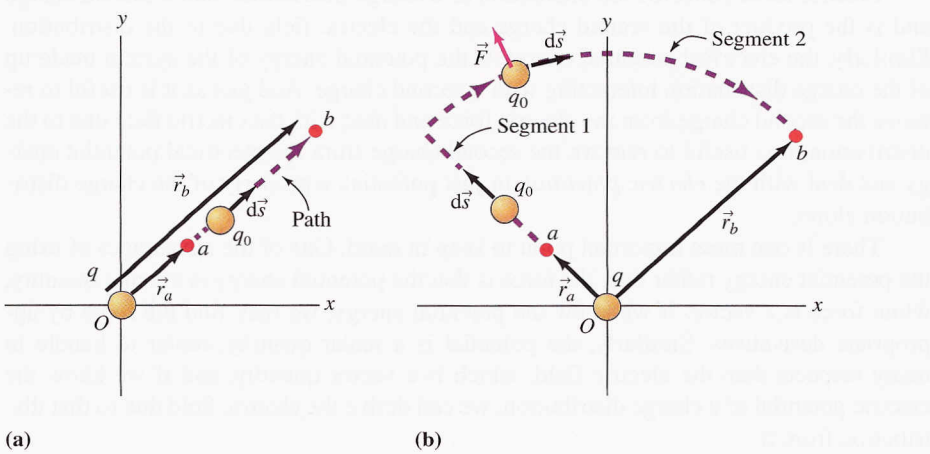
Let us now look at Coulomb's law. The electric force on charge q_0 due to charge q, separated by a distance r, is

$$\vec{F} = \frac{qq_0}{4\pi\varepsilon_0}\frac{1}{r^2}\hat{r}, \tag{24–1}$$

where $\hat{r}$ is the unit vector that points radially outward from the position of q to the position of q_0. Recall that the gravitational force between a mass m_0 and a mass m separated by a distance r is

$$\vec{F} = -Gmm_0\frac{1}{r^2}\hat{r}. \tag{24–2}$$

▲ **FIGURE 24–1** When a test charge q_0 moves from point a to point b in the presence of a charge q that is fixed in place, the potential energy of the system changes.



This is just the same form as Coulomb's law, although the gravitational force is always attractive, whereas the electric force is attractive or repulsive according to whether qq_0 is negative or positive. Each force is conservative, so a potential energy is associated with each force. This potential energy must of course take the same form for both cases.

Recall that only *changes* in potential energy have meaning. From Chapter 7, we know that we can express the change in potential energy of our system as the charge q_0 (or, in the case of gravitation, the mass m_0) moves from an initial point a at position $\vec{r}_a$ to a final point b at position $\vec{r}_b$ through a displacement (Fig. 24–1) as

$$\Delta U = U_f - U_i = U(\vec{r}_b) - U(\vec{r}_a) = -\int_{\vec{r}_a}^{\vec{r}_b}\vec{F}\cdot d\vec{s}. \tag{24–3}$$

The integral in this expression is a line integral whose value is *independent of the path of integration* between points a and b—that is precisely why Eq. (24–3) involves only a difference in the value of the potential energy at the two end points.

Let's now evaluate the change in electric potential energy for the point charge q at the origin and the point charge q_0 when q_0 moves from point a to point b. We start with the simplest situation (Fig. 24–2a), in which point a is on the same radius as point b.

▶ **FIGURE 24–2** The change in potential energy of the system of two charges q and q_0 when the charge q_0 moves from point a to point b, in terms of a path-independent line integral.
(a) Charge q_0 moves along a radius.
(b) The two points are not along the same radius. The path is here taken to run radially outward to the radius of point b, and then follow the circumference at that radius.

The path from a to b is along the dashed line shown in Fig. 24–2a, and as the Coulomb force points outward along this radial direction, we have for our path

$$\vec{F} \cdot d\vec{s} = F\, dr.$$

Then, from Eq. (24–3), the potential energy change when charge q_0 moves from a to b is

$$\Delta U = -\int_{r_a}^{r_b} F\, dr = -\int_{r_a}^{r_b} \frac{qq_0}{4\pi\varepsilon_0 r^2}\, dr$$

$$= -\frac{qq_0}{4\pi\varepsilon_0}\int_{r_a}^{r_b} \frac{dr}{r^2} = -\frac{qq_0}{4\pi\varepsilon_0}\left(\frac{-1}{r}\right)\Bigg|_{r_a}^{r_b} = \frac{qq_0}{4\pi\varepsilon_0}\left(\frac{1}{r_b} - \frac{1}{r_a}\right). \quad (24\text{–}4)$$

What if charge q_0 moves between two points that do not lie on the same radius, as in Fig. 24–2b? In this case, we follow the dashed path shown. [Remember, the result of the integration in Eq. (24–3) is path independent.] For segment 1, which runs outward radially from a to a distance r_b from the origin, the result is identical to Eq. (24–4). For segment 2, which follows a circumference at a distance r_b from the origin, the integral is zero because the force is perpendicular to the path segment $d\vec{s}$ everywhere. The result for the change in potential energy is still given by Eq. (24–4).

Let's look more closely at what Eq. (24–4) tells us. Suppose first that the charges move closer together ($r_a > r_b$). If the charges repel (qq_0 is positive), the change in potential energy is positive. This is like moving a mass *up* a mountain. If the charges attract (qq_0 is negative), the system loses potential energy when the charges move closer together. This is like moving a mass *down* the mountain. As with any potential energy, electric potential energy can be converted into kinetic energy. If there are no additional forces acting, then like-sign charges slow down—or lose kinetic energy—when they move closer together. Similarly, charges of opposite sign speed up—or gain kinetic energy—when they move closer together. We draw a similar set of conclusions when the charges move farther apart ($r_a < r_b$). Charges that repel lose electric potential energy and, if there are no other forces, gain kinetic energy. Opposite charges (which attract) gain electric potential energy when they move farther apart and lose kinetic energy in the absence of other forces.

Equation (24–3) shows that the change in electric potential energy is given by the difference of two functions, $U(r_b)$ and $U(r_a)$. We can therefore choose the zero of the potential energy function to be at whatever value of r we like. It is convenient and natural to choose zero potential energy to be at infinity. We can do this if we let $r_a \to \infty$ and let r_b take on a general value r in Eq. (24–4):

$$\Delta U = U(r) - U(r_a)\Big|_{r_a \to \infty} = \frac{qq_0}{4\pi\varepsilon_0}\frac{1}{r}.$$

We then say that the potential energy of a charge q_0 a distance r from charge q is the difference in potential energy between that point and infinity. When we reverse the roles of q and q_0, the potential energy of q at a distance r from q_0 is again $qq_0/4\pi\varepsilon_0 r$. We can then say that the **electric potential energy** $U(r)$ for a system of two point charges q and q_0 separated by a distance r is

$$U(r) = \frac{qq_0}{4\pi\varepsilon_0}\frac{1}{r}. \quad (24\text{–}5)$$

It is indeed true that $U(r) = 0$ in the limit $r \to \infty$. Thus the system has no potential energy when the two charges are infinitely far apart. Note that the potential energy of the two charges depends *only* on the distance r between them and on the magnitudes and signs of the charges. Equation (24–5) has the same form as Eq. (12–9), calculated in Chapter 12 for the gravitational potential energy.

CONCEPTUAL EXAMPLE 24–1 How much work is done by the electrical force when a point charge is brought from infinity to rest at a distance r from a fixed charge of the opposite sign? What is the meaning of the sign of your result?

Answer The work done is given by $W = \int_{\infty}^{r} \vec{F} \cdot d\vec{s}$, where $\vec{F}$ is the electrical force between the charges. The quantity is the negative of the corresponding change of electric potential energy, as in Eq. (24–3), namely $-[U(r) - U(\infty)]$. Since the zero of the potential energy is at infinity, this is just $-U(r)$, with U given by Eq. (24–5). For charges of opposite sign, $-U(r)$, and therefore the work done, is positive. This is a sensible result, because when the electrical force is the only force acting the work done by it is the change in kinetic energy, and that change would indeed be positive for charges of opposite sign, which attract one another.

EXAMPLE 24–2 One measure of the strength of the nuclear forces that hold the constituents of the nucleus together is provided by the comparative strength of the repulsive Coulomb force between the (positively charged) protons in the nucleus. Find the electrostatic potential energy between two protons that are separated by the average separation between the nuclear constituents, roughly 2×10^{-15} m.

Strategy This is a straightforward application of Eq. (24–5), an expression for the electrostatic potential energy. This expression assumes that the potential energy is zero at infinity.

Working It Out The proton charge is equal and opposite to that of the electron, $+e = 1.6 \times 10^{-19}$ C. Then

$$U = \frac{(e)^2}{4\pi\varepsilon_0 r} = \frac{(9 \times 10^9\ \text{N} \cdot \text{m}^2/\text{C}^2)(1.6 \times 10^{-19}\ \text{C})^2}{(2 \times 10^{-15}\ \text{m})} = 10^{-13}\ \text{J}.$$

This is a typical energy value on the nuclear scale and is about 10^5 times larger than the energy of a proton and electron that make up a hydrogen atom (see Example 24–4). This energy can be converted into kinetic energy in nuclear reactions (see Chapter 44).

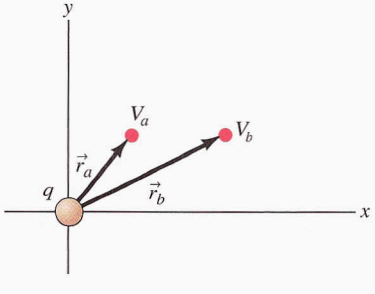
24–2 Electric Potential

A point charge q is the source of an electric field $\vec{E}$ that exists in the surrounding space. The electric field affects any charge q_0 introduced into that space through a force $\vec{F}$ on q_0 given by $\vec{F} = q_0\vec{E}$. We saw in Section 24–1 that the introduction of a charge q_0 a distance r from q gives rise to the potential energy $U(r)$ of Eq. (24–5). If we write $U(r) = q_0 V(r)$, we can make a statement analogous to the statement about the electric field: The charge q is the source of an *electric potential* (or just *potential*) $V(r)$, within which any charge q_0 a distance r from q will have potential energy $U(r) = q_0 V(r)$. Strictly speaking q_0 should be a small test charge, so that its presence does not disturb charge q or any other charge distribution that gives rise to the electric potential. This description tells us how to define the **electric potential** due to a charge distribution:

$$V(\vec{r}) \equiv \lim_{q_0 \to 0} \frac{U(\vec{r})}{q_0}, \tag{24–6}$$

where $U(\vec{r})$ is the potential energy of the test charge q_0 in the presence of the charge distribution. The potential $V(\vec{r})$ is independent of the test charge q_0, just as the electric field, defined by $\vec{E} = \vec{F}/q_0$, is independent of the test charge.

The Electric Potential of a Point Charge



Let's calculate the electric potential of the simplest possible system: one point charge. Consider a test charge q_0 separated by a distance r from a single point charge q. As Eq. (24–5) shows, the potential energy of the system is $U(r) = q_0 q/4\pi\varepsilon_0 r$, and hence $U/q_0 = q/4\pi\varepsilon_0 r$. We have found *the electric potential of a point charge q at a distance r from the charge*:

$$V(r) = \frac{q}{4\pi\varepsilon_0 r}. \tag{24–7}$$

In Eq. (24–7), we have assumed that zero potential energy is at infinity and, as a consequence, we have taken the electric potential due to a charge q to be zero at infinity. To emphasize this point, we might say that Eq. (24–7) is the potential of a single charge *with respect to infinity.*

As for potential energy, the only physically relevant feature of the potential is how it differs between two points. The *electric potential difference* due to the charge q between the points a and b at locations $\vec{r}_a$ and $\vec{r}_b$ is given by (Fig. 24–3):

$$\Delta V = V_b - V_a = \frac{U_b - U_a}{q_0} = \frac{q}{4\pi\varepsilon_0}\left(\frac{1}{r_b} - \frac{1}{r_a}\right). \tag{24–8}$$

▲ **FIGURE 24–3** The potential at two different locations in space. Only the potential *difference* has physical meaning.

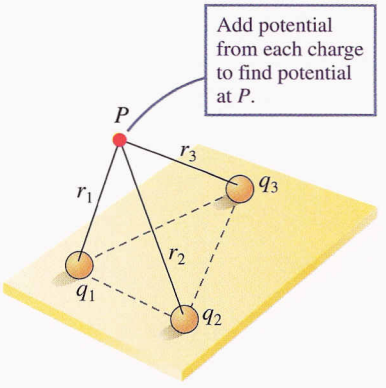
Here, we have abbreviated V as a function of r_a, or $V(r_a)$, as V_a, and so forth.

We can obtain another formulation of the electric potential difference by using Eqs. (24–3) and (24–8) and substituting $\vec{F} = q_0\vec{E}$:

$$\Delta V = \frac{U_b - U_a}{q_0} = -\int_{r_a}^{r_b} \vec{E} \cdot d\vec{s}. \tag{24–9}$$

Here, the electric potential difference is expressed as a path-independent integral over an electric field. The electric field in Eq. (24–9) is not necessarily the electric field of a point charge. Equation (24–3) is the potential energy change when a test charge q_0 moves from point a to point b in the field of *any* charge distribution. Thus Eq. (24–9) is a general expression for the electric potential difference between two points. Any charge distribution produces an electric field, and an electric potential is associated with any charge distribution.

Recall (Section 7–1) that the change in the potential energy of a system is equal to the negative of the work done by the system in moving an object from point a to point b. Equivalently, $U_b - U_a$ is the work done by an external agent to move the object. By the parallel relation between force and field we can then interpret Eq. (24–9) to mean that



The electrical potential difference $V_b - V_a$ is the work per unit charge that must be done by an external agent to move a test charge from point *a* to point *b* without changing its kinetic energy.

If there is no external agent, then a change in potential, which corresponds to a change in potential energy of the test charge, must be accompanied by a corresponding change in the kinetic energy of the test charge.

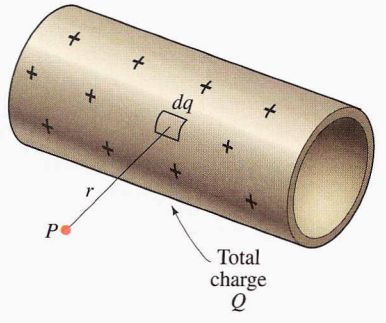
With knowledge of the electric potential $V(\vec{r})$ due to a charge distribution and the magnitude of a test charge q_0 we immediately have the potential energy $U(\vec{r})$ of the system composed of the distribution and the test charge q_0 placed at the position $\vec{r}$:

$$U(\vec{r}) = q_0 V(\vec{r}). \tag{24–10}$$

In the absence of other forces, this equation tells us that a positive test charge q_0 in the presence of an electric potential will move toward lower values of the potential because the potential energy decreases in that way. The charge speeds up as it moves to lower potentials.

▲ **FIGURE 24–4** The superposition principle determines the potential at point P due to multiple charges. We simply add the potential due to each of the charges.

The Electric Potential of Charge Distributions



The electric field obeys the superposition principle. Therefore the electric potential of a system of charges can also be determined from the superposition principle. The superposition principle states that the electric field of a collection of charges is the sum of the electric fields of each charge. Thus *the electric potential at a point P due to n point charges* $q_1, q_2, \ldots, q_n$ (Fig. 24–4 shows three charges) at distances $r_1, r_2, \ldots, r_n$ from point P is

$$V_P = \frac{q_1}{4\pi\varepsilon_0 r_1} + \frac{q_2}{4\pi\varepsilon_0 r_2} + \cdots + \frac{q_n}{4\pi\varepsilon_0 r_n} = \frac{1}{4\pi\varepsilon_0}\sum_{i=1}^{n}\frac{q_i}{r_i}, \tag{24–11}$$

where r_i is the distance from point charge q_i to point P. The electric potential due to a collection of charges is the *scalar* sum of the potentials due to single charges. This scalar sum is much easier to perform than the vector sum that expresses the electric field due to a collection of point charges, illustrating in another way the usefulness of the concept of potential.

The calculation of the electric potential due to a continuous charge distribution is also straightforward. We first find the electric potential dV at a point P due to a small charge dq that is part of an arbitrary charge distribution (Fig. 24–5). Because electric potential is a scalar quantity, the addition of all the tiny potentials dV is given by scalar integration. Thus *the potential due to a continuous charge distribution* takes the symbolic form

$$V = \int dV = \frac{1}{4\pi\varepsilon_0}\int \frac{dq}{r}. \tag{24–12}$$

▲ **FIGURE 24–5** To find the potential at point P due to a continuous charge distribution, here a cylinder, integrate over the contribution from the differential charges dq as if each dq were a point charge.

The integration must be done over the entire charge distribution. In Section 24–5 we discuss techniques for the calculation of V in specific situations.

Units of Electric Potential

The dimension of electric potential is energy per charge; thus the SI unit is joules per coulomb (J/C). Because electric potential is used frequently, it has a separate name in the SI: the **volt**(V):

$$1\ \text{V} \equiv 1\ \text{J/C}. \tag{24–13}$$

(Don't confuse the roman letter V that symbolizes the unit with the italic V that is the usual symbol for the function electric potential.) It is named after Alessandro Volta, who did research at the beginning of the nineteenth century on the nature of electric energy. Note that electric potential has the dimensions of electric field times length, so the dimensions of electric field must be the dimensions of potential divided by length (V/m):

$$1\ \text{N/C} = 1\ \text{V/m}. \tag{24–14}$$

The Potential Energy of a System of Charges

Equation (24–10) gives the potential energy $U(r) = q_0V(r)$ of a test charge q_0 placed in the electric potential of a charge distribution. If the charge distribution is a collection of charges, then the electric potential V_P is given by Eq. (24–11), and the potential energy of the test charge is $U(r) = q_0V_P$. But it would be incorrect to call this the potential energy of the entire system of charges $q_0, q_1, q_2, \ldots, q_n$, because the product q_0V_P just represents the work that needs to be done to bring charge q_0 in from infinity. It does *not* take into account the work that must be done to bring the charges $q_1, q_2, \ldots, q_n$ in from infinity. To calculate the potential energy of a collection of three charges, for example, we assemble them one by one. To bring the first charge, q_1, in to the point P_1 requires no work by the external agent if the kinetic energy of the charge is unchanged. To bring the second charge, q_2, in from infinity to the point P_2 does require work because of the potential due to q_1. For our two charges, the work the external agent must do to bring q_2 in from infinity—the potential energy—is given by

$$U_{12} = q_2V_1 = \frac{q_1q_2}{4\pi\varepsilon_0 r_{12}}, \tag{24–15}$$

where r_{12} is the distance between charges q_1 and q_2.

What happens if we bring a third charge, q_3, in from infinity? We must calculate the additional work done by an external force to bring q_3 in. This work is given by the product of q_3 and electric potentials V_1 and V_2 due to q_1 and q_2 in place. Thus, the additional contribution to the potential energy of the system is

$$U_{13} + U_{23} = \frac{q_1q_3}{4\pi\varepsilon_0 r_{13}} + \frac{q_2q_3}{4\pi_0 r_{23}}, \tag{24–16}$$

where r_{13} and r_{23} are the distances between q_3 and q_1, q_3 and q_2, respectively. The total potential energy U of the system is the sum of U_{12}, U_{13}, and U_{23}:

$$U = \frac{1}{4\pi\varepsilon_0}\left(\frac{q_1q_2}{r_{12}} + \frac{q_1q_3}{r_{13}} + \frac{q_2q_3}{r_{23}}\right). \tag{24–17}$$

This can be generalized to any number of charges, and the resulting formula for the *electric potential energy of the system* is a simple generalization of Eq. (24–17):

$$U = \frac{1}{4\pi\varepsilon_0}\sum_{i<j}\frac{q_iq_j}{r_{ij}}, \tag{24–18}$$

where r_{ij} is the distance between the locations of the charges q_i and q_j. The sum over i and j includes all charge pairs in the system, and the inequality $i < j$ avoids the

counting of pairs more than once. We can eliminate that restriction by writing the equivalent expression

$$U = \frac{1}{2}\sum_{\substack{i,j \\ i\neq j}} \frac{q_i q_j}{4\pi\varepsilon_0 r_{ij}}.$$

Now the sum is unrestricted, except that we omit the case $i = j$, which is not in the original sum, Eq. (24–18). Thus we can rewrite Eq. (24–18) as

$$\begin{aligned} U &= \frac{1}{2}q_1\sum\frac{q_j}{4\pi\varepsilon_0 r_{1j}} + \frac{1}{2}q_2\sum\frac{q_j}{4\pi\varepsilon_0 r_{2j}} + \frac{1}{2}q_3\sum\frac{q_j}{4\pi\varepsilon_0 r_{3j}} + \cdots \\ &= \frac{1}{2}q_1V_1 + \frac{1}{2}q_2V_2 + \frac{1}{2}q_3V_3 + \cdots, \end{aligned} \tag{24–19}$$

where V_1 is the electric potential due to all the other charges at the location of charge q_1, and so on. It should be stressed that the potential energy of q_1 in a given potential V_1 is still q_1V_1; this means that q_1V_1 can be converted into the kinetic energy of the particle that carries charge q_1. This potential energy must be distinguished from the potential energy of the *entire* charge configuration, Eq. (24–18) or (24–19). The potential energy of the entire charge configuration is the energy that would be made available if *all* the charges that appear in the problem were to move to infinity.

In Examples 24–3 and 24–4, we illustrate calculation techniques for the electric potential energy and the electric potential when two or more point charges are involved.

EXAMPLE 24–3 In an experiment to investigate the effects of electricity, Benjamin Franklin could well have placed two point charges, $q_1 = 2.0\,\mu\text{C}$ and $q_2 = -4.0\,\mu\text{C}$, at some distance apart (points P_1 and P_2, respectively) (Fig. 24–6). (a) Find the electric potential at points a and b due to these two point charges. (b) Find the potential difference between points b and a. (c) How much energy would Franklin have had to supply to bring a third charge, of magnitude $3.0\,\mu\text{C}$, in from infinity to point b?

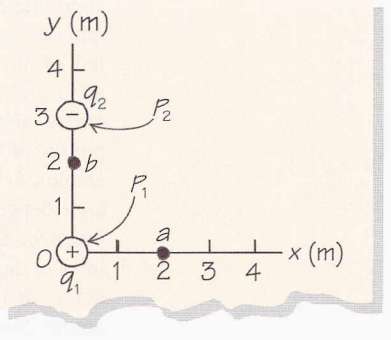
Setting It Up The only quantity that requires new labeling here is the third charge [part (c)], which we shall call q_3.

Strategy For part (a) we can use Eq. (24–11) to determine the electric potential. We'll require various distances; for example, to find the potential at point a, we'll need the distance from point a to points P_1 and P_2. These distances are a matter of geometry. Part (b) requires taking the difference of the potentials we found in part (a). Finally for part (c), we note that the work that must be done to bring q_3 in from infinity to point b is equal to the change in the potential energy of the system. But we know from part (a) the electric potential of the original system of two charges at point b, so we use Eq. (24–10), $U_b = q_0V_b$, to find the potential energy of the new charge at point b.

Working It Out (a) The distance from point a to point P_1 is $r_{1a} = 2\text{ m}$, and the distance from point a to point P_2 is $r_{2a} = \sqrt{(2.0\text{ m})^2 + (3.0\text{ m})^2} = 3.6\text{ m}$ (note that we work with two significant figures here). The electric potential V_a at point a is then

$$\begin{aligned} V_a &= \frac{1}{4\pi\varepsilon_0}\left(\frac{q_1}{r_{1a}} + \frac{q_2}{r_{2a}}\right) \\ &= (9.0\times10^9\,\text{N}\cdot\text{m}^2/\text{C}^2)\left(\frac{2.0\times10^{-6}\,\text{C}}{2.0\text{ m}} + \frac{-4.0\times10^{-6}\,\text{C}}{3.6\text{ m}}\right) \\ &= 1.0\text{ kV}. \end{aligned}$$

The SI units of potential are volts. A check is always useful—in this case, the unit combination is $\text{N}\cdot\text{m/C} = \text{J/C} = \text{V}$.



For the electric potential at point b, the distance from charge q_1 to b is $r_{1b} = 2.0\text{ m}$; similarly, $r_{2b} = 1.0\text{ m}$. Therefore, the potential V_b is

$$\begin{aligned} V_b &= \frac{1}{4\pi\varepsilon_0}\left(\frac{q_1}{r_{1b}} + \frac{q_2}{r_{2b}}\right) \\ &= (9.0\times10^9\,\text{N}\cdot\text{m}^2/\text{C}^2)\left(\frac{2.0\times10^{-6}\,\text{C}}{2.0\text{ m}} + \frac{-4.0\times10^{-6}\,\text{C}}{1.0\text{ m}}\right) \\ &= -27\text{ kV}. \end{aligned}$$

(b) The potential difference $V_b - V_a = -27\text{ kV} - 1\text{ kV} = -28\text{ kV}$. Thus the electric potential is higher at point a than at point b.
(c) We have

$$\begin{aligned} U_b &= q_3V_b = (3.0\,\mu\text{C})(-28\text{ kV}) \\ &= (3.0\times10^{-6}\,\text{C})(-28\times10^3\,\text{V}) = -8.4\times10^{-2}\,\text{J}. \end{aligned}$$

The work done is in the SI units of joules.

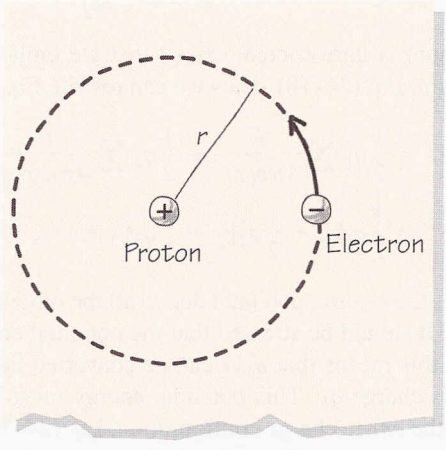
▲ FIGURE 24–6

What Do You Think? True or false: The sign of our result for the work that must be done in part (c) is wrong. *Answers to* ***What Do You Think?*** *questions are given in the back of the book.*

EXAMPLE 24–4 The classical model of a hydrogen atom in its normal, unexcited configuration has an electron that revolves around a proton at a distance of 5.3×10^{-11} m. What is the electric potential due to the proton at the position of the electron? Determine the electrostatic potential energy between the two particles. This energy is relevant to understanding the chemical activity of atoms.

Setting It Up We sketch this situation in Fig. 24–7.

Strategy The electric potential V_P due to the proton can be found by using Eq. (24–7), and we can subsequently find the electrostatic potential energy by using Eq. (24–15), $U = (-e)V_P$, where $-e$ is the electron charge.



Working It Out We have

$$V_P = \frac{+e}{4\pi\varepsilon_0 r} = \frac{(9.0 \times 10^9\ \text{N}\cdot\text{m}^2/\text{C}^2)(1.6 \times 10^{-19}\ \text{C})}{5.3 \times 10^{-11}\ \text{m}} = 27\ \text{V}.$$

In turn,

$$U = (-e)V_P = (-1.6 \times 10^{-19}\ \text{C})(27\ \text{V}) = -4.3 \times 10^{-18}\ \text{J}. \quad (24\text{–}20)$$

What Do You Think? What does the sign of U tell you about whether or not you must supply positive energy to separate the electron from the proton?

▲ **FIGURE 24–7** A simplistic representation of an electron that orbits a proton in the hydrogen atom.

The Electron-Volt

We have seen that the energy of a system is determined by multiplying charge by electrostatic potential. Because the charge on an electron is such a frequently used quantity, a useful unit of energy is that of the charge magnitude of an electron (or proton) times 1 V. We call this unit of energy an **electron-volt** (eV). An electron-volt is simply the energy an electron gains when it is accelerated though a potential difference of one volt. The electron-volt is not an SI unit. The relation between the electron-volt and the SI unit joule is

$$1\ \text{eV} = (1.6 \times 10^{-19}\ \text{C})(1\ \text{V}) = 1.6 \times 10^{-19}\ \text{J}.$$

The electron-volt is especially valuable for calculations in atomic, nuclear, and particle physics.

THINK ABOUT THIS. . .

IN WHAT REALM OF PHYSICS IS THE ELECTRON-VOLT A NATURAL UNIT?

As the name indicates, this is a unit of energy appropriate to an object with a charge comparable to that of an electron, moving in a potential of the magnitude of volts. It is in the atomic domain that we deal with particles whose charges are those of a single electron or proton, of the order of 10^{-19} C. We saw in Example 24–4 that the electrostatic potential energy between the proton and electron of the hydrogen atom is −27 eV. Chemical reactions involve the rearrangement of electrons among atoms, and in accordance with the result of Example 24–4, involve energies of the order of fractions of electron-Volts. This can translate into temperatures that are involved in chemical reactions, because energy can be expressed that way via the relation energy $= k_B T$, where k_B is Boltzmann's constant. As an example, consider the temperature at which paper burns, 451°F. This corresponds to 506K, and therefore to an energy of $E = (1.38 \times 10^{-23}\ \text{J/K})(506\text{K})/(1.6 \times 10^{-19}\ \text{J/eV}) = 4.4 \times 10^{-2}\ \text{eV}$. This number is much smaller than the ionization energy of hydrogen—the energy that must be supplied to remove the electron entirely—because rearrangements of electrons cost much less energy than stripping them off entirely.

In nuclear reactions the forces are much stronger than electrical ones, and distances are much shorter than typical atomic dimensions, and the natural unit is a million electron-volts, the MeV. For example, a typical "ionization energy" for nuclei—the energy required to remove a constituent particle from a nucleus—is 8 MeV, while rearrangement energies are in the hundreds of kilo-electron volts (keV).

EXAMPLE 24–5 Calculate the electric potential due to an electric dipole whose dipole moment has magnitude p at an arbitrary point Q. Work in the limit in which the distance of point Q from the dipole is much larger than the dipole length.

Setting It Up We draw the dipole in Fig. 24–8, which also contains some necessary geometrical and label information. In particular, the charges are $\pm q$, and they are separated by a distance $\ell = p/q$. The distances to the point P from the charges $\pm q$ are r and $r + \Delta r$, respectively.

Strategy A dipole consists of two pointlike charges, so Eq. (24–11)— superposition—determines the potential, which will be zero at infinity. We can see from the figure that point Q is specified in part by the angle between $\vec{p}$ and the line between the $-q$ charge and Q, and as the figure shows, Δr can be expressed in terms of that angle and the separation between the charges in the limit in which $r \gg \Delta r$, a limit that is equivalent to the limit that the distance to the dipole is much greater than the linear size of the dipole.

Working It Out Equation (24–11) gives

$$V = \frac{q}{4\pi\varepsilon_0 r} + \frac{-q}{4\pi\varepsilon_0(r + \Delta r)} = \frac{q}{4\pi\varepsilon_0}\left(\frac{1}{r} - \frac{1}{r + \Delta r}\right)$$
$$= \frac{q}{4\pi\varepsilon_0}\frac{(r + \Delta r) - r}{r(r + \Delta r)} = \frac{q}{4\pi\varepsilon_0}\frac{\Delta r}{r(r + \Delta r)}. \qquad (24\text{–}21)$$

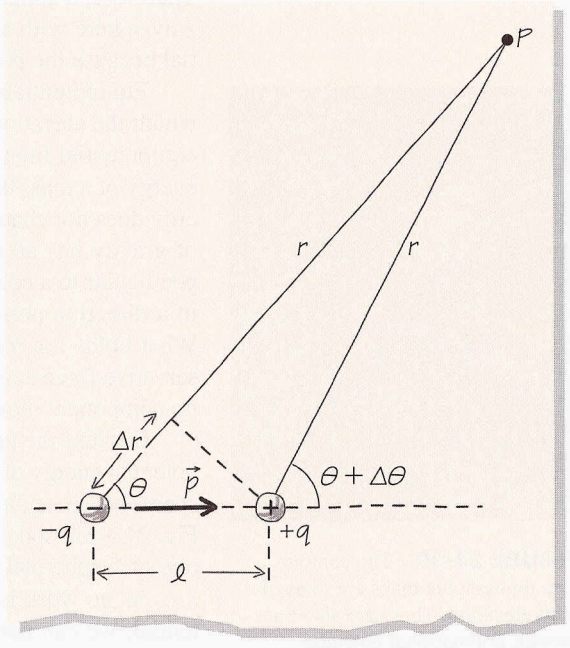
From the figure we see that in the large r limit the dotted line is normal to the longer line, so that

$$\Delta r = \ell \cos\theta = \frac{p \cos\theta}{q}. \qquad (24\text{–}22)$$

When this result is substituted into Eq. (24–21), we find

$$V = \frac{p \cos\theta}{4\pi\varepsilon_0}\left[\frac{1}{r(r + \ell \cos\theta)}\right] = \frac{pq \cos\theta}{4\pi\varepsilon_0}\left[\frac{1}{r(qr + p \cos\theta)}\right], \qquad (24\text{–}23)$$

where in the last step we have multiplied and divided by q.

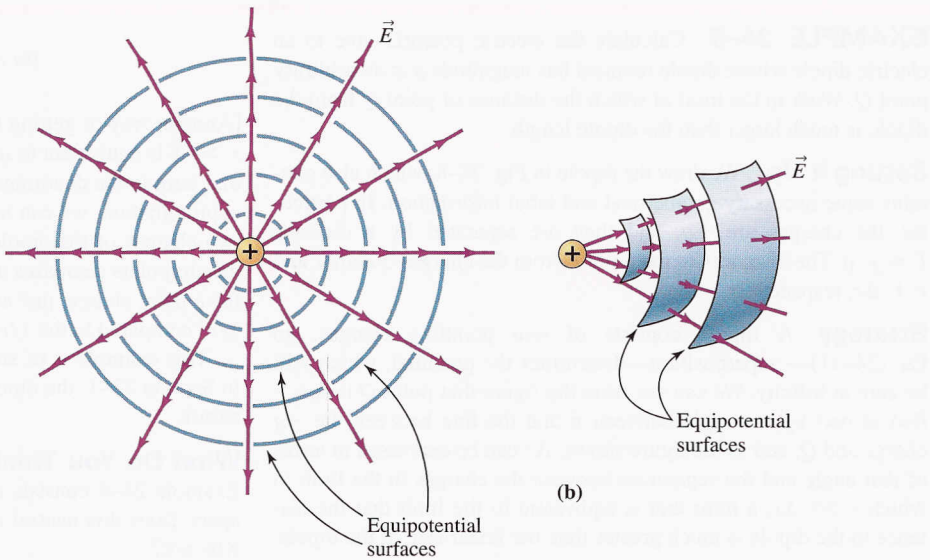


It is a mathematical exercise to calculate the electric dipole potential of Eq. (24–23) in the large r limit. While Eq. (24–23) is rather complicated, it takes a simple approximate form far from the dipole, when $r \gg \ell$. The easiest place to make an approximation is in Eq. (24–21), where we can use the fact that $\Delta r \ll r$. The numerator has one power of Δr, and if we want a calculation that is correct to first order in the small quantity Δr, we can drop the Δr in the denominator. From that point on we make our substitutions and end up with

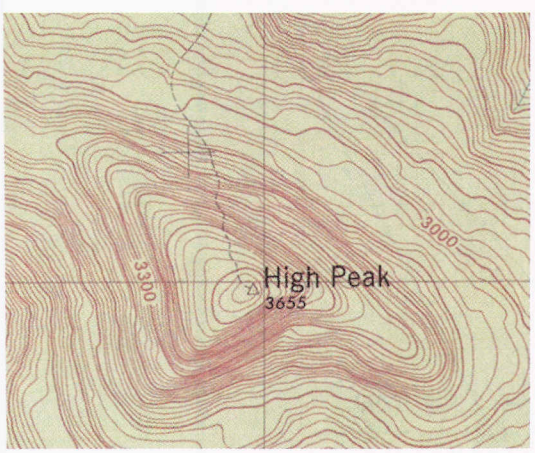
$$\text{for } r \gg \ell\text{: } V = \frac{p \cos\theta}{4\pi\varepsilon_0 r^2}. \qquad (24\text{–}24)$$

[Another way of getting the same result is to note that the condition $r \gg \ell$ is equivalent to $qr \gg q\ell = p$, so that we can drop the second term in the denominator of Eq. (24–23).] Because of the large r approximation, we can now measure θ from anywhere between the two charges of the dipole. Note that the potential of the dipole for distant points decreases as $1/r^2$, as compared to the $1/r$ dependence for a point charge, just as the electric field of the dipole falls off as $1/r^3$ compared to the $1/r^2$ dependence of the point charge.

This example is of some importance because, as we mentioned in Section 22–1, the dipole charge distribution occurs repeatedly in nature.



What Do You Think? Our picture of the hydrogen atom in Example 24–4 consists of a charge $+e$ and $-e$ a certain distance apart. Does this neutral atom give rise to a dipole field, and if not, why not?



▲ **FIGURE 24–8** Using geometry to find the potential at a point P for an electric dipole. The dipole moment $p = q\ell$.

24–3 Equipotentials

Regions for which the electric potential of a charge distribution has constant values are called **equipotentials**. They are particularly interesting and worth investigating—we shall see, for example, that the surfaces of conductors form equipotentials. Suppose that a system of charges produces a certain potential. The positions in space that have the same electric potential form surfaces in three dimensions and lines in two dimensions. We say that the places where the potential has a constant value form **equipotential surfaces** in three dimensions or **equipotential lines** in two dimensions. As an example, consider the equipotential surfaces formed by a point charge. The electric potential is proportional to $1/r$ and has a constant value at any fixed radial distance from the charge.

▶ **FIGURE 24–9** (a) The equipotential surfaces for a point charge in a two-dimensional representation. (b) The full three-dimensional representation; the equipotential surfaces are spheres centered on the charge.

▲ **FIGURE 24–10** The contour lines on topographic maps are lines of constant elevation. These are also lines of constant gravitational potential energy. The force of gravity has no component *along* contour lines, only perpendicular to them.

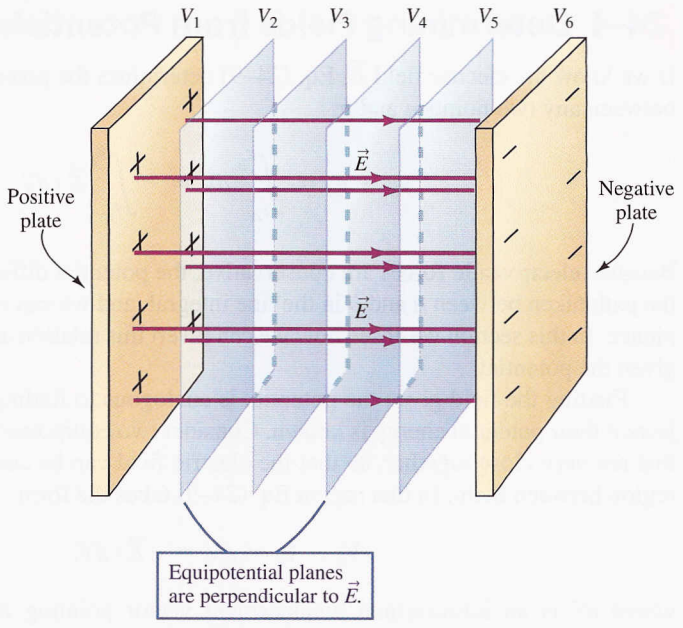
Therefore, a sphere centered on the charge forms an equipotential surface (Fig. 24–9). Any sphere with a different radius centered on the charge forms a different equipotential because the potential varies only with the radius of the sphere.

Equipotentials are analogous to contour lines on a topographic map—lines for which the elevation from sea level is constant (Fig. 24–10). The lines on such maps are equipotential lines for the potential energy of local gravity. The gravitational potential energy of a mass depends only on the mass's elevation, so the gravitational potential energy does not change when a mass moves along a contour line. Consequently, the force of gravity has no component along contour lines. Gravity only has a component perpendicular to a contour line; a ball that starts on a particular contour line will accelerate in a direction perpendicular to the line, or what we would call straight down the hill. What holds for contour lines holds for any equipotential surface or line, and any conservative force acts in a direction perpendicular to the equipotential because it can have no component along the equipotential.

Because the potential has exactly the same value along an equipotential, so does the potential energy of a test charge. No work is done when the test charge moves at constant speed on an equipotential surface or line. The equipotentials for the point charge in Fig. 24–9 are spheres centered on the charge, and a test charge can move freely about any one such spherical surface without work being done by the electric field.

As no work is done by the electric force when a test charge moves on an equipotential, we can understand why the electric field does not have a component along an equipotential surface. If it did, then that component of the electric field would do work to move a charge on the equipotential surface, which is not possible. Thus

the electric field is everywhere perpendicular to the equipotential surface.

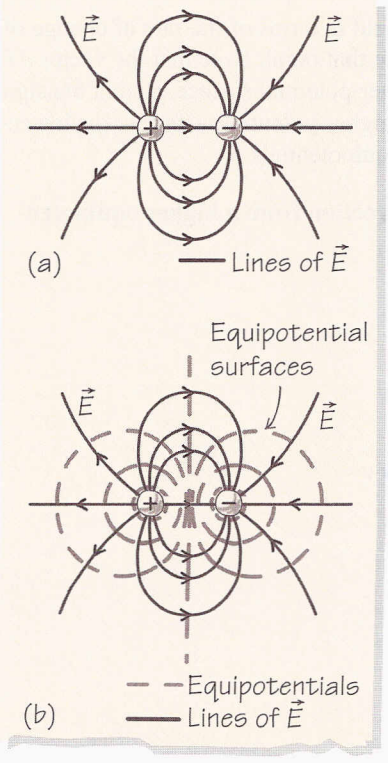


Furthermore, because all the charge on a conductor in equilibrium resides on the surface, a potential difference between two points on the surface would be quickly equalized by a flow of free charge, so

the surface of a conductor is an equipotential.

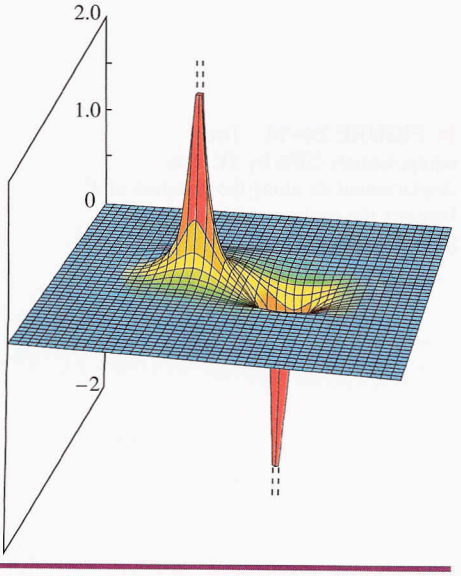
The same reasoning shows that in static equilibrium the entire conductor will be at that same electric potential—there is no field within the conductor, so it takes no work to move a charge through it.

Electric Field Lines from Equipotentials and Vice Versa



The fact that the electric field and the equipotentials are everywhere perpendicular to each other is helpful in finding equipotential surfaces if the field is known, and in finding the electric fields if the equipotentials are known. We illustrate this process for some charge

◀ **FIGURE 24–11** The electric field lines (burgundy) and the equipotentials (blue) for two oppositely charged parallel plates.



configurations for which the fields are known. We have already seen how the equipotential surfaces of a point charge are perpendicular to the (radial) electric field. For another example, this time starting from known field lines, consider two oppositely charged plates, for which the field lines are as in Fig. 24–11. The equipotential surfaces are perpendicular to these lines, and hence form planes parallel to the charged plates. If the charged plates are conductors, then they must also be equipotential surfaces. Thus we have a series of n equipotential planes $V_1, V_2, V_3, \ldots, V_n$ between and including the two charged plates.

CONCEPTUAL EXAMPLE 24–6 Sketch the equipotentials for an electric dipole given the field lines shown in Fig. 24–12a.

◀ **FIGURE 24–12** (a) The electric field lines for an electric dipole. (b) The equipotentials are drawn as dashed lines.

Answer Starting from Fig. 22–12a, we draw our equipotential surfaces everywhere perpendicular to the electric field lines, arriving at the dashed lines shown in Fig. 24–12b. These lines represent the locations in the plane of the page where the equipotential surfaces cut the page. You can visualize them in three dimensions as a series of nested but not concentric closed surfaces—each is a sort of flattened sphere—that encircles each charge. By sketching in this way we can visualize what the equipotential surfaces are like, even without using the algebraic form of the electric dipole potential derived in Example 24–5. A computer-generated drawing of the dipole potential is shown in Fig. 24–13.

▶ **FIGURE 24–13** The dipole potential. Height represents the potential here.

24–4 Determining Fields from Potentials

If we know the electric field $\vec{E}$, Eq. (24–9) determines the potential difference $V_b - V_a$ between any two points a and b:

$$V_b - V_a = \int_{r_a}^{r_b} dV = -\int_{r_a}^{r_b} \vec{E} \cdot d\vec{s}.$$

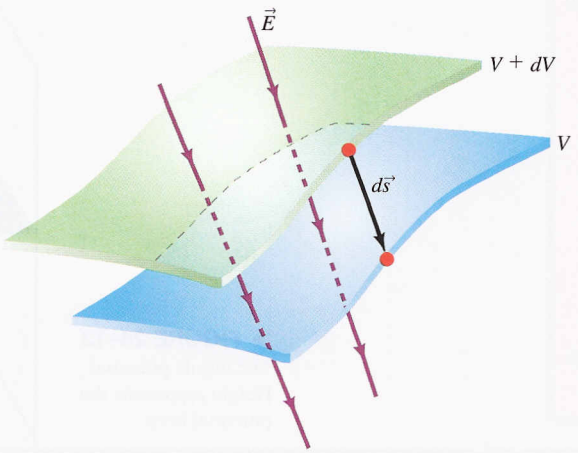
Because electrostatic forces are conservative, the potential difference is independent of the path taken between a and b in the line integral, and we can choose a path for convenience. In this section we'll see how we can invert this relation and find the electric field given the potential.

Finding the field given the potential is analogous to finding the force between objects if their potential energy is known. Consider two equipotentials, labeled by b and a, that are very close together, so that the electric field can be considered constant in the region between them. In that region Eq. (24–9) takes the form

$$V_b - V_a = dV = -\vec{E} \cdot d\vec{s}, \tag{24–25}$$

where $d\vec{s}$ is an infinitesimal displacement vector pointing from equipotential a to equipotential b. (Actually, this relationship is true for any $d\vec{s}$ connecting the equipotentials, even a large displacement, as long as the electric field can be treated as constant along the displacement.)

It is simplest to take our infinitesimal path as in Fig. 24–14, with $d\vec{s}$ perpendicular to the two equipotential surfaces. As the electric field also points in that direction, Eq. (24–25) reads



$$dV = -E\, ds.$$

Equivalently,

$$E = -\frac{dV}{ds}. \tag{24–26}$$

This equation gives the magnitude of the electric field in terms of the rate of change of V in a direction perpendicular to the equipotential at that point. Note that the vector $d\vec{s}$ pointed from the lower-potential surface to the higher-potential surface, so that the sign in Eq. (24–26) shows that the field points from the higher-potential surface to the lower-potential surface. In summary, for closely spaced equipotentials,

the electric field points along the shortest direction from a higher equipotential to a lower one.

▶ **FIGURE 24–14** Two equipotentials differ by dV. The displacement $d\vec{s}$ along the direction of $\vec{E}$ between the equipotentials is perpendicular to them.

How the Potential Determines the Field in Cartesian Coordinates

For a different point of view, suppose that an arbitrary displacement vector $d\vec{s}$ is decomposed into Cartesian coordinates:

$$d\vec{s} = dx\,\hat{i} + dy\,\hat{j} + dz\,\hat{k}.$$

Here $\hat{i}$, $\hat{j}$, and $\hat{k}$ are the unit vectors in the x-, y- and z-directions, respectively. Then the scalar product in Eq. (24–25) takes the form

$$dV = -\vec{E}\cdot d\vec{s} = -E_x\,dx - E_y\,dy - E_z\,dz, \tag{24–27}$$

where we have separated the field $\vec{E}$ into its Cartesian components. In general, the potential depends on all three space coordinates, $V = V(x, y, z)$. The change in V in going from an initial position $\vec{r} = x\hat{i} + y\hat{j} + z\hat{k}$ to a new position $\vec{r} + d\vec{s} = (x + dx)\hat{i} + (y + dy)\hat{j} + (z + dz)\hat{k}$ is

$$dV = \frac{\partial V}{\partial x}dx + \frac{\partial V}{\partial y}dy + \frac{\partial V}{\partial z}dz. \tag{24–28}$$

Note the use of the partial derivatives here; this is necessary because V depends on all three Cartesian coordinates. Recall that partial derivatives are simple to use: The partial derivative with respect to x means that y and z are held fixed while the ordinary derivative with respect to x is taken. To illustrate, if $V = xz^2$, then $\partial V/\partial x = z^2$, $\partial V/\partial y = 0$, and $\partial V/\partial z = 2zx$. We can equate the coefficients of dx, dy, and dz in Eqs. (24–27) and (24–28):

$$E_x = -\frac{\partial V}{\partial x}, \quad E_y = -\frac{\partial V}{\partial y}, \quad E_z = -\frac{\partial V}{\partial z}.$$

Equivalently, *the electric field vector is given in terms of derivatives of the electric potential* by

$$\vec{E} = -\hat{i}\frac{\partial V}{\partial x} - \hat{j}\frac{\partial V}{\partial y} - \hat{k}\frac{\partial V}{\partial z}. \tag{24–29}$$

THE FIELD IN TERMS OF THE POTENTIAL

Equation (24–29) gives the Cartesian components of the electric field in terms of the potential. We have found a way to express a particular vector, the electric field, in terms of the derivatives of a scalar, the electric potential. It can be simpler to calculate the electric field of a charge distribution by first finding the potential and then differentiating, rather than doing a vector integration to get the field.

EXAMPLE 24–7 Use the electric potential of a point charge q to find its electric field.

Setting It Up Specifying the electric field means finding both its magnitude and its direction.

Strategy From the discussion above, we know that the direction of the electric field is perpendicular to the equipotential surfaces, pointing from a region of higher to lower potential. Here the potential is a function only of the radial distance from the charge, $V = q/4\pi\varepsilon_0 r$. The equipotential surfaces are therefore spheres at a constant distance from the charge. This means that the electric field lines point in the radial direction, and they point from higher potential (smaller r) to lower potential (larger r), that is, outward. We can find the magnitude of the field by using Eq. (24–26).

Working It Out We know already that the direction is the *outward radial direction*, and the magnitude is

$$E = -\frac{dV}{dr} = -\frac{q}{4\pi\varepsilon_0}\frac{d}{dr}\left(\frac{1}{r}\right) = \frac{q}{4\pi\varepsilon_0 r^2}.$$

Although we already know this answer from previous discussion, the technique is useful in contexts where we do not already know the answer!

24–5 The Potentials of Charge Distributions

We rarely deal with the electric field and potential of a single point charge. More often, we have collections of charges spread over regions of space, as when charges spread over the surface of a metal, or when the field of a complicated ionic molecule determines its chemical or biological behavior. We must therefore be able to find the potentials of continuous charge distributions. These charge distributions may not be simple ones, and we must develop strategies for calculating the corresponding electric potentials. In this section, we first summarize the underlying techniques, then illustrate them with a series of examples.

The qualitative shapes of equipotential surfaces due to a charge distribution are most easily found by graphical techniques. For quantitative calculations, we have learned two different ways to determine the electric potential of a charge distribution:

1. If the electric field is known, then Eq. (24–9) can be used to determine the potential:

$$\Delta V = V_b - V_a = -\int_{r_a}^{r_b} \vec{E} \cdot d\vec{s}.$$

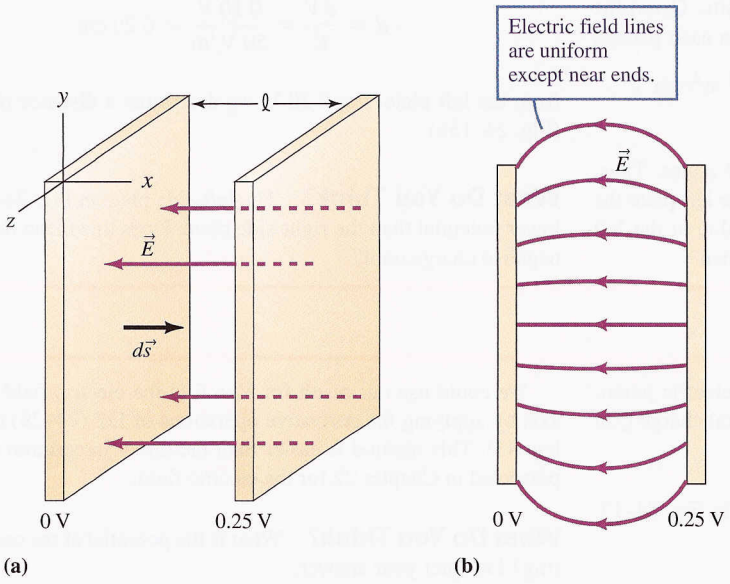
2. If the electric field is not known, we may calculate the potential directly by using one of various forms:

for one point charge, Eq. (24–7): $V = \dfrac{q}{4\pi\varepsilon_0 r}$;

for many point charges, Eq. (24–11): $V = \dfrac{1}{4\pi\varepsilon_0}\sum_i \dfrac{q_i}{r_i}$;

for a continuous charge distribution, Eq. (24–12): $V = \dfrac{1}{4\pi\varepsilon_0}\displaystyle\int \frac{dq}{r}$.

In a direct calculation of electric potential, we must decide the location of zero potential. In fact, the convention that zero potential is at infinity is already implicit in Eqs. (24–7), (24–11), and (24–12), and is almost always the most convenient choice for a charge distribution that does not extend all the way to infinity. If a potential *difference* is calculated directly, no decision need be made about the zero level.



Examples

Let's first look at the relation between electric field and potential for two parallel conducting plates (a *parallel-plate capacitor*, a circuit device to be revisited in Chapter 25), each brought to different potentials (Fig. 24–15a). We suppose that the plates are close enough together or large enough that we can ignore the distortions of the field near the edges, as shown in Fig. 24–15b. In Fig. 24–15a, the left-hand plate is at a lower potential than the right-hand plate. The electric field between parallel plates is known to be constant, and it runs from regions of higher potential to lower potential—from right to left in this case. In Eq. (24–9), we take the path to be a straight line from the left to the right plate, so that $\vec{E}$ is antiparallel to $d\vec{s}$. We will let the direction from left to right define the x-axis, with the left plate at $x = 0$. Then the potential difference between the plates is given in terms of the field E between the plates and the separation ℓ of the plates by

$$\Delta V = V_{\text{right}} - V_{\text{left}} = -\int_{\text{left}}^{\text{right}} \vec{E} \cdot d\vec{s} = +E\int_0^{\ell} dx = E\ell,$$

and the electric field between parallel plates has magnitude

$$E = \frac{\Delta V}{\ell}. \tag{24–30}$$

▲ **FIGURE 24–15** (a) Two parallel plates, viewed from the side, with a potential difference between them. A differential displacement $d\vec{s}$ is indicated. (b) The fields do show distortions at the edges for a real (not infinitely large) pair of plates.

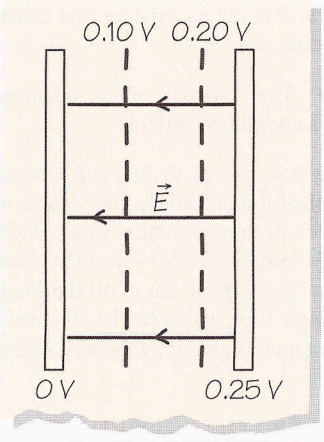
Equation (24–30) and the preceding discussion yield an important practical result:

> **The magnitude of the constant electric field between parallel conducting plates is the potential difference between the plates divided by the distance between the plates. It points from the higher to the lower potential plate.**

This result gives the electric field between two parallel-plane conducting plates whose potential difference is ΔV. We can also use it to find the equipotential surfaces associated with *any* constant field. These surfaces are planes perpendicular to the field, and the potential difference for a plane a distance ℓ from a reference equipotential changes *linearly* with ℓ, $\Delta V = E\ell$. Note the sign: The potential decreases along the direction in which the electric field points.

EXAMPLE 24–8 Two parallel metal plates carrying equal and opposite charges have area $A = 225\ \text{cm}^2$ and are separated by 0.50 cm. There is a potential difference of 0.25 V between them. Find the numerical value of the electric field. What is the charge density and total charge on each plate? Draw the equipotential surfaces at 0.10 V and 0.20 V.

Setting It Up Figure 24–15a labels axes and places the plates within them. We call ΔV the given potential difference between the plates and ℓ the known separation.



Strategy Equation (24–30) directly applies here and allows us to calculate the magnitude of the electric field. The field points from the higher to the lower potential plate. Given the electric field, we can calculate the charge density, since $E = \sigma/\varepsilon_0$, and given the area, we can calculate the total charge on each plate.

Working It Out

$$E = \frac{\Delta V}{\ell} = \frac{0.25\ \text{V}}{0.0050\ \text{m}} = 50\ \text{V/m},$$

and it points from right to left in Fig. 24–16. Since the electric field between the plates is σ/ε_0,

$$\sigma = E\varepsilon_0 = (50\ \text{V/m})(8.85 \times 10^{-12}\ \text{C}^2/\text{N}\cdot\text{m}^2)$$
$$= 4.4 \times 10^{-10}\ \text{C/m}^2.$$

▲ **FIGURE 24–16** The electric field for parallel plates points from right to left when the potential of the left-hand plate is lower than that of the right-hand plate.

(continues on next page)

The answer is in coulombs per square meter—SI units. Given the area of the plates, the magnitude of the total charge on each plate is

$$Q = \sigma A = (4.4 \times 10^{-10}\ \text{C/m}^2)(225\ \text{cm}^2)(10^{-4}\ \text{m}^2/\text{cm}^2) = 1.0 \times 10^{-11}\ \text{C}.$$

The electric field is constant between the parallel plates. Thus, from Eq. (24–30), we find that at a distance d from the left plate the potential differs by an amount $\Delta V = Ed$ from its value at the left plate, $d = 0$. The equipotential surface for 0.10 V is then

$$d = \frac{\Delta V}{E} = \frac{0.10\ \text{V}}{50\ \text{V/m}} = 0.20\ \text{cm}$$

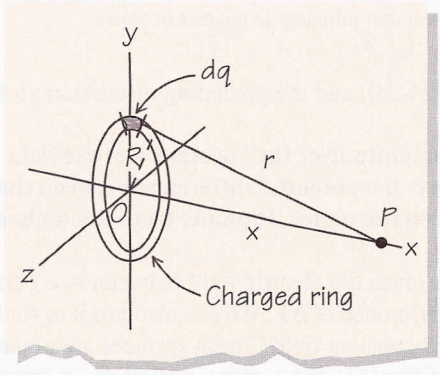
from the left plate. For 0.20 V, we determine a distance of 0.40 cm (Fig. 24–15b).

What Do You Think? The left-side plate in Fig. 24–15 is at a lower potential than the right-side plate. Does this mean that it has a negative charge on it?

EXAMPLE 24–9 *The Charged Ring.* Find the electric potential due to a uniformly charged ring of radius R and total charge Q at a point P on the axis of the ring.

Setting It Up The charge distribution is shown in Fig. 24–17, together with point P and a distance labelled r.

Strategy Symmetry plays an important role in the solution, with each point on the ring the same distance $r = \sqrt{R^2 + x^2}$ from the point P. The potential due to an infinitesimal section of the ring that carries charge dq is given by $dV = \dfrac{dq}{4\pi\varepsilon_0}\dfrac{1}{\sqrt{R^2 + x^2}}$. An integration of this yields the answer—the integration is simple because of the fact that each point on the ring is the same distance from P.



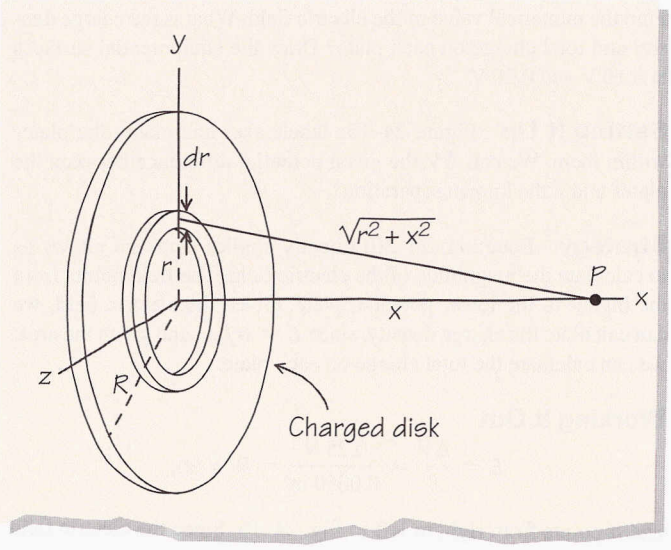
Working It Out The integral expressing the potential is

$$V = \int dV = \int \frac{dq}{4\pi\varepsilon_0}\frac{1}{\sqrt{R^2 + x^2}} = \frac{1}{4\pi\varepsilon_0}\frac{1}{\sqrt{R^2 + x^2}}\int dq = \frac{Q}{4\pi\varepsilon_0}\frac{1}{\sqrt{R^2 + x^2}}. \qquad (24\text{–}31)$$

In the second to last step, we have removed the constant distance r from the integral, leaving an integral over dq, which gives the total charge Q.

We could use our result for V to find the electric field along the axis by applying the derivative operations of Eq. (24–29) (see Problem 43). This method is easier than the direct integration technique presented in Chapter 22 for the electric field.

What Do You Think? What is the potential at the center of the ring? Interpret your answer.



▲ **FIGURE 24–17** Geometry to find the potential at a point P on the axis of a charged ring of radius R by using a differential charge dq.

EXAMPLE 24–10 *The Charged Disk.* Find the electric field due to a thin, flat, uniformly charged disk of radius R and total charge Q at a point P along its axis, by first calculating the electric potential at this point.

Setting It Up The geometry of the situation is shown in Fig. 24–18, including a coordinate system.

Strategy The first task is to find the potential. Figure 24–18 contains in a nutshell the procedure that we can use: We divide the disk up into a series of thin concentric rings. We know the potential for a single ring from Example 24–9, and the potential of the disk is obtained by summing the potential of all the rings. We first require the charge on a single ring, which can be obtained by calculating the charge density and multiplying it by the area of the strip.

▶ **FIGURE 24–18** Geometry to find the potential at a point P on the axis of a charged disk of radius R. The potential due to the ring of radius r and width dr is first found and then integrated.

For the second part of the problem we can find the field given the potential by taking the appropriate derivative of the potential. Symmetry is helpful here: You can see that along the axis the electric field can only have an x-component. The reason is that a component in a direction perpendicular to the x-axis coming from any point on any of the concentric rings will have an equal and opposite component coming from the point on the ring at the opposite side of that ring.

Working It Out The charge density is $\sigma = Q/\pi R^2$. The area of a ring with inner and outer radius r and $r + dr$ respectively is $dA = \pi(r + dr)^2 - \pi r^2 \cong 2\pi r\, dr$ for infinitesimal dr and the charge on the ring is then $\sigma(2\pi r\, dr)$. From Example 24–9, the potential due to the ring on the axis is

$$dV = \frac{\sigma(2\pi r\, dr)}{4\pi\varepsilon_0}\frac{1}{\sqrt{r^2 + x^2}}$$

The potential for the whole disk is obtained by summing the potentials from all the rings, i.e. integrating this result from $r = 0$ to $r = R$:

$$V = \int dV = \int_0^R \frac{\sigma}{4\pi\varepsilon_0}\frac{1}{\sqrt{r^2 + x^2}}(2\pi r\, dr)$$
$$= \frac{\sigma}{2\varepsilon_0}\int_0^R \frac{r\, dr}{\sqrt{r^2 + x^2}}$$
$$= \frac{\sigma}{2\varepsilon_0}\sqrt{r^2 + x^2}\Big|_0^R = \frac{\sigma}{2\varepsilon_0}\left(\sqrt{R^2 + x^2} - x\right)$$
$$= \frac{Q}{2\pi\varepsilon_0 R^2}\left[\sqrt{R^2 + x^2} - x\right]. \qquad (24\text{–}32)$$

In turn, the only component of the electric field is

$$E_x = -\frac{\partial V}{\partial x} = -\frac{Q}{2\pi\varepsilon_0 R^2}\left(\frac{x}{\sqrt{R^2 + x^2}} - 1\right).$$

What Do You Think? The result for the x-component of the field for $x \gg R$ is (a) $\sigma x/(2\varepsilon_0)$; (b) $\sigma/(2\varepsilon_0 x)$; (c) $Q/(4\pi\varepsilon_0 x)$; (d) $(Q/4\pi\varepsilon_0 x^2)$?

EXAMPLE 24–11 *The Charged Line.*

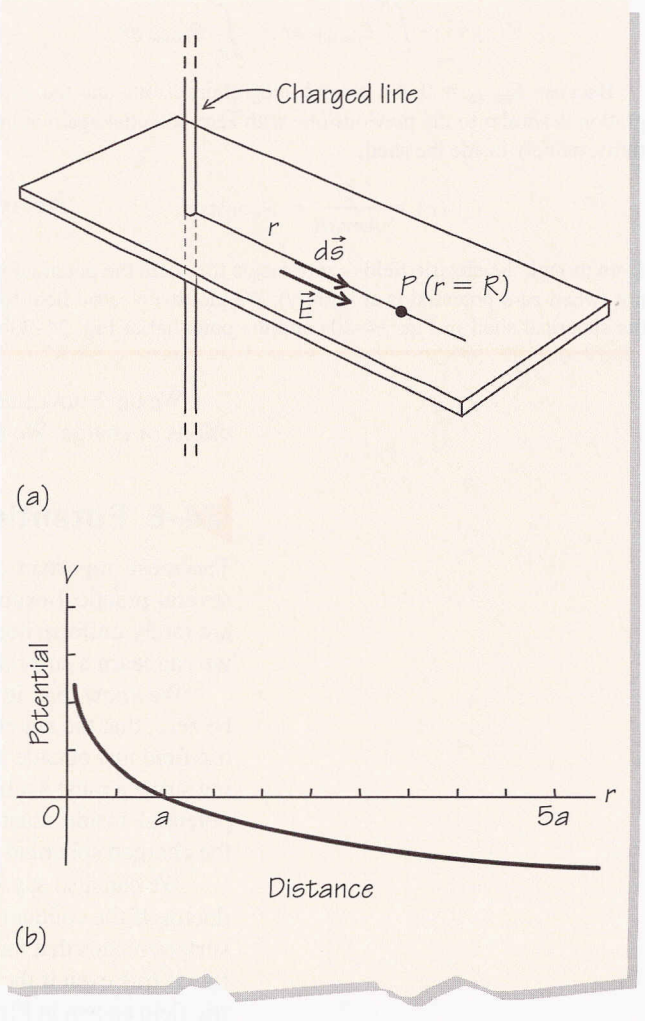
Find the electric potential as a function of the radial distance R from an infinite charged line of uniform charge density λ.

Strategy We found the field for this charge configuration earlier [Eq. (22–32)], and we can here use Eq. (24–9) to find the potential from the electric field. Since the electric field has only a radial component, we integrate along a radial direction in Eq. (24–9), that is, $d\vec{s} = d\vec{r}$ in Fig. 24–19a.

Working It Out Equation (24–9) becomes

$$\Delta V = -\int E_r\, dr = -\frac{\lambda}{2\pi\varepsilon_0}\int \frac{dr}{r}.$$

The potential difference depends on the end points of the integration. Let zero potential be at $r = a$, so that



$$\Delta V = V_R - V_a \equiv V = -\frac{\lambda}{2\pi\varepsilon_0}\int_a^R \frac{dr}{r} = -\frac{\lambda}{2\pi\varepsilon_0}\ln r\Big|_a^R,$$

or

$$V = -\frac{\lambda}{2\pi\varepsilon_0}\ln\frac{R}{a}. \qquad (24\text{–}33)$$

Note that it is not possible to set zero potential at infinity in this case because the logarithm is infinite at $a = \infty$. Physically, this is because the line itself reaches to infinity. We graph the potential of Eq. (24–33) in Fig. 24–19b, assuming that the charge of the line is positive.

What Do You Think? It is not possible to do this calculation directly by putting the charge along the z-axis, then calculating the potential by integrating the potential $\lambda\, dz/\left(4\pi\varepsilon_0\sqrt{R^2 + z^2}\right)$ due to a charge $\lambda\, dz$ a distance $\sqrt{R^2 + z^2}$ away from the point P. Why?

▶ **FIGURE 24–19** (a) An infinite charged line has a radial electric field. To find the potential at the point P, we consider a displacement $d\vec{s}$ in the direction of the electric field $\vec{E}$ and use the known expression for the electric field. (b) The resulting potential, defined to be zero at $r = a$, goes to positive infinity at $r = 0$ and continues to negative infinity for large r.

EXAMPLE 24–12 *The Charged Spherical Shell.* Find the potential for a uniformly charged spherical shell of total charge Q and radius R at positions both inside and outside the shell. Set zero potential at infinity.

Strategy As in the previous example, we can best work backwards from the electric field to the potential. We already know the electric field of the spherical shell from Example 23–4 and can use Eq. (24–9) to determine the electric potential, or more precisely a potential difference. But as zero potential is set at infinity, the potential $V(r)$ is the potential difference $\Delta V = V(r) - V(\infty)$. From Example 23–6, we have

$$\text{outside a spherical shell, } r > R: \quad E = \frac{Q}{4\pi\varepsilon_0 r^2};$$

$$\text{inside a spherical shell, } r < R: \quad E = 0.$$

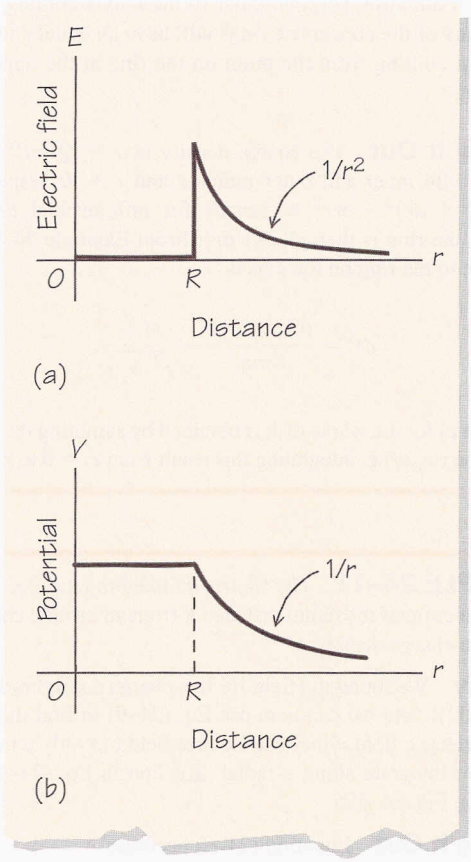
We must integrate these to find the potential.

Working It Out The electric field is purely radial, so by choosing a radial path from ∞ to a radial position r, we have in Eq. (24–9) $\vec{E} \cdot d\vec{s} = E\,dr$. Then for a point *outside* the spherical shell,

$$V(r) = V(r) - V(\infty) = -\int_{\infty}^{r} E\,dr = -\frac{Q}{4\pi\varepsilon_0}\int_{\infty}^{r}\frac{dr}{r^2}$$

$$= \frac{Q}{4\pi\varepsilon_0}\left(\frac{1}{r} - \frac{1}{\infty}\right) = \frac{Q}{4\pi\varepsilon_0 r} \qquad (24\text{–}34)$$

If r is *inside* the shell, we have



$$V(r) = -\int_{\infty}^{R} E_{\text{outside}}\,dr - \int_{R}^{r} E_{\text{inside}}\,dr.$$

Because $E_{\text{inside}} = 0$, the second integral drops out, and the integration is similar to the previous one with zero potential again at infinity, namely inside the shell,

$$V(r) = \frac{Q}{4\pi\varepsilon_0 R} = \text{a constant.} \qquad (24\text{–}35)$$

Even though the electric field is zero inside the shell, the potential is not (when zero potential is at infinity). We plot the electric field for the spherical shell in Fig. 24–20a and the potential in Fig. 24–20b.

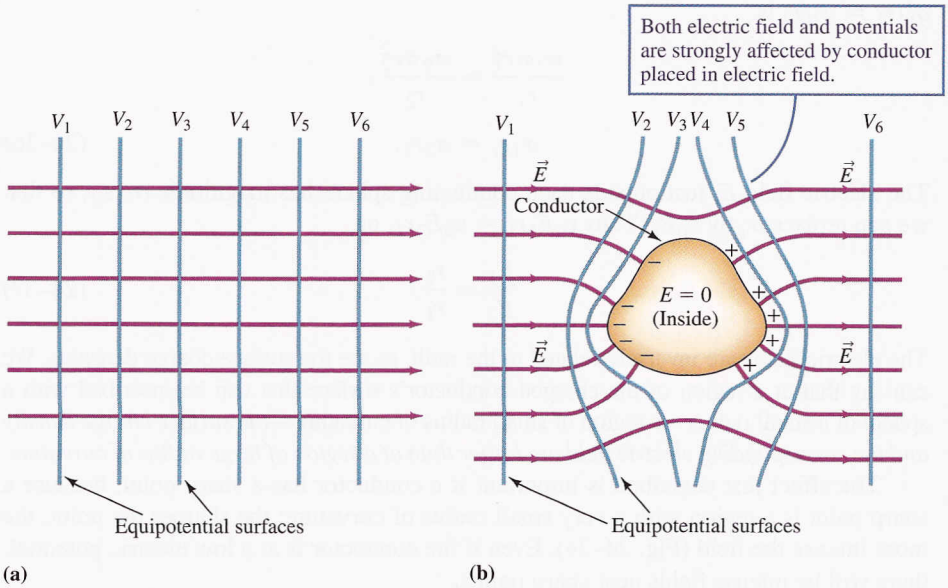
What Do You Think? How is the fact that the field is zero inside the shell consistent with a potential that is not zero?

▲ **FIGURE 24–20** (a) The electric field and (b) electric potential for a spherical shell of radius R. Even though the electric field is zero inside the shell, the potential has a constant value equal to that on the shell's surface.

We have now calculated the electric field and potential for several different distributions of charge. We summarize these results in Table 24–1.

24–6 Potentials and Fields Near Conductors

The most important cases of continuous charge distributions are those on metals; for several practical examples you can glance ahead to Section 24–7. These distributions are rarely uniform because charges are free to move on and within metals. Despite this, we can learn a surprising amount about the electric potentials near metals.



We know that, in electrostatics, the electric field inside a conducting material must be zero, that the net charge on a conductor lies on the outside surface, and that the electric field just outside that surface must be normal to the surface. Moreover, the conducting surface must itself be an equipotential and, as there is a zero electric field inside, the potential inside must have the same value as it has at the surface. Example 24–12, the charged spherical shell, provides an illustration of these features.

We can also say something about properties of the electric potential outside a conductor. If the conductor is charged, the fact that the electric field is perpendicular to the surface means that the equipotentials near the surface will be parallel to the surface, and this is true even if the conductor is uncharged. Consider, for example, the constant electric field shown in Fig. 24–21a due to two parallel plates (not shown). If we place an uncharged conductor of arbitrary size in this electric field, the field around the conductor

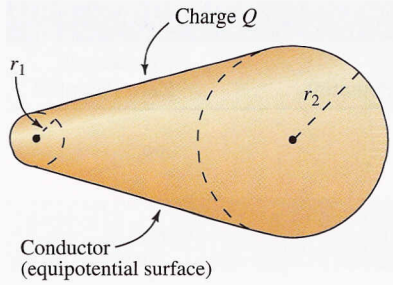


TABLE 24–1 • Electric Fields and Potentials for Various Charge Configurations

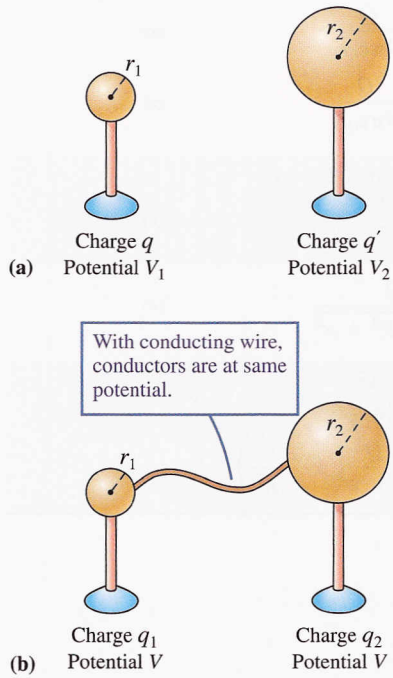
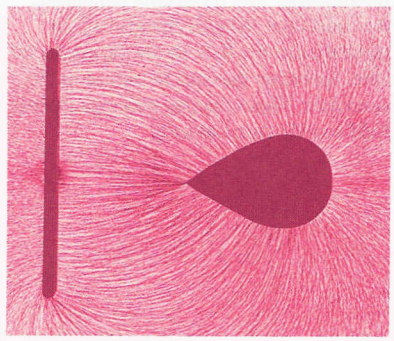
Charge Configuration	Magnitude of Electric Field	Electric Potential	Location of Zero Potential
Point charge	$\frac{q}{4\pi\varepsilon_0 r^2}$	$\frac{q}{4\pi\varepsilon_0 r}$	∞
Infinite line of uniform charge density λ	$\frac{\lambda}{2\pi\varepsilon_0 r}$	$-\frac{\lambda}{2\pi\varepsilon_0}\ln\frac{r}{a}$	$r = a$
Parallel, oppositely charged plates of uniform charge density σ, separation d	$\frac{\sigma}{\varepsilon_0}$	$\Delta V = -Ed = -\frac{\sigma d}{\varepsilon_0}$	anywhere
Charged disk of radius R, along axis at distance x	$\frac{Q}{2\pi\varepsilon_0 R^2}\left(\frac{\sqrt{R^2 + x^2} - x}{\sqrt{R^2 + x^2}}\right)$	$\frac{Q}{2\pi\varepsilon_0 R^2}\left(\sqrt{R^2 + x^2} - x\right)$	∞
Charged spherical shell of radius R	$r \geq R$: $\frac{Q}{4\pi\varepsilon_0 r^2}$	$r \geq R$: $\frac{Q}{4\pi\varepsilon_0 r}$	∞
	$r < R$: 0	$r \leq R$: $\frac{Q}{4\pi\varepsilon_0 R}$	∞
Electric dipole	Along bisecting axis only, far away: $\frac{p}{4\pi\varepsilon_0 r^3}$	Everywhere, far away: $\frac{p\cos\theta}{4\pi\varepsilon_0 r^2}$	∞
Charged ring of radius R, along axis	$\frac{Qx}{4\pi\varepsilon_0(R^2 + x^2)^{3/2}}$	$\frac{Q}{4\pi\varepsilon_0\sqrt{R^2 + x^2}}$	∞
Uniformly charged nonconducting solid sphere of radius R	$r \geq R$: $\frac{Q}{4\pi\varepsilon_0 r^2}$	$r \geq R$: $\frac{Q}{4\pi\varepsilon_0 r}$	∞
	$r < R$: $\frac{Qr}{4\pi\varepsilon_0 R^3}$	$r < R$: $\frac{Q}{8\pi\varepsilon_0}\left(3 - \frac{r^2}{R^2}\right)$	∞



will be greatly modified (Fig. 24–21b). Charge will be induced on the outside of the conductor in equilibrium, thereby forcing the electric field to be normal to the conducting surface and, again, *the equipotential surfaces near a conductor of arbitrary shape are parallel to the conductor's surface.*



◀ **FIGURE 24–21** (a) A uniform electric field before an uncharged conductor is placed in the field. (b) Afterward, the electric field is changed dramatically, with no electric field inside the conductor. Induced charges, which make the electric field inside the conductor zero, appear on the outside surface of the conductor. These charges affect the electric field outside the conductor.

▲ **FIGURE 24–22** A conductor of irregular shape can be modeled by spheres of radii r_1 and r_2 at its ends.

▲ **FIGURE 24–23** (a) Two conductors initially are at different potentials. (b) If the conductors are connected by a wire, charge must flow to make the potential equal everywhere throughout the connected conductors.

▲ **FIGURE 24–24** The electric field near small radii of curvature can be quite large, as seen for the point of this charged object.

There is a last important result to consider: Charge density on a conductor will vary if the surface has an irregular shape. In the next subsection we shall see how the concept of potential allows us to say more about the charge density and hence the fields near irregularly shaped charged conductors.

The Role of Sharp Points on Conducting Surfaces

Many real conductors have irregular shapes and the shape of a conductor affects the electric field in its vicinity. Consider the irregular conductor shown in Fig. 24–22. To simplify its analysis, we can think of the two ends shown as approximated by sections of spheres with radii r_1 and r_2, respectively. The left region is more sharply curved than the right region, so $r_1 < r_2$. We model this conductor with a two-step process; for the first step, we consider the field and potential for the two spherical conductors shown in Fig. 24–23a. The sizes of these spheres match the two ends of our irregular conductor (Fig. 24–22). The charges q and q' are placed on the two spheres, and the electric potentials at the spheres are, respectively,

$$V_1 = \frac{q}{4\pi\varepsilon_0 r_1} \quad \text{and} \quad V_2 = \frac{q'}{4\pi\varepsilon_0 r_2}.$$

If we now connect the two spheres by a long conducting wire (Fig. 24–23b), charge will flow between the two spheres, and the entire system will come to the same potential. This potential is

$$V = \frac{q_1}{4\pi\varepsilon_0 r_1} = \frac{q_2}{4\pi\varepsilon_0 r_2},$$

where q_1 and q_2 are the equilibrium charges on the two spheres. Since the entire connected object is at a single potential, these charges and radii must be related by

$$\frac{q_1}{r_1} = \frac{q_2}{r_2}.$$

In this discussion we did not use the fact that the spheres are connected by a thin wire, only that they are connected; this is the information that ensures that the entire system is at a single potential. Therefore this calculation will apply to our irregular conductor (Fig. 24–22). In particular, the connected spheres form a model for the relative size of the electric fields at the two ends of the conductor.

Let us now relate what we have done to the surface charge density σ. For a sphere of radius r this quantity is the charge q on the sphere divided by the surface area: $\sigma = q/(\pi r^2)$, or $q = \sigma\pi r^2$. For our two connected spheres, therefore, the equation $q_1/r_1 = q_2/r_2$ is

$$\frac{\sigma_1 \pi r_1^2}{r_1} = \frac{\sigma_2 \pi r_2^2}{r_2};$$

$$\sigma_1 r_1 = \sigma_2 r_2. \tag{24–36}$$

The electric field E_i just outside each conducting sphere has magnitude σ_i/ε_0, so that we can replace σ_i by $\varepsilon_0 E_i$. Thus $\varepsilon_0 E_1 r_1 = \varepsilon_0 E_2 r_2$, or

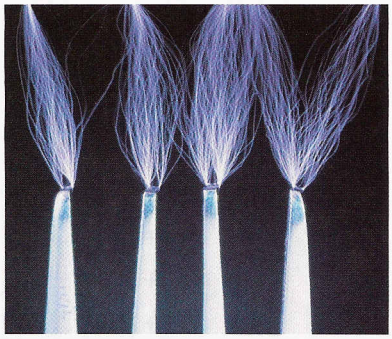
$$\frac{E_1}{E_2} = \frac{r_2}{r_1}. \tag{24–37}$$

The electric fields are inversely related to the radii, as are the surface charge densities. We can say that at a region of the charged conductor's surface that can be inscribed with a sphere of a small radius—a region of small radius of curvature—*the surface charge density and the corresponding electric field are larger than at a region of large radius of curvature.*

The effect just described is important if a conductor has a sharp point, because a sharp point is a region with a very small radius of curvature; the sharper the point, the more intense the field (Fig. 24–24). Even if the conductor is at a low electric potential, there will be intense fields near sharp points.

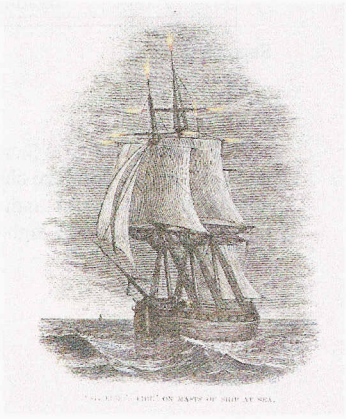
THINK ABOUT THIS. . .

HOW DO LIGHTNING RODS WORK?



Observations show that there is an electric potential over much of the land and seas of Earth that increases with height at a rate of about 100 V/m; that is, there is an electric field that points downward and has a nearly constant strength of about 100 V/m. (To be more exact, the magnitude of the field decreases slowly till it is almost zero at about 50–100 km above the surface of Earth.) Depending on weather conditions, the electric field can be very much larger—a lightning strike is preceded by the presence of large fields. Air is a fairly good insulator; what, then, conducts electricity in air? Molecules of nitrogen and oxygen are occasionally *ionized*—electrons are removed from them—by collisions with incoming *cosmic rays*, energetic particles that come from beyond the solar system. The resulting ratio of ions (positive and negative) to molecules that are not ionized is about 1 in 10^{16}, and it is these charged particles that conduct electricity in the atmosphere.

We know that there are large electric fields near the pointed parts of a charged conductor, and ions of the opposite charge are attracted to this part of the conductor while ions of the same charge are repelled. The positive and negative ions may be strongly accelerated, and ionize other neutral molecules in their path. In this way the conductivity of the air near the pointed conductor increases measurably, and a flow of charge acts to cancel the field. On a small scale this gives rise to sparks (see Fig. 24–25); a more massive charge transfer produces a *corona discharge*. Sailors long ago saw the glow of corona discharge at the pointed tops of their masts and spars and dubbed the phenomenon *St. Elmo's fire* (see Fig. 24–26). More generally we speak of *dielectric breakdown*.

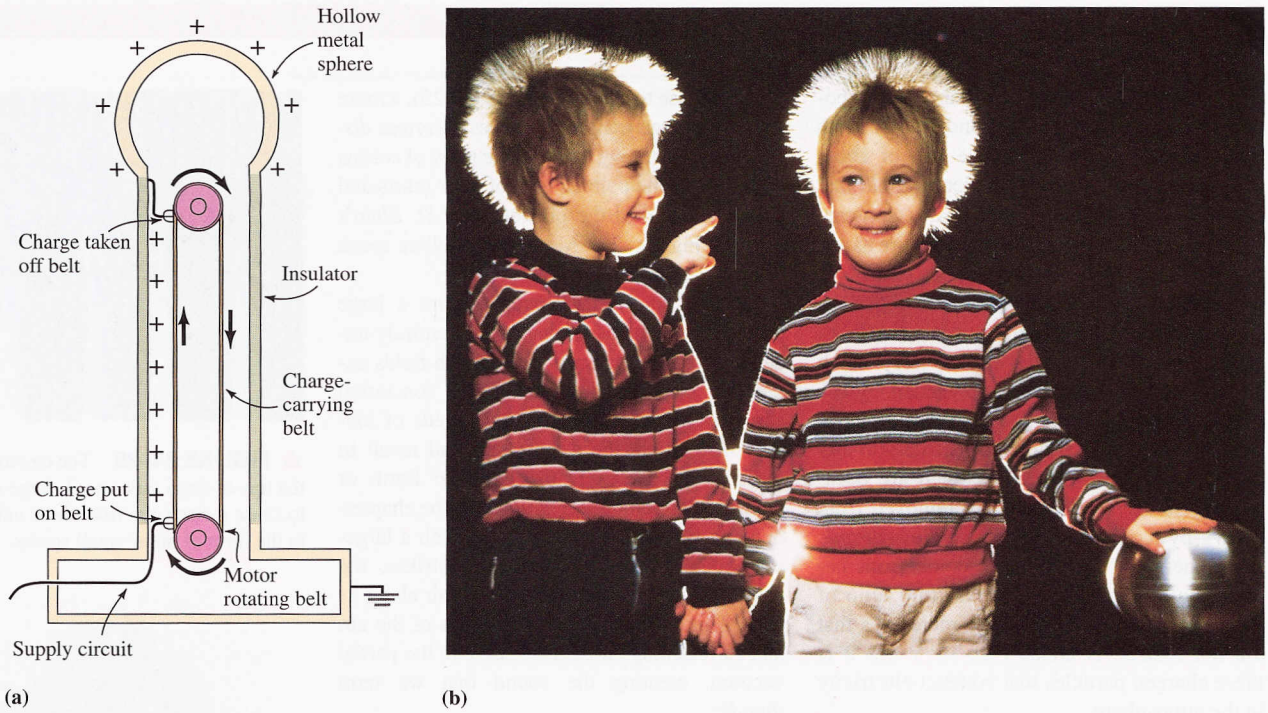


In electric storms clouds acquire a large charge by mechanisms that are not entirely understood,[†] and this gives rise to high fields extending over large regions. An ionization cascade can develop from small seeds of ionized material in the atmosphere and result in massive discharges from clouds to Earth or from cloud to cloud. *Lightning* (see the chapter-opening photo) is an example of such a large-scale discharge. When lightning strikes, the passage of electric charge heats the air along its path. This causes a rapid expansion of the air, and surrounding air rushes back into the partial vacuum, creating the sound that we term *thunder*.

If there is a pointed, grounded conductor (lightning rod) beneath the highly charged cloud, then the strong field at the point acts to lead the charged particles to the rod. More important than providing a convenient path for a lightning stroke, the steady discharge from the rod will serve to decrease the potential difference between the rod and the clouds and discourage the formation of a catastrophic discharge in the vicinity.

[†]A detailed discussion of electricity in the atmosphere may be found in Chapter 9, Vol. II of *Lectures on Physics*, by R. P. Feynman.

▲ **FIGURE 24–25** The electric field at the tips of these fork tines is large enough to cause a discharge from them into the air in the form of many small sparks.

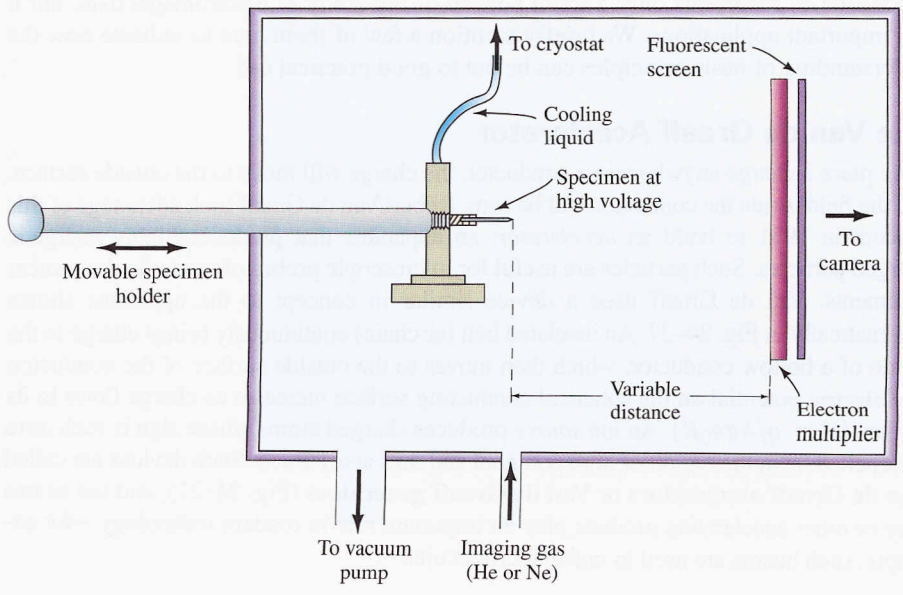


▲ **FIGURE 24–26** St. Elmo's fire at the end of the masts.

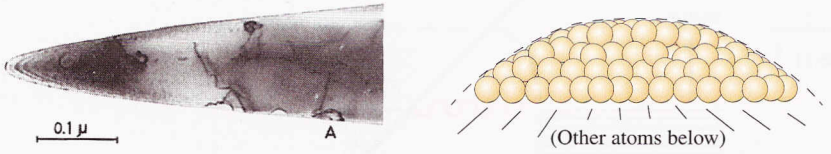
24–7 Electric Potentials in Technology

Electrostatics represents only a small portion of our study of electromagnetism, but it has important applications. We briefly mention a few of them here to indicate how the understanding of basic principles can be put to good practical use.

The Van de Graaff Accelerator



If we place a charge anywhere in a conductor, the charge will move to the outside surface, and the field inside the conductor will be zero. Robert Van de Graaff took advantage of this concept in 1931 to build an *accelerator*: an apparatus that produces highly energetic charged particles. Such particles are useful for microscopic probes of matter and as cancer treatments. Van de Graaff used a device similar in concept to the apparatus shown schematically in Fig. 24–27. An insulated belt (or chain) continuously brings charge to the inside of a hollow conductor, which then moves to the outside surface of the conductor. The electric potential on the spherical conducting surface increases as charge flows to its surface ($V = q/4\pi\varepsilon_0 R$). An *ion source* produces charged atoms whose sign is such as to be repelled from the region of high potential and thus accelerated. Such devices are called **Van de Graaff accelerators** or **Van de Graaff generators** (Fig. 24–27), and the beams they or other accelerators produce play an important role in modern technology—for example, such beams are used to make microcircuits.

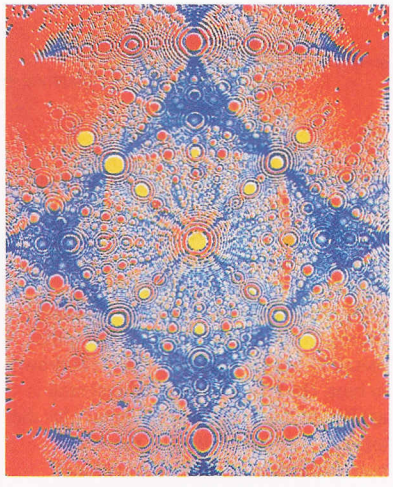


▲ **FIGURE 24–27** (a) Schematic diagram of a simple Van de Graaff accelerator. Charge is sprayed on the rotating belt at the bottom and taken off at the top. The charge goes to the outside surface of the conductor, and the potential continues to build up to high values. The symbol in the bottom right indicates that the base of the accelerator has been grounded. (b) The children touching this Van de Graaff generator are brought to a high electric potential. The individual hairs behave like the leaves of an electroscope.

The Field-Ion Microscope

The phenomenon that large electric fields occur at sharp points on a conductor is carried to its extreme in **field-ion microscopy**. The high electric fields involved in this technique allow us to produce images of individual atoms in the crystalline structure of the sharp point, or tip, of a metal. A fine tip of the crystalline material is prepared, commonly by dipping a mechanically formed tip in a substance that dissolves atoms off the end of the tip. These tips can be as small as 200 nm across, depending on the particular metal and the crystal being prepared. On the 200-nm scale, such a tip looks smooth, but it is still very rough at the atomic level. The tip is then introduced into a vacuum, and a large positive potential of several kilovolts is applied (Fig. 24–28). The end of the tip is thereby smoothed off even further as protruding groups of atoms of

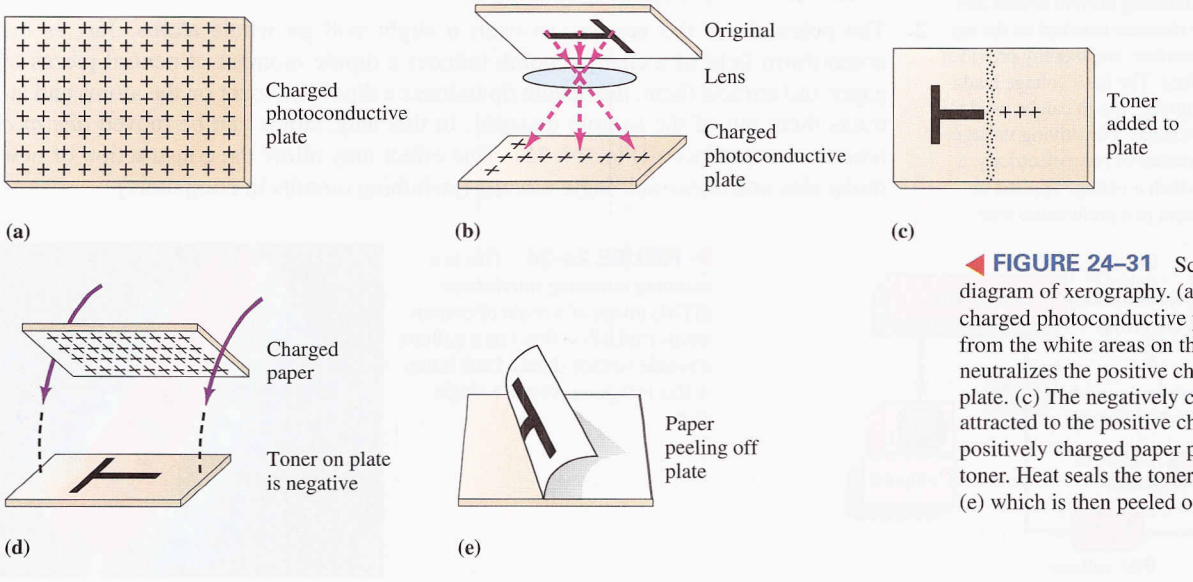
▶ **FIGURE 24–28** Schematic diagram of a field-ion microscope. The cryostat maintains a steady, low temperature in the chamber.



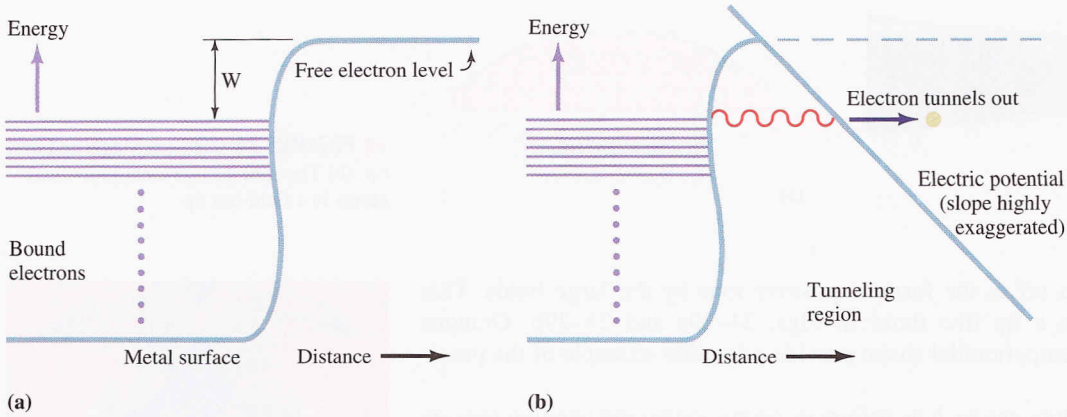
(a) (b)

◀ **FIGURE 24–29** (a) Magnified iron tip. (b) The spheres represent individual atoms in a field-ion tip.

the metal itself are driven off in the form of positive ions by the large fields. This smoothing process leaves a tip like those in Figs. 24–29a and 24–29b. Oranges stacked in layers into a semipyramidal shape provide a familiar example of the possible structure of such a tip.



In the next stage, a dilute gas such as helium or neon—called the *imaging* gas—is introduced into the chamber that contains the tip. The positive potential on the tip is increased, again to several kilovolts, until the gas atoms just begin to be ionized. This happens only where the field is largest: right above individual atoms of the tip, where the field is strong enough to ionize the gas. The gas ions are then driven away from the tip, following the electric field lines out from the tip atoms to a grounded screen, where the impinging gas ions leave a visible trace. The image formed corresponds to the position of the individual atoms of the tip, which thus become visible in a picture such as Fig. 24–30. Field-ion microscopy is useful for observing crystal structures and the effects of impurities and defects in crystals. Even some noncrystalline materials can be investigated this way. Learning about the structure of materials is certainly one of the important steps in our ability to use them in applications.



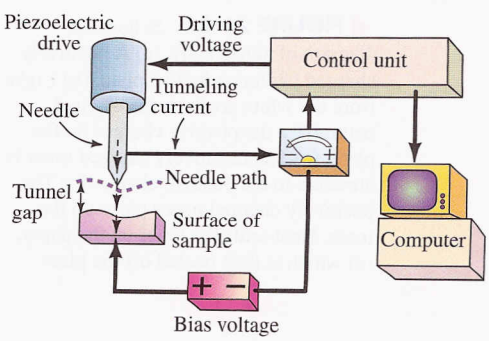
▲ **FIGURE 24–30** This field-ion micrograph of a platinum crystal allows the atomic structure of the crystal to be determined from the many overlapping geometrical patterns. The magnification is 200,000.

Xerography

Photocopying machines take advantage of electrostatics in several steps of **xerography**, or photoreproduction. The process is illustrated in Figure 24–31. It begins with a positively charged plate coated with photoconducting material (a photoconductor is a good conductor in light but not in the dark, because light releases conducting electrons within it) such as selenium (Fig. 24–31a). Light reflected from the original to be copied passes through a lens onto the charged plate, where the dark areas remain charged, but charges flow to the plate underneath at the areas that receive light (Fig. 24–31b). The resulting image of the dark areas is represented by the remaining charges. Negatively charged toner (a black powder) is added to the positively charged plate, leaving the original dark areas with black toner on the plate (Fig. 24–31c). In the next step, paper that has also been positively charged is placed over the plate and attracts the black, negatively charged toner (Fig. 24–31d). Heat is used to fuse the toner (and thus the image) to the paper.

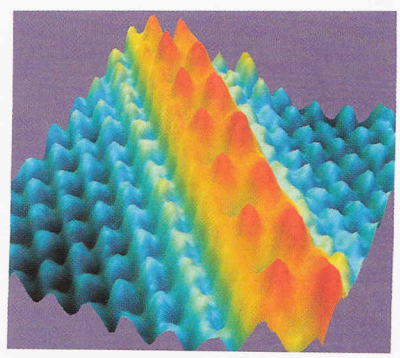
◀ **FIGURE 24–31** Schematic diagram of xerography. (a) A positively charged photoconductive plate. (b) Light from the white areas on the original neutralizes the positive charges on the plate. (c) The negatively charged toner is attracted to the positive charge. (d) The positively charged paper picks up the toner. Heat seals the toner on the paper, (e) which is then peeled off the plate.

▲ **FIGURE 24–32** (a) Electrons in a metal take on a range of energies up to a highest level. This level is still negative compared to the energy of a free electron. It takes an energy W—typically 4 to 5 eV—to sufficiently raise the electron energy to allow the electron to leave the metal. The potential energy curve is drawn in blue. (b) When an external potential is applied to the metal, that potential plus the existing potential yields an effective potential barrier. Electrons can tunnel through this barrier.

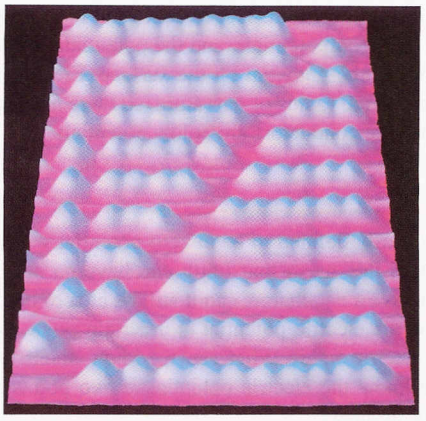


Electric Potentials and Quantum Engineering

Electrons are trapped within a metal by electrostatic attractions to their parent ions. These forces can be represented in classical physics by a potential barrier that the electrons cannot cross. Figure 24–32a is an energy diagram of the potential energy of an electron as well as the electron's (constant) total energy. Classically, the electron cannot enter the region where its total energy is less than its potential energy.



A positively charged object brought near the metal surface pulls on the electrons. The positively charged object has an electric potential with respect to the metal, and an electron has a potential energy due to the external object (Fig. 24–32b). When the potential energy due to the external object is added to the original potential energy that holds the electron within the metal, the barrier is, in effect, reduced. Even if the external potential is too weak to lower the maximum potential energy below the electron's total energy and allow the electrons to escape classically, penetration through a barrier (*barrier tunneling*) is possible in quantum physics (Chapter 40). The tunneling is enhanced when the barrier is lowered. By tunneling, the electrons can emerge on the other side of the barrier and escape the electrostatic attraction of the parent ion, though many of them are absorbed on the way. This effect is utilized in the *scanning tunneling microscope* (Fig. 24–33). A weak positive potential is placed on an ultrafine tungsten needle. The needle scans the surface of a sample and provides the necessary potential to help electrons escape the sample by making it easier for them to penetrate the barrier. These electrons are attracted to the needle and form a flow of charge (*electric current*) through it, whose magnitude depends on the distance between the needle and the surface. This effect is used in two ways.



1. A feedback mechanism that constantly repositions the needle can be set up so that the current is constant. The distance between the needle tip and the sample's surface is therefore constant. The repositioning can be measured, and the topography of the surface is thereby mapped (Fig. 24–34).
2. The potential on the needle can exert a slight pull on whole atoms. Just as the nonuniform field of a charged comb induces a dipole moment of neutral pieces of paper and attracts them, the needle tip induces a dipole moment on the atoms and attracts them out of the sample material. In this way, atoms can be moved *one at a time* to new positions (Fig. 24–35). This effect may allow the construction of new molecules and ultrasmall logic circuits (switching circuits in computers).

▼ **FIGURE 24–33** Schematic diagram of a scanning tunneling microscope. The fine-tipped needle in the scanning head comes to within 1 nm of the sample; this distance is the tunnel gap. The tunneling current across this gap holds the gap distance constant as the tip scans the sample surface and thereby provides a map of that surface. The base voltage leads to the tunneling current, which can be used to form the driving voltage. The driving voltage moves the tip by means of piezoelectricity, a phenomenon in which a voltage applied to crystals distorts them in a predictable way.

▶ **FIGURE 24–34** This is a scanning tunneling microscope (STM) image of a chain of cesium atoms (reddish yellow) on a gallium arsenide surface (blue). Each bump in this image represents a single atom.

◀ **FIGURE 24–35** Individual atoms, whose size is less than a nanometer, have been moved one at a time to form the pattern shown. The vertical scale of the figure is enhanced by a factor of ten for a more dramatic effect.

The combination of electrostatics and quantum mechanics (through the use of the wavelike behavior of electrons) is an important tool in what is aptly called *quantum engineering*.

Summary

The Coulomb force is conservative, so a potential energy—electric potential energy—is associated with it. If a test charge q_0 moves from point a to point b in the presence of a point charge q at the origin, the change in potential energy is given by

$$\Delta U = \frac{qq_0}{4\pi\varepsilon_0}\left(\frac{1}{r_b} - \frac{1}{r_a}\right). \tag{24–4}$$

The electric potential difference due to any charge distribution between points a and b is defined as the change in potential energy divided by the magnitude of a test charge q_0:

$$\Delta V = \frac{U_b - U_a}{q_0} = -\int_{r_a}^{r_b} \vec{E} \cdot d\vec{s}. \tag{24–9}$$

Here $\vec{E}$ is the electric field due to the charge distribution. The integral in Eq. (24–9) is independent of the path between the end points. The potential difference $V_b - V_a$ is the work done per unit charge by an external agent in moving a test charge from point a to point b with no change in kinetic energy. The potential is independent of the test charge.

The electric potential can be determined by the following methods, in addition to graphical methods:

1. If the electric field is known, then Eq. (24–9) may be used.
2. If the electric field is not known, it is generally easier to calculate the potential directly by using one of these forms:

for one point charge: $$V(r) = \frac{q}{4\pi\varepsilon_0 r}; \tag{24–7}$$

for many point charges: $$V_P = \frac{1}{4\pi\varepsilon_0}\sum_{i=1}^{n}\frac{q_i}{r_i}; \tag{24–11}$$

for a continuous charge distribution: $$V = \frac{1}{4\pi\varepsilon_0}\int \frac{dq}{r}. \tag{24–12}$$

In each of these cases, zero potential is chosen to be at infinity.

The SI unit of electric potential is the volt (V); 1 V = 1 J/C. A useful unit of energy for atomic and subatomic systems is the electron-volt (eV); 1 eV = 1.6×10^{-19} J.

If the potential is known, then the electric field can be determined in terms of derivatives of the potential:

$$\vec{E} = -\hat{i}\frac{\partial V}{\partial x} - \hat{j}\frac{\partial V}{\partial y} - \hat{k}\frac{\partial V}{\partial z}. \tag{24–29}$$

The electric field between two parallel plates is constant and is given by the potential difference divided by the distance between the plates:

$$E = \frac{\Delta V}{\ell}. \tag{24–30}$$

The electric field and potential for several charge configurations are given in Table 24–1.

Equipotential surfaces are surfaces at a fixed potential. The electric field is perpendicular to equipotentials. The surfaces of conductors form equipotentials, and the potentials inside conductors in equilibrium are everywhere the same as the potential on the surface. Electric fields just outside conductors are inversely proportional to the radius of curvature, so there are high electric fields near sharp points on conductors even if the conductors are at low potentials.

Understanding the Concepts

1. How many joules are in 1 V · C?
2. An infinite plane is uniformly charged with positive charge of density σ. How would you use a known negative test charge to measure σ?
3. How would you create an electric field inside the hollow space of a spherical metal shell that is constant in magnitude and direction in a small region of the interior space?
4. In good weather, the electric field in the lower atmosphere is approximately 100 V/m, pointing downward. What happens when a 3-m metal rod is planted in the ground?
5. When an electric field moves a charge by doing work on it, what is the source of the energy to do the work? Where did this energy come from originally?
6. In describing the potential difference as the work per unit charge to move a test charge, we added the phrase "without changing its kinetic energy" (see the boldface statement on p. 687). Why is this important?
7. For a dipole $\theta = 0$ is a point on the axis, while $\theta = \pi/2$ is a point on the perpendicular bisector of the line between the two charges. Without looking at the equations, and given that one is at the same distance from the dipole center, at which angle is the field larger, and why?
8. Are the children in Fig. 24–27 grounded?
9. Will a conductor always be an equipotential? If not, under what circumstances will that occur?
10. Using Eq. (24–29), explain why changing the location of zero potential does not affect the value of the electric field.
11. A small Van de Graaff generator can be used as a lecture demonstration device. If a person touches the dome, his or her hair stands up (see Fig. 24–27b). Explain why. Why should the person stand on an insulated mat during this demonstration?
12. Earth is typically defined to be at zero potential with respect to infinity. Does this mean that Earth can have no net charge? If Earth does have a net charge, can it still be at zero potential?
13. If we know the electric potential at a certain point, do we also know the electric field? What can we know about the electric field if we know the electric potential at two points arbitrarily close to one another?
14. Examine Fig. 24–24. In what regions do the field lines seem to be denser? In what regions do you expect dense lines, and why?
15. Is the electric potential energy of a system of point charges independent of the order in which the system is assembled?
16. Why are there so many curved surfaces on the Van de Graaff generator?
17. How do we really know that electric forces are conservative?
18. In the potential associated with a point charge, we chose zero potential to be infinitely far from the charge. What would change in our predictions about electric charges if we had chosen the potential to be zero at $r = 10^{-10}$ m from the charge?
19. If we start with point charges, for each of which zero potential is at infinity, is it possible for a superposition of charges to have zero potential other than at infinity?
20. The potential of a configuration of point charges is zero at certain points. Does this mean that the force on a test charge is zero at these points?
21. Is it possible to arrange charges so that the potential is zero over a small but finite region?
22. Consider Fig. 24–10. What is the easiest way off High Peak? Think in particular about whether or not your path is perpendicular or not to the contour lines, and how the spacing between the contours affect your choice. Describe the relevance of your reasoning to a possible set of equipotentials for a two-dimensional distribution of charge.

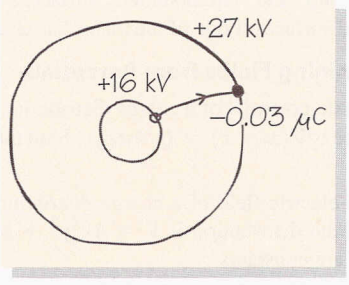
Problems

24–1 Electric Potential Energy

1. (I) Two protons are separated by a nuclear diameter of 5×10^{-15} m. What is their mutual electrostatic energy?
2. (I) What is the electrical potential energy between the nucleus of a uranium atom (92 protons) and a single electron located 3×10^{-12} m from the nucleus?
3. (I) A charge of 7.0×10^{-7} C is fixed at the origin of a coordinate system. A charge of 3.0×10^{-6} C is placed on a raisin of mass 0.30 g. The raisin is then brought from far away to a point 20 cm from the origin. What is the electric potential energy of the system?
4. (I) Suppose that the raisin of Problem 3 is released from rest from its position 20 cm from the origin. If no other forces act on the raisin, where will it move? What will its final kinetic energy be?
5. (I) A 3-μC charge is brought in from infinity and fixed at the origin of a coordinate system. (a) How much work is done? (b) A second charge, of 5 μC, is brought in from infinity and placed 10 cm away from the first charge. How much work does the electric field of the first charge do when the second charge is brought in? (c) How much work does the external agent do to bring the second charge in if that charge moves with unchanging kinetic energy?
6. (I) Charges $q_1 = 2.0 \times 10^{-5}$ C and $q_2 = -9.0 \times 10^{-5}$ C are placed at rest 0.50 mm apart. How much work must be done by an outside agent to move these charges slowly and steadily until they are 0.05 mm apart?
7. (II) A positive charge of magnitude 3.0×10^{-6} C is placed 5.0 cm above the origin of a coordinate system, and a negative charge of the same magnitude is placed 5.0 cm below the origin, both on the z-axis. What is the potential energy of a positive charge of magnitude 0.20×10^{-6} C placed at the position $(x, y, z) = (30\text{ cm}, 0\text{ cm}, 50\text{ cm})$? at $(30\text{ cm}, 0\text{ cm}, 0\text{ cm})$?
8. (II) Repeat the calculation of Problem 7 for the case that (a) both charges on the z-axis are positive and the third charge is negative; (b) the signs and magnitudes of all charges are the same.
9. (II) A charge of 1.5 μC is placed at the point $x = 12$, $y = 25$, $z = 0$ (all distances given in centimeters). Calculate the work done in bringing a charge of -3 μC from $x = 12$, $y = 60$, $z = 50$ to the point $x = 12$, $y = 50$, $z = -25$, assuming that the charge is moved at a steady speed.
10. (II) Use potential energy arguments to show that charges of the same sign cannot form a system with a closed circular orbit.

24–2 Electric Potential

11. (I) Two equal charges of -4 mC are placed along the y-axis at -3 mm and 4 mm, respectively. Where is the electric potential zero?



12. (I) Two charges are placed along the x-axis; 3 μC at 14 cm, and -4 μC at 15 cm. Find those points along the x-axis where the potential is zero.

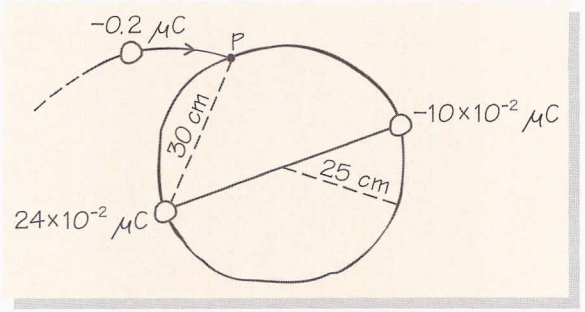
13. (I) The electrostatic potential of a single unknown charge 2.5 mm from that charge is 0.12 V. (The value of the potential at infinity is zero.) What is the value of the charge?

14. (I) A proton moves from point A to point B under the sole influence of an electric field, losing speed as it does so from $v_A = 8 \times 10^5$ m/s to $v_B = 5 \times 10^4$ m/s. What is the potential difference between the two points?

15. (I) An external force steadily moves a point charge of $+3.0 \times 10^{-7}$ C from a negatively charged to a positively charged plate. The plates are large and parallel, and the negatively charged plate is at a potential of +3.0 kV, whereas the positively charged plate is at a potential of +17 kV. How much work does the external force do?

16. (I) Consider two very long coaxial cylinders that carry opposite charges. The interior cylinder, negatively charged, is at a potential of +16 kV, whereas the exterior cylinder, positively charged, is at a potential of +27 kV. An external force steadily moves a point charge of -3×10^{-8} C from the negatively to the positively charged cylinder (Fig. 24–36). How much work does the external force do?

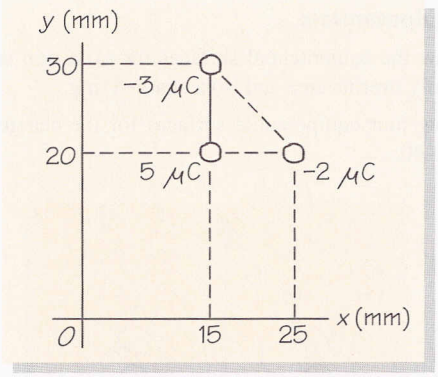
▲ **FIGURE 24–36** Problem 16.



17. (II) Three charges are at rest on the z-axis, $q_1 = 2$ mC at $z = 0$ m, $q_2 = 0.5$ mC at $z = 1$ m, and $q_3 = -1.5$ mC at $z = -0.5$ m. What is the potential energy of this system?

18. (II) Charges $+q$, $-q$, $+q$, and $-q$ are placed on successive corners of a square in the xy-plane. Plot all the locations in the xy-plane where the potential is zero.

19. (II) Consider two charges of $24 \times 10^{-2}\mu$C and $-10 \times 10^{-2}\mu$C, respectively, at opposite ends of a diameter of a circle of radius 25 cm (Fig. 24–37). (a) What is the potential on a point of the circle that is 30 cm from the positive charge? (b) How much work is required to bring a charge of -0.2 μC from infinity to that point on the circle?



20. (II) The origin of a coordinate system is at the intersection point of the perpendicular bisectors of the sides of an equilateral triangle of sides 3 cm. Calculate the potential at the origin due to three identical charges of 0.5 μC placed at the corners of the triangle.

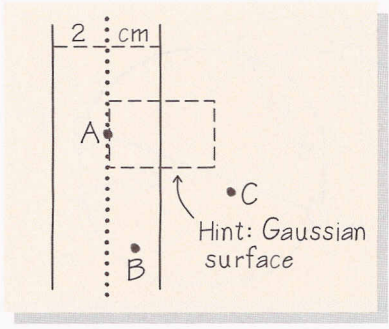
21. (II) Consider a square of sides 14 cm. Charges are placed on the corners of the square as follows: 2 μC at (0 cm, 0 cm); -3 μC at (0 cm, 14 cm); 5 μC at (14 cm, 14 cm); +3 μC at (14 cm, 0 cm). What is the potential at the point (30 cm, 30 cm)?

▲ **FIGURE 24–37** Problem 19.

22. (II) A 5-μC charge is fixed at $(x, y) = (15\text{ mm}, 20\text{ mm})$, a -3-μC charge is fixed at (15 mm, 30 mm), and a -2-μC charge is fixed at (25 mm, 20 mm) (Fig. 24–38). What is the potential energy of the system? Does the order in which the charges are brought in from infinity matter?

▲ **FIGURE 24–38** Problems 22 and 23.

23. (II) Calculate the electric potential at the origin due to the three charges considered in Problem 22.



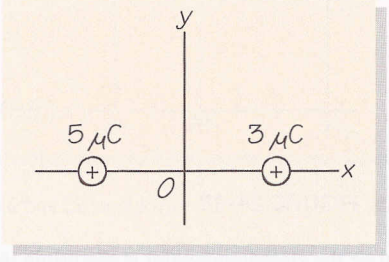
24. (II) Two parallel conducting plates are brought to a potential difference of 600 V, and a small pellet of mass 2 mg carrying a charge of 3×10^{-7} C accelerates from rest at one plate. With what speed will it reach the other plate?

25. (II) Charges of +12 μC and -20 μC are placed along the y-axis at positions $y = +5.0$ cm and $y = -9.0$ cm respectively. (a) What is the potential at $y = 0$ and $x = 12.0$ cm? (b) What is the potential at $y = 0$, $x = 0$? (c) What is the electric field at that point?

26. (II) Two positive charges of magnitude 2.5 μC and 7.5 μC are placed a distance of 0.80 m apart. What is the electric potential along a line joining them? Where along that line will the electric field vanish? If a test charge is placed at that point, will it be in stable or unstable equilibrium as far as its motion along the line is concerned? Does your answer depend on the sign of the test charge?

27. (II) Figure 24–39 shows the cross section of a very large insulating slab that is uniformly charged to a charge density of 10^{-5} C/m^3. The thickness of the slab is 2 cm. (a) Determine the electric field of the charge on the slab at points A, B, and C. (b) Calculate the potential at points B and C, assuming that it is zero at A. (c) Plot the electric field and the potential as a function of distance from the center of the slab.

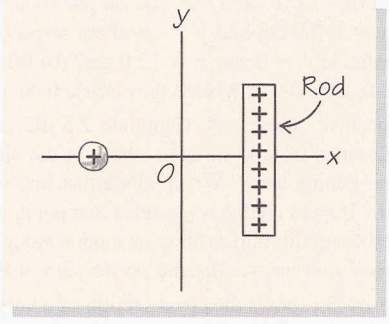
28. (II) A charge Q is distributed uniformly over the surface of a spherical shell of radius R. How much work is required to move these charges to a shell with half the radius? The charges are again distributed uniformly.



▲ **FIGURE 24–39** Problem 27.

29. (III) Calculate the potential inside and outside a sphere of radius R and charge Q, in which the charge is distributed uniformly throughout. [*Hint*: The additive constant for the potential inside the charged sphere must be chosen so that the two potentials, inside and outside, agree at $r = R$.]

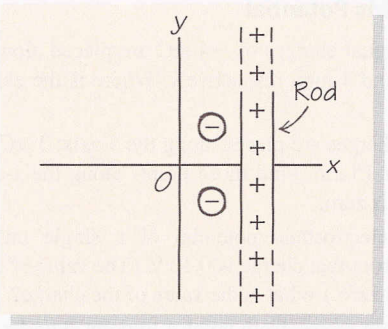
24–3 Equipotentials



30. (I) Draw the equipotential surfaces for (a) a thin disk charged uniformly over its area and (b) a charged ring.

31. (I) Draw four equipotential surfaces for the charges shown in Fig. 24–40.

▲ **FIGURE 24–40** Problem 31.



32. (I) Sketch the equipotential surfaces for the charges shown in Fig. 24–41. Assume that the rod is an insulator.

▲ **FIGURE 24–41** Problem 32.

33. (I) Sketch the electric fields and the equipotentials for the charge distribution shown in Fig. 24–42. Assume that the rod (of infinite length) is an insulator.

34. (I) Three metallic spheres are placed on the corners of an equilateral triangle. The radii of the spheres are 1/4 of the side of the triangle. All the spheres are at the same potential V_0. Sketch the equipotentials for this system.

▲ **FIGURE 24–42** Problem 33.

35. (II) A uniformly charged metal rod is placed parallel to an infinite, uncharged metal plate. Sketch the equipotentials in a plane perpendicular to the plate and to the rod, and in a plane perpendicular to the plate but parallel to the rod.

36. (II) Sketch the equipotentials in the xy-plane due to an infinite number of identical point charges q that lie on a line and are separated by a distance a, so that the coordinates of the point charges are $x_n = na$ and $y_n = 0$, where $n = 0, \pm1, \pm2, \pm3, \ldots$.

37. (II) Two charges of equal magnitude but opposite sign are separated by a distance L. Sketch the equipotentials. What equipotential surfaces will have a potential of zero when the separate potentials for the two charges are chosen to be zero at infinity?

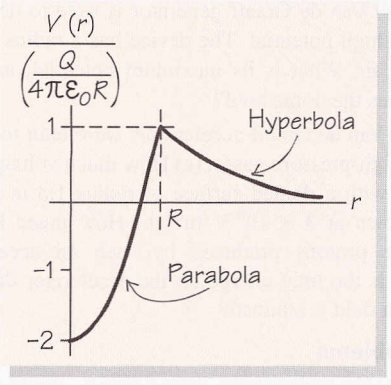
38. (II) Two infinite plates, each charged uniformly with charge density σ, are placed at right angles to each other and are almost touching. What are the equipotential surfaces? What are the equipotential surfaces if one of the plates has charge density $-\sigma$?

24–4 Determining Fields from Potentials

39. (I) The electric potential of a charge distribution within some region of space is $V(x, y, z) = Q/4\pi\varepsilon_0 x$. Find the electric field in this region.

40. (I) Find the electric field of a charge distribution if the electric potential of the distribution is $V = Ax^2y^2 + Byz^2 + C$, where A, B, and C are constants.

41. (I) In a certain region of space, the electric potential due to a charge distribution varies only with x, changing according to $V = a_0 + a_1x$ where $a_0 = 12.7$ V, $a_1 = -6.68$ V/m, and x is in meters. Find the electric field, magnitude, and direction in this region.



42. (II) Starting from the solution in Example 24–9 of the potential due to a uniformly charged ring, use the derivative operations in Eq. (24–29) to find the electric field along the axis of the ring.

43. (II) Find the electric field far away along the bisecting axis of an electric dipole from the potential given in Eq. (24–24).

44. (II) Consider charge distributed in an infinitely long cylinder of radius R whose axis forms the z-axis. The charge distribution depends only on the distance r from the z-axis. The potential is given for $r < R$ by $V(r) = (Q/2\pi\varepsilon_0)[A(r/R) + B(r/R)^2 + C]$, where A, B, and C are constants. What is the electric field within the rod? What is the value of C if the potential is defined to be zero on the cylinder's surface?

45. (II) The potential $V(r)$ of a spherically symmetric charge distribution is given by $V(r) = (Q/4\pi\varepsilon_0 R)[-2 + 3(r/R)^2]$ for $r < R$ and $V(r) = Q/4\pi\varepsilon_0 r$ for $r > R$ (Fig. 24–43, see next page). Calculate the electric field.

46. (II) Use the results of Problem 45 and Gauss' law applied to Gaussian surfaces at various radii to calculate the charge distribution that gives rise to the potential given in that problem.

▲ **FIGURE 24–43** Problem 45.

47. (III) The potential in the xy-plane due to a certain charge distribution is given by

$$V(x, y) = \frac{Q}{4\pi\varepsilon_0 L} \times \left[\arctan\left(\frac{y}{x - a_0}\right) - 2\arctan\left(\frac{y}{x}\right) + \arctan\left(\frac{y}{x + a_0}\right)\right],$$

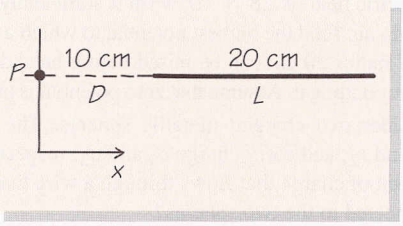
where L and a_0 are constant lengths. Show that the electric field at distances $x \gg a_0$, $y \gg a_0$ is proportional to a_0^2, and find its dependence on x and y. Express your answer in terms of r, the distance to the origin, and θ, the angle that the line from the origin to the point (x, y) makes with the x-axis.

24–5 The Potentials of Charge Distributions

48. (I) Two large, metal, parallel plates have a potential difference of 200 V, and the electric field between them has magnitude 7×10^3 V/m. What is the separation distance between the plates?

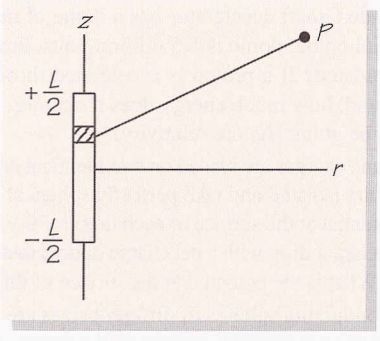
49. (I) The voltage along the axis of a uniformly charged ring of radius 10 cm is 5 V at a point 15 cm from the center of the ring. How much charge is on the ring?

50. (I) In fair weather, there is a constant electric field near Earth's surface whose magnitude is roughly 100 V/m, directed downward. (a) Find the potential associated with this field. (b) What is the most convenient point to choose for zero potential? (c) How does the potential energy of a test charge near Earth compare in form with the potential energy of gravity? (d) How much negative charge would have to be placed on a person of mass 50 kg to have the electric force balance the force of gravity?



51. (II) Find the potential as a function of the perpendicular distance R from an infinite line of uniform charge density by using Gauss' law and Eq. (24–9).

52. (II) Charges are distributed with uniform charge density λ along a semicircle of radius R, centered at the origin of a coordinate system. What is the potential at the origin?

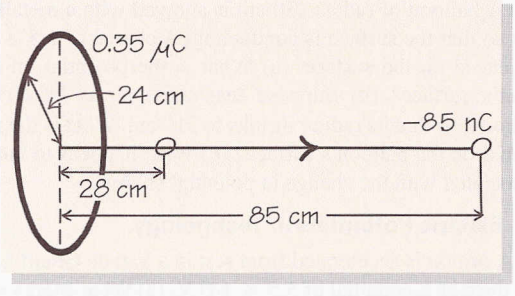


53. (II) A rod that is 20 cm long is given a uniformly distributed charge of 2 μC (Fig. 24–44). Calculate the potential at a point P, which is a distance of 10 cm from the end of the rod, assuming that $V = 0$ at infinity.

54. (III) Find an expression for the electric potential at all points due to a rod of length L and uniform charge density λ, using Eq. (24–12). The rod is oriented along the z-axis, with its center at the origin (Fig. 24–45). Show that at distances much greater than L from the rod, the potential reduces to that of a point charge $Q = \lambda L$ at the origin.

55. (III) A charge $3q_0$ is placed on the x-axis at the point $x = x_0$ (where x_0 is positive), and a second charge, $-q_0$, is placed on the x-axis at the point $x = -x_0/2$. (a) What is the potential on the x-axis of this distribution of charges? Assume that zero potential for a point charge is at infinity. (b) Show that your result for part (a) can be approximated for large x by a term proportional to $1/x$, plus a term proportional to $1/x^2$, plus higher powers of $1/x$. (c) Show that the expansion of part (b) is that of a point charge at the origin, plus an electric dipole oriented along the x-axis and centered at the origin, plus other terms. Find the strength of the point charge as well as the dipole moment of the electric dipole. (d) How large must x be so that the approximation of a point charge plus a dipole comes within 1 percent of the exact answer? [*Hint*: Use the approximation $(1 + z)^k = 1 + kz + \frac{1}{2}k(k - 1)z^2 + \cdots$ good for $z \leq 1$.]

▲ **FIGURE 24–44** Problem 53.



▲ **FIGURE 24–45** Problem 54.

24–6 Potentials and Fields Near Conductors

56. (I) A thin disk of radius 2.8 cm carries a total charge of 6.0×10^{-8} C spread evenly over its surface. What is the minimum work required to bring a charge $q = 3.2 \times 10^{-7}$ C at rest from infinity to a distance of 8.8 cm from the disk along its axis?

57. (I) A thin ring of radius 24 cm carries a uniformly distributed charge of 3.5×10^{-7} C. A negative charge $q = -8.5 \times 10^{-8}$ C is placed on the axis of the ring 28 cm from the plane of the ring (Fig. 24–46). How much work must an external agent do to move the charge slowly and steadily to a distance 85 cm away, also on the axis?

▲ **FIGURE 24–46** Problem 57.

58. (I) An electric field of 2.8×10^6 V/m is sufficiently large to cause sparking in air. Find the highest potential to which a spherical conductor of radius 30 cm can be raised before breakdown occurs in the air surrounding it. Assume that zero potential is taken at infinity.

59. (I) Consider two charged metallic spheres. The spheres have radii r_1 and r_2, and carry charge q_1 and q_2, respectively. What is the amount of charge that flows through a wire that is brought in and connected to the two spheres?

60. (II) A spark plug has a gap of 2 mm. What must be the potential difference across the gap in order for it to ionize a bridge across the gap? Assume air fills the gap.

61. (II) A Van de Graaff accelerator has a dome of radius 0.61 m. If the potential on the dome is 5.5 million volts, how much charge has accumulated? If a proton is accelerated through this potential to ground, how much energy does it acquire? Calculate how fast it will be going (ignore relativity).

62. (II) The same charges are placed on two identical drops of mercury. The drops are isolated and take perfectly spherical shapes, and the electric potential at the surface of each drop is 70 V. The drops coalesce into a larger drop with a net charge double that of either smaller charge. What is the potential at the surface of this larger charge?

63. (II) Two conducting spheres of different sizes are connected by a thin conducting wire. The radius of the larger sphere is three times that of the smaller sphere. If a total charge Q is placed on this apparatus, what fraction of Q sits on each sphere?

64. (II) Concentric metal shells, perfect conductors, have radii R and $1.5R$, respectively. A charge q is placed on the inner shell, and a charge $-3q$ is placed on the outer shell. (a) What are the electric fields in all space due to the two shells? (b) What is the potential difference between the two shells? (c) If a thin, perfectly conducting wire now joins the two shells, how does the charge redistribute itself?

65. (II) A cloud is made up of raindrops, each carrying a positive charge of 16×10^{-19} C. There are 1.2×10^{10} raindrops per cubic meter. When the electric field at the surface of the cloud builds up to 3.2×10^6 V/m there will be electrical breakdown and lightning will be seen. What will be the radius of the cloud, assuming it is spherical, when this occurs?

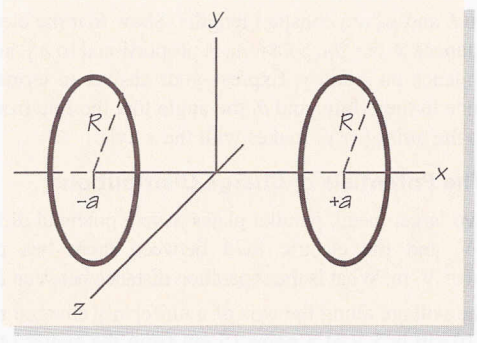
66. (II) Two metallic spheres of radii 0.05 m and 0.08 m respectively are placed far away from each other. They are then connected by a thin wire and a charge of 40 μC is placed on the system. Assuming that we can neglect the charge on the wire, how will the charge be distributed between the two spheres? What is the potential of the system?

67. (II) Two spherical conductors of radii 20 mm and 100 mm are connected by a thin wire and carry charges q_1 and q_2, respectively. If the wire is cut and the centers of the spheres are 250 mm apart, there is a repulsive force of 3.5 N between them. Use this information to calculate (a) q_1 and q_2 and (b) the electric fields at the surfaces of the conductors when they are connected by the wire.

68. (II) A balloon of radius 430 cm is sprayed with a metallic coating so that the surface is conducting. A charge of 1.5×10^{-5} C is placed on the surface. (a) What is the potential on the balloon's surface? (b) Suppose that some air is let out of the balloon, so that its radius shrinks to 310 cm. What is the new potential on the balloon's surface? (c) What happens to the energy associated with the change in potential energy?

24–7 Electric Potentials in Technology

69. (I) A proton is accelerated from rest in a Van de Graaff accelerator through a potential of 5.5×10^6 V. (a) What energy does the proton have—in electron-volts and joules? (b) What is the proton's final speed?



70. (I) A small Van de Graaff generator is used to demonstrate the effects of high potential. The device has a radius of 41 cm and stands in air. What is its maximum potential, and how much charge does the dome hold?

71. (II) Early Van de Graaff accelerators were built to operate in air without high-pressure gases. (a) How much voltage could an accelerator with a domed surface of radius 1.3 m produce if air breaks down at 3×10^6 V/m? (b) How much kinetic energy could the protons produced by such an accelerator have? (c) What is the total charge on the accelerator dome when the maximum field is attained?

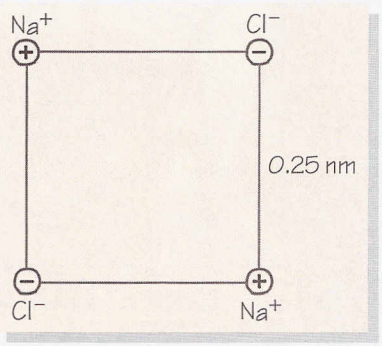
General Problems

72. (I) We have a high-voltage power supply capable of producing 15,000 V, and we want to ionize the air molecules between parallel plates. What plate separation will give us electrical breakdown?

73. (I) The potential at a point x due to a thin, flat, uniformly charged disk of radius R and total charge Q at a point on the disk's axis a distance x away from the disk is given in Eq. (24–32). Consider two such identical disks, one in the yz-plane at $x = -a$, and another in the yz-plane at $x = +a$, both centered on the x-axis (Fig. 24–47). What is the potential at an arbitrary point on the x-axis between the two disks?

▲ **FIGURE 24–47** Problem 73.

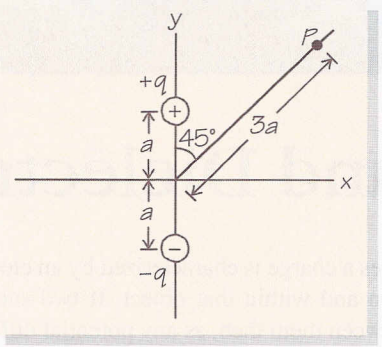
74. (I) A metallic ring of radius R, carrying charge Q, has an associated electric potential at a distance x from the center of the ring along its axis given in Table 24–1. What is the potential at some point x due to two rings, one carrying charge Q and the other $-Q$, both in the yz-plane, centered on the x-axis, one located at $x = a$, the other at $x = -a$?



75. (II) What is the electric field at a point x on the axis due to the two charged rings described in the previous problem for $x \gg a$? [*Hint*: Use the approximation $(x^2 + 2ax + b^2)^{-1/2} \cong x^{-1}(1 - a/x + (3a^2 - b^2)/2x^2)$.]

76. (II) Write an expression for the total energy of two point charges—one positive and of magnitude Q, fixed at the origin; the other negative and of magnitude q and mass m, located at a point a distance r from the origin. Suppose the charge q, instead of being stationary, moves in a circular orbit of radius r around the charge Q. Assuming that the Coulomb attraction is responsible for the centripetal acceleration, calculate the energy. Why is the angular velocity of this motion constant?

77. (II) A nonconducting sphere of radius R carries a charge $+Q$ distributed uniformly throughout its volume. What is the potential energy of a point charge $-q$ a distance r $(r < R)$ from the center of the sphere? Show that if there is a hole drilled through the sphere so that the point charge can move through it, then the point charge oscillates as though it were attached to a spring. Find the effective spring constant.



78. (II) Three electrons are located along the x-axis at positions $-6\ \mu$m, $0\ \mu$m, and $6\ \mu$m, respectively. How much energy was required to move each of the electrons in turn from infinity? Does the order in which they were moved matter?

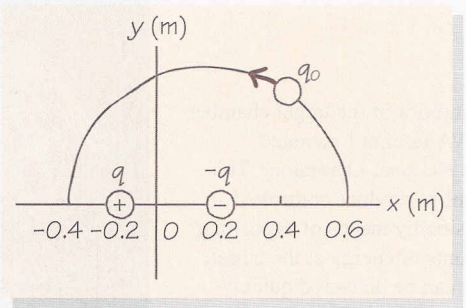
79. (II) A salt crystal consists of an array of positive Na and negative Cl ions, both carrying an elementary charge of magnitude e. Assume that a small "seed" crystal consists of four ions, forming a square of side 0.25 nm (Fig. 24–48). Find the electric force acting on one of the sodium atoms due to the other atoms of the seed and the work needed to remove this ion from the seed. Give your result in electron volts.

▲ **FIGURE 24–48** Problem 79.

80. (II) Calculate the potential at the point $P(x, y)$ due to the dipole in Fig. 24–49, which consists of a charge $+q$ placed at $(0, a)$ and a charge $-q$ placed at $(0, -a)$, and use this potential to calculate the electric field at point P.

▲ **FIGURE 24–49** Problem 80.

81. (II) Find the electric field along the axis of a uniformly charged ring of radius R and total charge Q by taking the appropriate derivatives of the potential found in Example 24–9. Set up the problem by using the direct integration techniques presented in Chapter 23. Compare the difficulties of the two ways of calculating the electric field.



82. (II) A positron (charge $+e$ and same mass as that of the electron) approaches a proton (charge $+e$) head-on. As a result of the repulsion, the positron turns around a distance $r_0 = 6.5 \times 10^{-10}$ m from the proton. What is the kinetic energy of the positron when it is very far from the proton? You may assume that the proton motion can be neglected.

83. (II) An electron is moving in the field of a helium nucleus (atomic number $Z = 2$). What is the change in the electron's potential energy when it moves from a circular orbit of radius 3×10^{-10} m to one of radius 2×10^{-10} m? What is the change in kinetic energy? in the total energy of the electron? Energy conservation is not violated in this process because it can be carried away by radiation that is emitted during the change of orbits.

84. (II) Four charges $+Q$, $-Q$, $+Q$ and $-Q$ are placed at a corners of a square of side L. What is the electric potential magnitude at a point P which lies on one of the diagonals of the square at a distance R from the center of the square, with $R \gg L$. [*Hint*: Use the binomial expansion $(R^2 \pm x^2)^n = R^{2n} \pm nR^{2n-2}x^2 + \dfrac{n(n-1)}{2}R^{2n-4}x^4 \pm \cdots$, good for $x < R$.] The field's dependence on R is characteristic of an *electric quadrupole*.

85. (II) Two concentric metal shells of radii r_1 and r_2 respectively carry charge q_1 and q_2 respectively. Assuming $r_1 < r_2$, what is the potential in the range $0 \le r \le \infty$?

86. (II) An electric dipole fixed in space consists of a charge $+q$ at the point $x = -0.2$ m and a charge $-q$ at the point $x = +0.2$ m, where $q = 5\ \mu$C. A test charge $q_0 = 3\ \mu$C is steadily moved from the point $x = +0.6$ m to the point $x = -0.4$ m by following a semicircular path of radius 0.5 m that takes the test charge through the y-axis (Fig. 24–50). How much work is required to move the test charge?

▲ **FIGURE 24–50** Problem 86.

87. (II) Two identical cork balls of charge $2.0\ \mu$C are suspended from the same point by thin threads 0.80 m long. (a) Calculate the mass of the cork balls if the threads each make a 30° angle with the vertical. (b) Calculate the potential energy of the system of two balls due to the presence of charges and to the presence of gravity as a function of the angle θ the threads make with the vertical. Choose zero gravitational potential energy to correspond to $\theta = 0$.

88. (II) A large, square plane with sides of length L, parallel to the yz-plane and located at x_1, has charge density σ_1. A similar plane, located at x_2, has charge density σ_2. How much work must be done to bring the second plane to within a distance a of the first one? Neglect end effects; that is, calculate the fields as though the planes were infinite.

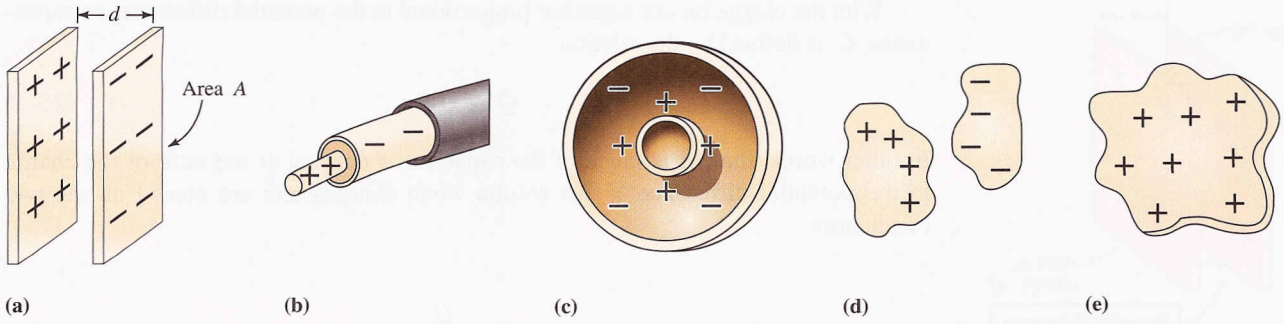
89. (III) An infinitely long cylinder of radius R is filled with uniform charge density ρ. Calculate the potential inside and outside the cylinder.

90. (III) The inner radius of a spherical dielectric shell is 16 cm, and the outer radius is 45 cm. The shell carries a charge of 5.0×10^{-6} C, distributed uniformly. Sketch the shape of the potential for all values of r, the distance from the center of the shell, and evaluate it at the center and at the inner and outer radii.

91. (III) A solid sphere of radius R has uniform charge density ρ. Calculate the total potential energy by calculating the energy required to bring a spherical shell of thickness dr and charge density ρ from infinity to a distance r from the sphere's center in the potential due to a uniformly charged sphere of radius r.

Chapter 25

▶ The interior of the target chamber of the NOVA laser at Lawrence Livermore National Laboratory. This project aims to produce controlled nuclear fusion by means of depositing large amounts of energy at the target; the energy can be delivered quickly because it is stored in large capacitor banks.



Capacitors and Dielectrics

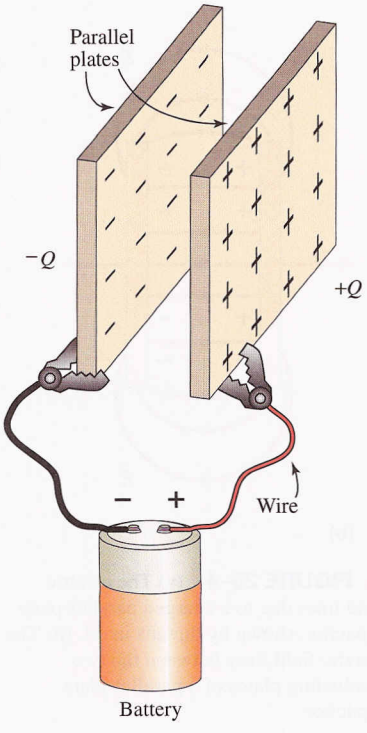
Any conducting object that carries a charge is characterized by an electric potential that is constant everywhere on and within that object. If two such conductors have a potential difference between them then, as any potential difference is able to accelerate charges, the system effectively stores energy. A capacitor is a device that can maintain a potential difference, storing energy by storing charge. The relation between the amount of charge a capacitor stores and the potential difference it maintains depends on the geometry of the capacitor. The storage of charge is also affected by the presence of insulating (nonconducting) material—dielectric material. In this chapter, we study the role capacitors play in electrical circuits, where they are indispensable elements, how they can be used directly as energy storage devices, as well as how geometry and dielectric materials affect the properties of capacitors. We also extend our fundamental knowledge about the behavior of matter by thinking about the microscopic structure of dielectrics and how that microscopic behavior shows itself at the everyday level.

25–1 Capacitance

A pair of conductors, whether separated by empty space or by an insulating material, forms the simplest type of **capacitor**. Capacitors store separated equal and opposite charges. In their most common and useful form, capacitors are made from two conductors with charge $+Q$ on one conductor and charge $-Q$ on the other. In Chapter 24 we saw that the potential difference[†] between the conductors is linearly dependent on this

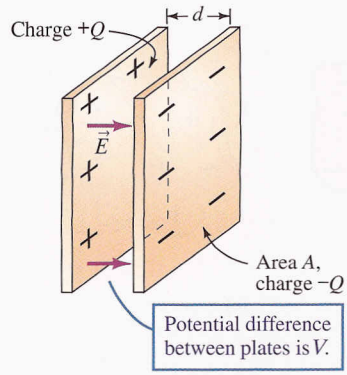
[†] We will also use the terms "potential," "voltage drop," or "voltage" rather than "potential difference."

▲ **FIGURE 25–1** Various kinds of capacitors: (a) parallel-plate; (b) coaxial cable; (c) spherical (two hollow conducting spheres); (d) conductors of arbitrary size and shape; (e) isolated conductor infinitely far from second conductor.



charge; that is, $V \propto Q$. Thus, if we double the charge, we double the potential difference between the two conductors, so that the ratio of Q to V between two conductors is constant. We call this constant ratio Q/V the **capacitance** C. It depends on the shape and arrangement (the geometry) of the two conductors of the capacitor, and on the material between the conductors. Figures 25–1a to 25–1e illustrate different configurations of conductors that can act as capacitors.

CONCEPTUAL EXAMPLE 25–1 In the case of Fig. 25–1e, there is a charge of only one sign. Where is the charge of the other sign?



Answer An isolated conductor has a capacitance because when charge is placed on it, the charge must be brought in from infinity. Remember that charge must be conserved, so that the second piece of the capacitor is, in effect, at infinity. The potential difference in this case is the difference between the potential at infinity, normally taken to be zero, and the potential on the isolated conductor itself. Accordingly, an isolated conductor held high above Earth forms a capacitor. Even Earth itself is a capacitor—we'll calculate its capacitance below.

Why are capacitors important? Capacitors of differing capacitance allow us to hold different amounts of charge for a given potential difference or to maintain different potential differences for a given amount of charge. Capacitors thus control the storage and delivery of charge. Since it requires work to separate charges, capacitors store energy as well as charge. This energy is quite visible in certain circumstances, particularly through the often rapid release of the energy. A lightning strike is the spectacular discharge of a large capacitor formed by the system of a cloud and Earth. In its simplest form, a camera photoflash contains a capacitor that stores energy and then discharges it when the flash is fired. The slow but smooth delivery of energy when capacitors are coupled with other circuit elements represents another type of application. Emergency backup systems for computers and electrical power distribution systems use capacitors in this way. Lastly, because capacitors play a crucial role in controlling the time dependence of the electric charges that move through circuits, almost any device with an electronic circuit contains capacitors. We regularly use capacitors both large and small. Devices for the possible generation of fusion energy employ gigantic capacitors whose energy content rivals that of the largest lightning strike. In the realm of microscopic circuits—nanotechnology, or quantum engineering—capacitors are used that may consist of small collections of atoms.

Consider a capacitor formed by placing equal but opposite charges, $+Q$ and $-Q$, on two conductors. This is easily done by touching the two conductors with wire leads attached to the + and − terminals of a battery (Fig. 25–2). The battery will give the two pieces a potential difference, and the amount of charge that accumulates depends on the shape of the conductors and on their relative positions. We call Q the *charge on the capacitor* even though the *net* charge on the oppositely charged pair of elements is zero.

▶ **FIGURE 25–2** We can construct a capacitor by connecting two wires to two conductors such as the plates shown here, and then attaching one wire to the positive terminal of a battery and the other wire to the negative terminal of the battery. This will place charge $+Q$ on one conductor and charge $-Q$ on another conductor.

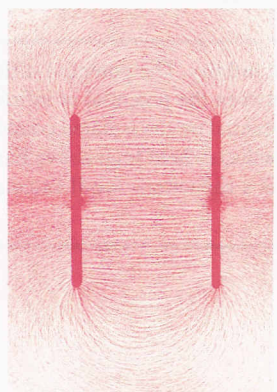
▲ **FIGURE 25–3** Two parallel plates with equal and opposite charges make up the most basic capacitor.

With the charge on our capacitor proportional to the potential difference, its capacitance, C, is defined by the relation

$$Q = CV. \tag{25–1}$$

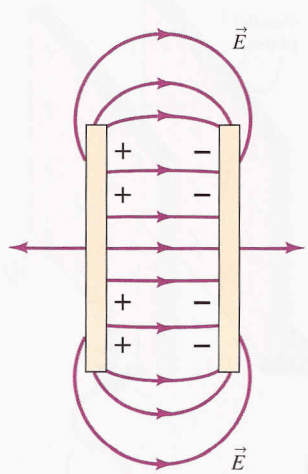
In other words, the capacitance of the capacitor is defined as the ratio of the charge to the potential difference V that results when charges $\pm Q$ are placed on the two conductors:

$$C \equiv \frac{Q}{V}. \tag{25–2}$$



DEFINITION OF CAPACITANCE

When there is charge on a capacitor, we say it is *charged*. When a capacitor *discharges*—for example, when it is used to fire a flashbulb—it can deliver its stored energy rapidly as the charges on the plates flow off.



C is always taken to be positive; that is, Eq. (25–2) should contain magnitudes only. The unit of capacitance is coulombs per volt (C/V), but capacitance occurs so frequently that it has been given its own SI unit, the **farad** (F), in honor of Michael Faraday:

$$1\ \text{F} \equiv 1\ \text{C/V}. \tag{25–3}$$

In practice, the farad is inconveniently large, and for practical use units of μF, nF, and pF ("puffs") are more common.

(a)

(b)

▲ **FIGURE 25–4** (a) The electric field lines due to a charged parallel-plate capacitor, shown by threads in oil. (b) The electric field lines between the two conducting plates of a parallel-plate capacitor.

Calculating Capacitance

The capacitance of a capacitor can be calculated easily if the geometry is simple. (Keep in mind that even if we can't calculate a capacitance, we can always measure it.) The most basic capacitor consists of two parallel conducting plates of area A, separated by a distance d, with charges $+Q$ and $-Q$, respectively, distributed uniformly over the plates (Fig. 25–3). If the dimensions of the plates are large compared with d, then the electric field between the plates is to a very good approximation constant. Neglecting (small) edge effects, we found previously that the field between the plates has magnitude $E = \sigma/\varepsilon_0$, where σ is the charge density Q/A and ε_0 is the permittivity of free space. The potential difference between the plates is $V = Ed$, and we can combine these results to find that

$$V = Ed = \frac{\sigma}{\varepsilon_0}d = \frac{Q}{A}\frac{d}{\varepsilon_0} = Q\frac{d}{\varepsilon_0 A}.$$

Thus $Q/V = \varepsilon_0 A/d$, and the capacitance $C \equiv Q/V$ of a parallel-plate capacitor is

$$C = \frac{Q}{V} = \frac{\varepsilon_0 A}{d}. \tag{25–4}$$

The fields near the edge, the *fringe fields*, are not uniform (Fig. 25–4). Their effect is small if the linear dimensions of the plates are much larger than the separation. Fringe fields do not affect the linear relationship between the charge and the potential, but do modify the simple form of Eq. (25–4). We will use the approximation of Eq. (25–4) throughout this chapter in reference to parallel-plate capacitors.

Equation (25–4) gives us a second commonly used unit for the permittivity of free space, ε_0, namely farads per meter (F/m):

$$\varepsilon_0 = 8.85 \times 10^{-12}\ \text{C}^2/\text{N}\cdot\text{m}^2 = 8.85 \times 10^{-12}\ \text{F/m} = 8.85\ \text{pF/m}.$$

Either unit is consistent with the SI.

EXAMPLE 25–2 (a) Calculate the capacitance C of parallel plates of area $A = 100\ \text{cm}^2$ separated by a distance $d = 1.0\ \text{cm}$. (b) Find the area of a parallel-plate capacitor with plate separation of 1.0 cm and a capacitance of 1.0 F.

Setting It Up The setup is similar to that of Fig. 25–3.

Strategy For part (a) we use Eq. (25–4) to determine the unknown capacitance. For part (b) we can again use this equation, but this time we solve it for A.

Working It Out (a) Substituting the known values into Eq. (25–4) gives

$$C = \frac{\varepsilon_0 A}{d} = \frac{(8.85\ \text{pF/m})(1.0 \times 10^{-2}\ \text{m}^2)}{1.0 \times 10^{-2}\ \text{m}} = 8.9\ \text{pF}.$$

The plate area is rather large, yet the capacitance is only 8.9 pF.

(b) We again use Eq. (25–4), this time solving for A:

$$A = \frac{dC}{\varepsilon_0} = \frac{(1.0 \times 10^{-2}\ \text{m})(1.0\ \text{F})}{8.85 \times 10^{-12}\ \text{F/m}} = 0.11 \times 10^{10}\ \text{m}^2.$$

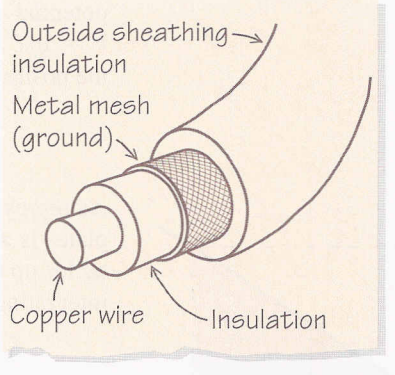
This represents a square with sides of length $0.33 \times 10^5\ \text{m} = 33\ \text{km}$! Most common practical capacitors have capacitances much smaller than 1 F.

What Do You Think? Suppose the charge on each plate doubles. By how much does C change? *Answers to **What Do You Think?** questions are given in the back of the book.*

EXAMPLE 25–3 Consider a system made of a solid conducting cylinder of radius a surrounded by a thin coaxial conducting tube, or sheath, of radius b. Find the capacitance per unit length of this system, assuming that there is a vacuum between the central wire and the sheath. This is a model of a *coaxial cable*, a wire used for the high-speed transmission of signals. In a real coaxial cable, there would be some type of material, not a vacuum, between the central wire and the sheath, but for simplicity we assume here that there is a supporting material that has the electrical properties of a vacuum.

Setting It Up The system is sketched in Fig. 25–5. (Keep in mind that the material that mechanically supports the outer cylinder has the electrical properties of the vacuum.) We want to find the potential difference for a given charge. For an infinitely long system, however, we can specify only the charge *per unit length*, so we must similarly calculate the capacitance per unit length.

Strategy The capacitance is the ratio of the charge to the potential difference, and the capacitance per unit length is the ratio of the charge per unit length to the potential difference. Therefore we set a charge per unit length $+\lambda$ on the outer (and $-\lambda$ on the inner) conductor of the cable and calculate the resulting potential between the conductors. This calculation was already done in Example 24–11. There, we saw how Gauss' law gives the electric field, and hence the potential, outside a wire of finite radius. That example applies directly to the potential in the space *between* the conductors of our system.



Working It Out From Example 24–11, we have

$$V_b - V_a = \frac{\lambda}{2\pi\varepsilon_0} \ln \frac{b}{a}.$$

Dividing the charge per unit length λ by this potential difference gives the capacitance per unit length, a quantity we denote by c:

$$c = \frac{\lambda}{V_b - V_a} = \frac{2\pi\varepsilon_0}{\ln(b/a)} \qquad (25\text{–}5)$$

Equivalently, the capacitance of a length L of the cable is L times this value.

▲ **FIGURE 25–5** The coaxial cable has an inner solid wire of radius a and a cylindrical metal sheath of radius b. An insulator is placed between the two conductors.

EXAMPLE 25–4 *The Isolated Sphere.* What is the capacitance of an isolated conducting sphere of radius R? Calculate Earth's capacitance.

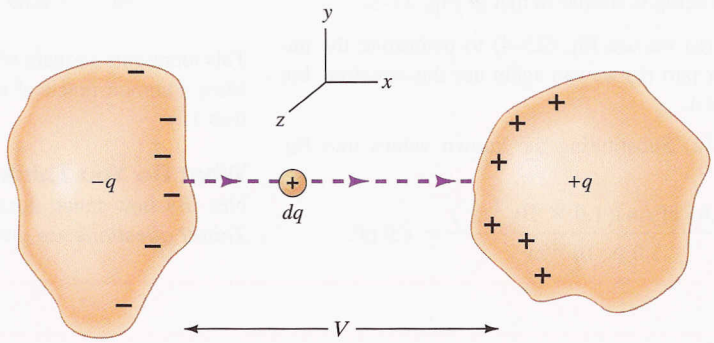
Strategy We place a charge Q on the sphere and find its potential V, assuming the potential at infinity is zero; because the "second piece" of the capacitor is at infinity, V is indeed the appropriate potential difference. The ratio Q/V is, by definition, the capacitance.

Working It Out We found in Example 24–12 that, for the potential at infinity set at zero, the potential of a conducting sphere is

$$V = \frac{Q}{4\pi\varepsilon_0 R}.$$

The capacitance of the isolated sphere is Q divided by V:

$$\text{for an isolated sphere: } C = \frac{Q}{V} = 4\pi\varepsilon_0 R. \qquad (25\text{–}6)$$



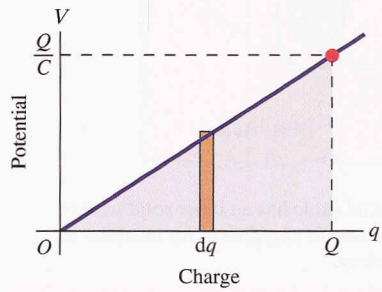
Earth's capacitance is determined by setting R equal to Earth's radius, $R_E = 6.38 \times 10^6\ \text{m}$. Therefore

$$C = 4\pi\varepsilon_0 R = 4\pi(8.85 \times 10^{-12}\ \text{F/m})(6.38 \times 10^6\ \text{m})$$
$$= 7.10 \times 10^{-4}\ \text{F}.$$

It is interesting to compare this number to the value of the largest capacitors in use, of the order of 1 F.

What Do You Think? Perform a dimensional analysis to confirm the dependence of the capacitance on the radius.

The technique for determining the capacitance is always the same. We assume that the conductors have a charge $\pm Q$; then we find the potential difference V between the conductors due to this charge. The ratio Q/V gives the capacitance.



▶ **FIGURE 25–6** Work is done when an infinitesimal charge dq is moved between the two conductors of a capacitor already charged to a potential difference V.

25–2 Energy in Capacitors

There is an electric field between the two conductors of a charged capacitor, and this field can accelerate a test charge. Thus, a charged capacitor is capable of doing work and must contain energy. The energy contained in a charged capacitor is in fact the work required to charge it, and we can calculate this work to find the energy the capacitor contains. Start by taking a positive charge dq from one neutral conductor and moving it to the other neutral conductor. The second conductor then has charge $+dq$, and the first conductor has charge $-dq$. If we do this for a time, the conductors will be charged to a potential difference V with charge q (Fig. 25–6), and V is given in terms of q by $V = q/C$. To move an *additional* charge dq from the negatively charged conductor to the positively charged one, we must then do work

$$dW = V\,dq = \frac{q}{C}\,dq.$$

▲ **FIGURE 25–7** The amount of work $dW = V\,dq$ that is done to move a charge element dq from one part of a capacitor to the other increases as the charge on the conductors—and hence the potential V across them—builds up. The total work is found by adding the work elements together. This work is the area under a curve of potential difference versus charge on the plates: the integral of $V\,dq$.

As represented in Fig. 25–7, the infinitesimal work done to place a charge dq on the plates is zero when the plates are uncharged and increases as the charge on the plates builds up to $\pm Q$. The total work done as the charge increases from 0 to Q is obtained by integrating the above expression from $q = 0$ to $q = Q$:

$$W = \int dW = \int_0^Q \frac{q}{C}\,dq = \frac{1}{C}\int_0^Q q\,dq = \frac{Q^2}{2C}. \qquad (25\text{–}7)$$

This is a general result for all capacitors.

Once charged, the stored energy in the capacitor can do work. We can think of the stored energy as a potential energy. This potential energy can be used to move a test charge placed between the conductors or to cause a flashbulb to flash.

To summarize, the potential energy of a charged capacitor is

$$U = \frac{Q^2}{2C}. \qquad (25\text{–}8)$$

ENERGY IN A CAPACITOR

Because $Q = CV$, this result is equivalent to

$$U = \frac{CV^2}{2}. \qquad (25\text{–}9)$$

ENERGY IN A CAPACITOR

The first form is used when the charge is known; the second when the potential is known. Another equivalent form that is useful when the charge and voltage are both known is

$$U = \frac{QV}{2}. \qquad (25\text{–}10)$$

ENERGY IN A CAPACITOR

As we know from Chapter 24, the electric potential energy associated with the movement of a charge Q through a fixed potential V is $U = QV$. This expression differs by a factor of 2 from the capacitor energy $QV/2$, Eq. (25–10). The reason for this difference is that, as a capacitor is charged, the potential increases from 0 to V, and in effect the average potential as the charging takes place is $V/2$.

Batteries vs. Capacitors

A *battery* is a chemical device for the storage of energy. Whereas the potential of a capacitor decreases as the capacitor delivers its charge, a battery ideally maintains a fixed potential between two points (terminals) as it delivers charge. If we want to charge a capacitor to a certain potential, we can use a battery because it can hold the desired potential even as it delivers charge to the capacitor.

EXAMPLE 25–5 A 12-V car battery is used to charge a 100-μF capacitor. (a) How much energy is stored in the capacitor? (b) Compare this energy with the energy stored in the battery itself, if the battery is capable of delivering a total charge of $Q = 3.6 \times 10^5$ C at the given voltage. (This is the charge that can be delivered by a battery rated at 100 ampere-hours; the ampere-hour is a standard unit for charge.)

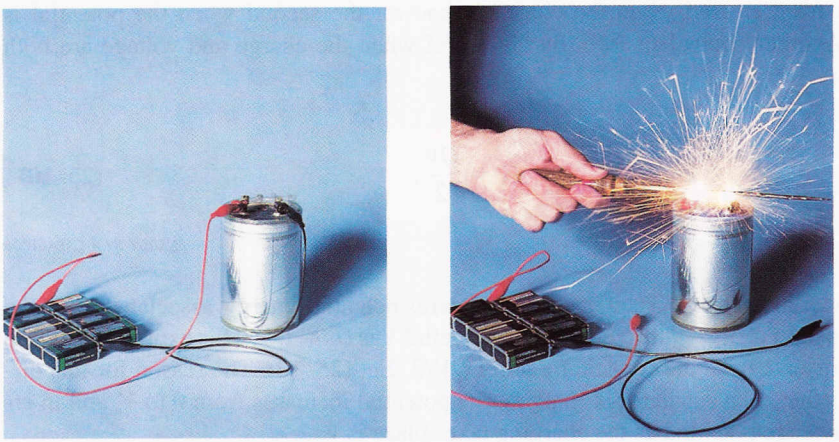
Setting It Up By a "12-V battery" we mean a battery with a 12-V potential difference across its leads. In the charging process the battery brings the potential difference across the capacitor plates to that same value.

Strategy (a) To find the energy in the capacitor given the capacitance and the potential difference across it, we apply Eq. (25–9). (b) The electric potential energy associated with the movement of a charge Q through a fixed potential V is $U = QV$. If the battery is capable of moving a given amount of charge through a given potential, as described here, then the battery must contain at least this amount of energy.

Working It Out (a) We have

$$U = \frac{CV^2}{2} = \frac{(100 \times 10^{-6}\ \text{F})(12\ \text{V})^2}{2} = 7.2 \times 10^{-3}\ \text{J}.$$

The answer is in joules—we have used SI units throughout.



(b) The potential energy in the battery is (at least)

$$U = QV = (3.6 \times 10^5\ \text{C})(12\ \text{V}) = 4.3 \times 10^6\ \text{J}.$$

The battery contains a factor of 6×10^8 more energy than is stored in the capacitor!

What Do You Think? Why is it possible to store so much more energy in the battery?

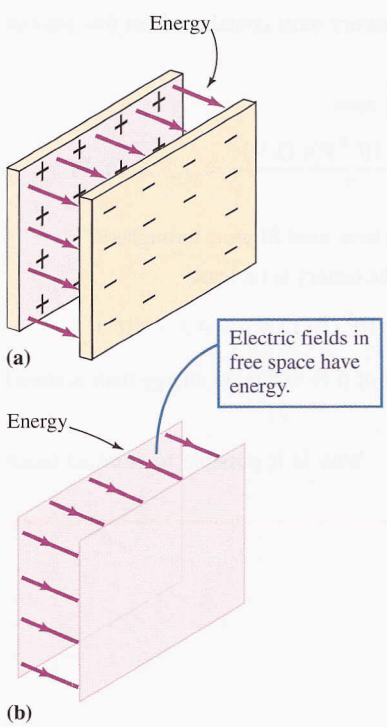
The car battery of Example 25–5 has a potential energy of about 10^6 J. This is far more energy than that of a typical practical capacitor of 100 μF charged to a moderate potential. A typical capacitor would require a potential of about 10^{10} V to store the amount of energy in a car battery. The largest available commercial capacitors have capacitance on the order of 1 F, and it would require a potential of about 1000 V for a 1-F capacitor to contain as much energy as that contained in the car battery. However, high voltages across capacitors present their own difficulties, and large capacitors can be charged to a potential of only a few volts. A battery's energy is stored in chemical bonds rather than in the macroscopic separation of charge. Batteries provide a practical way to store large amounts of energy for long periods, but they are not a practical way to quickly deliver electrical energy when it is needed. (By electrical energy, we essentially mean the movement of charge. Chemical energy can in other situations be delivered quickly, as in chemical explosives.) Conversely, whereas a capacitor cannot store as much energy as a battery, it can deliver electrical energy much more quickly. This is achieved if a charged capacitor is "shorted," meaning that the two plates are connected by a conducting wire, as in Fig. 25–8.

(a) (b)

▶ **FIGURE 25–8** (a) Energy is stored in a capacitor by charging it. (b) Shorting the capacitor allows the charges on the capacitor to recombine and results in a rapid release of the stored energy, which makes a spectacular display of light and heat.

25–3 Energy in Electric Fields

The electric field is of fundamental physical significance. In this section, we develop the concept that the energy of a capacitor is contained in the electric field itself.



We start by relating the expression for the energy in a capacitor to the strength of the electric field in that capacitor. The parallel-plate capacitor is convenient for this purpose because both the capacitance and the field are known (Fig. 25–4). Equation (25–4) gives the capacitance for this case, $C = \varepsilon_0 A/d$, where A is the plate area and d is their separation. The field has constant strength E, and the potential difference between the plates is $V = Ed$. Thus Eq. (25–9) gives the energy

$$U = \frac{CV^2}{2} = \frac{\varepsilon_0 A}{2d}(Ed)^2 = \left[\frac{\varepsilon_0 E^2}{2}\right](Ad). \tag{25–11}$$

We have written Eq. (25–11) so that the *volume* of the space between the plates, Ad, stands out. This is the volume that contains the electric field and, because the field is constant, the coefficient of the volume (the quantity in square brackets) in Eq. (25–11) is the **energy density**, u, or energy per unit volume:

$$u \equiv \frac{U}{\text{volume}} = \frac{\varepsilon_0 E^2}{2}. \tag{25–12}$$

ENERGY DENSITY IN ELECTRIC FIELD

▲ **FIGURE 25–9** Electric fields have energy whether they are (a) inside a capacitor or (b) in free space.

This result suggests that the energy of a capacitor is located where the associated electric field exists, in the space between the plates (Fig. 25–9a). Now imagine that the plates aren't there but the field remains (Fig. 25–9b). Equation (25–12) is in fact *a general expression for the local energy density in free space, for a constant or variable electric field.* Wherever there is an electric field—even one that varies throughout space—the energy density, or energy per unit volume, at a particular location in space is found by squaring the electric field there and multiplying by $\varepsilon_0/2$. This makes sense if we use the reasoning that if a physical configuration can do work, it must contain energy—after all, if we place a test charge in a region of space where there is an electric field, it will accelerate, gaining energy in the process. In Section 25–5 we shall see that we must modify the coefficient $\varepsilon_0/2$ when dielectrics are present, but the energy density is always *proportional* to the square of the field.

CONCEPTUAL EXAMPLE 25–6 The plates of an isolated parallel-plate capacitor with a fixed charge on the plates are pulled slightly apart. Does the energy density change in the region between the plates? Does the overall energy in the field increase and, if so, why?

Answer We have argued that the energy density u depends on the electric field, but the field magnitude is σ/ε_0, and as long as the plate separation is small compared to their size, this doesn't depend on the distance between the plates. The energy density is constant. However, the volume between the plates has increased, so that the total energy in the field increases. This makes sense because the two oppositely charged plates attract, and it takes positive work to separate them further. We have added energy to the system by moving them apart, and this shows up in the greater total energy in the field.

EXAMPLE 25–7 An isolated spherical conductor of radius R carries a total charge Q. (a) Determine the energy density at each point in space as a function of the distance r from the sphere's center. (b) Use this energy density to compute the system's total energy. (c) Compare this total energy to the work done in charging the sphere.

Strategy (a) Equation (25–12) expresses the energy density in terms of the electric field. Equation (22–5) gives the electric field at a radius r outside the charged sphere. This field is radial and has magnitude $E = Q/(4\pi\varepsilon_0 r^2)$. Inside the conducting sphere, the field is zero.

(b) We must integrate the energy density over all space to find the total energy. As we have spherical symmetry, we can reduce the three-dimensional integral over all space to a one-dimensional integral over the radial distance by considering the volume as a series of concentric spherical shells. Because the energy density is zero inside the sphere, we need integrate only over radii larger than R.

(c) To calculate the work required to charge the sphere by bringing charge in from infinity, suppose that the sphere already has charge q and is at a potential of $V = q/(4\pi\varepsilon_0 R)$. The additional work to bring charge dq in is $dW = V\,dq$, and this must be integrated from $q = 0$ to $q = Q$.

Working It Out (a) Given our value for the electric field, the energy density at distance r is

$$u = \frac{\varepsilon_0 E^2}{2} = \frac{Q^2}{32\pi^2\varepsilon_0 r^4}$$

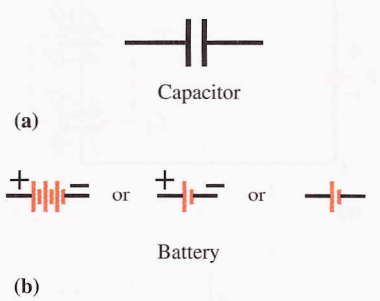
outside the sphere ($r > R$) and zero inside ($r < R$).

(b) The volume dV of a thin shell of thickness dr is the product of dr and the surface area of the shell, $4\pi r^2$. Then the volume element $dV = 4\pi r^2\,dr$, and the system's total energy is

$$U = \int_{\text{volume}} u\,dV = \frac{Q^2}{32\pi^2\varepsilon_0}\int_R^\infty \frac{4\pi r^2}{r^4}\,dr$$
$$= \frac{Q^2}{8\pi\varepsilon_0}\int_R^\infty \frac{dr}{r^2} = -\frac{Q^2}{8\pi\varepsilon_0}\frac{1}{r}\Big|_R^\infty = \frac{Q^2}{8\pi\varepsilon_0 R}.$$

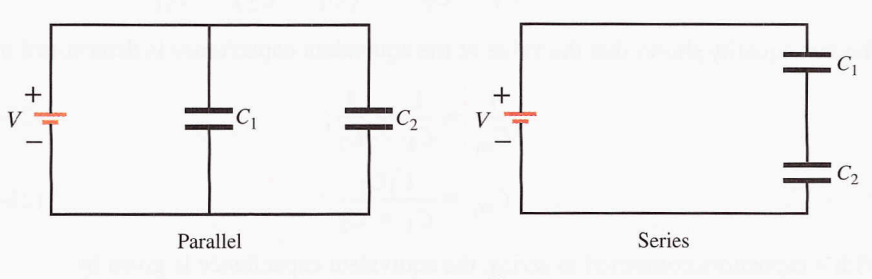
(c) We integrate $V dq$ from $q = 0$ to Q to determine the total work done. This gives

$$W = \int dW = \int V\,dq$$
$$= \int_0^Q \frac{q}{4\pi\varepsilon_0 R}\,dq = \frac{1}{4\pi\varepsilon_0 R}\int_0^Q q\,dq = \frac{Q^2}{8\pi\varepsilon_0 R}.$$



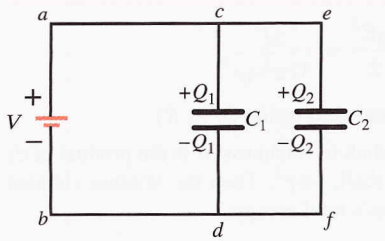
The work done to bring the charge in from infinity is indeed equal to the total energy of the system found in part (b). This is a good check on the validity of our calculations.

What Do You Think? Our results indicate that the energy density increases dramatically for smaller R. Does this make sense?

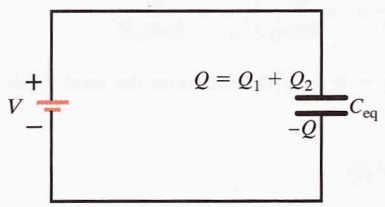


25–4 Capacitors in Parallel and in Series

Circuits

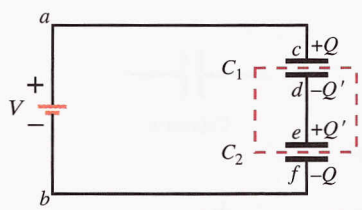


Here we begin our discussion of electric circuits, in which the physics of electric and magnetic fields have direct application to a myriad of electrical devices that we use each day. We have already mentioned two circuit elements: capacitors and batteries. We use the universal symbols shown in Fig. 25–10 for batteries and capacitors in circuit diagrams, which are schematic drawings that illustrate the connection of various circuit elements. The lines connecting circuit elements in these diagrams are assumed to be perfectly conducting wires, which means that they form equipotentials. We can use circuit diagrams to single out some interesting capacitor combinations. In a **parallel** combination, capacitors are connected as in Fig. 25–11a, with equal voltage drops across the capacitors; in a **series** combination, capacitors are connected as in Fig. 25–11b, with equal charges on the capacitors. We can simplify the analysis of circuits by finding the capacitance of the single *equivalent capacitor* that can replace these combinations without changing the potential across them.

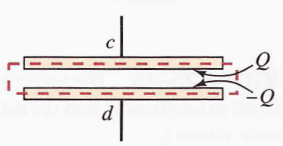


▲ **FIGURE 25–10** The symbols used to indicate (a) capacitors and (b) batteries in electric circuits.

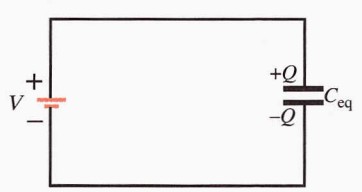
▲ **FIGURE 25–11** (a) Circuit with two capacitors connected in parallel. (b) Circuit with two capacitors connected in series.



(a)



(b)



▲ **FIGURE 25–12** (a) A battery is used to place the same voltage V across the two capacitors connected in parallel. The charge on each capacitor depends on their individual capacitances. (b) The two capacitors can be replaced by an equivalent capacitor C_{eq}.

(a)

(b)

(c)

▲ **FIGURE 25–13** (a) Two capacitors connected in series must have identical charges $\pm Q$ but can have different voltages. The net charge within the dashed region is zero. (b) By drawing a Gaussian surface we establish that $Q' = Q$. (c) The two capacitors can be replaced by an equivalent capacitor C_{eq}.

Parallel Connection

The battery in Fig. 25–12a maintains a potential V across the points a and b. Because the connecting wires are perfect conductors, the line *ace* is an equipotential, as is the line *bdf*. The potential difference from points c to d and from e to f must therefore also be V. *Capacitors connected in parallel have the same potential between their conductors.*

What is the equivalent capacitance, C_{eq}, of the single capacitor—defined by Fig. 25–12b—that could replace the parallel combination of capacitors C_1 and C_2 in such a way that the behavior of the circuit outside the parallel combination is unchanged? The equivalent capacitor will have the same potential difference V and total charge Q as the parallel combination of C_1 and C_2 and it is this condition that determines C_{eq}. The charges on C_1 and C_2 are related to the voltage across each capacitor:

$$Q_1 = C_1V \quad \text{and} \quad Q_2 = C_2V.$$

The charge for the equivalent capacitor is $Q = C_{eq}V$, and the total charge produced by the battery for the circuit in Fig. 25–12a is $Q_1 + Q_2$, so

$$Q = Q_1 + Q_2 = C_1V + C_2V = (C_1 + C_2)V = C_{eq}V.$$

The last equality shows that

$$C_{eq} = C_1 + C_2. \tag{25–13}$$

With n capacitors connected in parallel, we can similarly show that the equivalent capacitance is

$$C_{eq} = C_1 + C_2 + \cdots + C_n. \tag{25–14}$$

When capacitors are arranged in parallel, the total capacitance is larger than any of the individual capacitances.

Series Connection

We can also determine the single capacitor equivalent to capacitors connected in series (Fig. 25–13a). Because the battery maintains a fixed potential V, charge $+Q$ appears at c and charge $-Q$ at f. The positive charge at c induces a charge $-Q'$ at d, and because the isolated piece of metal enclosed by the dashed line in Fig. 25–13a is neutral, $+Q'$ also appears at e. We now show that $Q' = Q$ by drawing a Gaussian surface like that shown in Fig. 25–13b. Because there is no field within the metal plates and because there is no electric flux through the short side portions, the flux through the surface is zero, the net charge enclosed must be zero, and $Q' = Q$. Capacitors C_1 and C_2 thus have identical charges Q. *Capacitors connected in series have identical charges.*

The single equivalent capacitor C_{eq} in the circuit of Fig. 25–13c must carry the identical charges $+Q$ and $-Q$ and have the same potential difference V across it as exists between c and f in the circuit of Fig. 25–13a. Capacitor C_1 has potential $V_1 = Q/C_1$; similarly, capacitor C_2 has potential $V_2 = Q/C_2$. The total potential is $V = V_1 + V_2$, so we have

$$V = V_1 + V_2 = \frac{Q}{C_1} + \frac{Q}{C_2} = Q\left(\frac{1}{C_1} + \frac{1}{C_2}\right) = \frac{Q}{C_{eq}}.$$

The last equality shows that the value of the equivalent capacitance is determined by

$$\frac{1}{C_{eq}} = \frac{1}{C_1} + \frac{1}{C_2}; \tag{25–15}$$

$$C_{eq} = \frac{C_1C_2}{C_1 + C_2}. \tag{25–16}$$

With n capacitors connected in series, the equivalent capacitance is given by

$$\frac{1}{C_{eq}} = \frac{1}{C_1} + \frac{1}{C_2} + \cdots + \frac{1}{C_n}. \tag{25–17}$$

When capacitors are arranged in series, the total capacitance is given by the reciprocal of the expression in Eq. (25–17), and this capacitance is less than any of the individual capacitances.

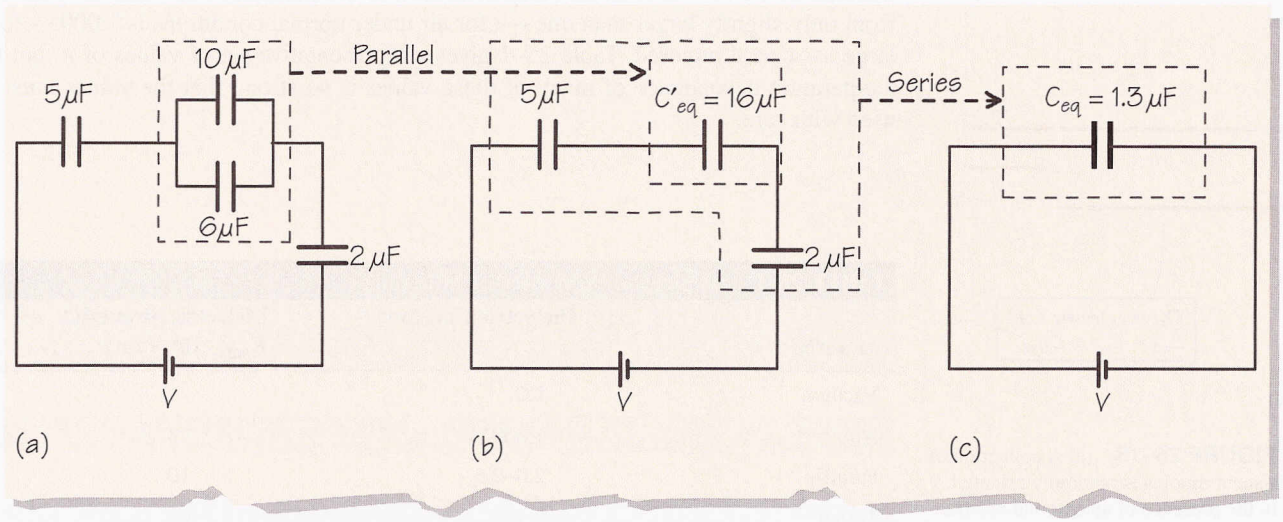
CONCEPTUAL EXAMPLE 25–8 Suppose you add an additional capacitor in series to a group of capacitors already in series. Does the equivalent capacitance increase or decrease?

Answer According to Eq. (25–17), if we add another capacitor in series, the value of $1/C_{eq}$ increases, so that C_{eq} decreases.

EXAMPLE 25–9 Determine the equivalent capacitance for the capacitors in the circuit shown in Fig. 25–14a.

Strategy In this circuit, the capacitors are combined both in series and in parallel, and we want to find the single equivalent capacitance for the whole combination. Our first step is to combine the two capacitors in parallel into one capacitor of value C'_{eq} (Fig. 25–14b); we then combine the three remaining capacitors in series into one final equivalent capacitor (Fig. 25–14c).

Working It Out We use Eq. (25–14) to combine the parallel capacitors in Fig. 25–14a:



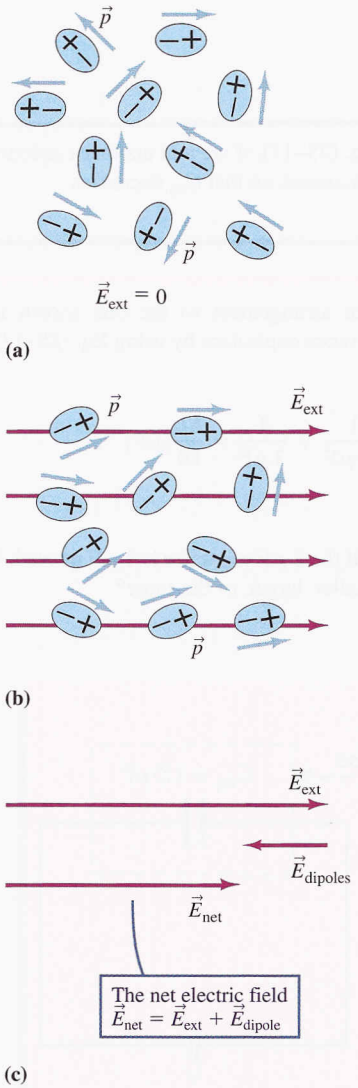
$$C'_{eq} = 10\ \mu\text{F} + 6\ \mu\text{F} = 16\ \mu\text{F}.$$

Having reduced the capacitor arrangement to the one shown in Fig. 25–14b, we combine the series capacitors by using Eq. (25–17), as in Fig. 25–14c:

$$\frac{1}{C_{eq}} = \frac{1}{5\ \mu\text{F}} + \frac{1}{16\ \mu\text{F}} + \frac{1}{2\ \mu\text{F}} = \frac{61}{80}(\mu\text{F})^{-1};$$

$$C_{eq} = 1.3\ \mu\text{F}.$$

What Do You Think? If the 2 μF capacitor is 1 μF instead, is the equivalent capacitance smaller, larger, or the same?



▲ **FIGURE 25–14** (a) Four capacitors of this electric circuit can be combined into one. (b) The two parallel capacitors are combined, giving three capacitors in series, (c) which are then combined into one *equivalent capacitor* C_{eq}.

25–5 Dielectrics

Many materials, including paper, plastics, and glass, do not conduct electricity easily; we referred to them earlier as *insulators*. Nevertheless, they modify the external electric fields in which they are placed. We call these materials **dielectrics**. We shall see that a dielectric placed in a capacitor allows more charge on the capacitor for a given voltage. A solid dielectric placed between a capacitor's two conductors also lends strength and mechanical stability to the capacitor. Finally, a dielectric can reduce the possibility of charge leakage and of sparking across the plates of a capacitor.

In this section, we take an experimental point of view of dielectrics, and in the next section we explore the microscopic origin of this behavior. Before we describe the basic experimental facts, however, it is worthwhile to take a peek ahead and describe in a conceptual way the underlying mechanism. Electrons are not free to move in dielectrics as they do in conductors, but that does not mean there is no response to an applied field. Dielectrics contain molecules that can behave as dipoles, either permanent ones or induced ones, and we can illustrate the possible effects with a collection of permanent

▲ **FIGURE 25–15** (a) A collection of permanent dipoles is randomly oriented. (b) In the presence of an external electric field, the dipoles tend to align themselves along the external field. (c) The aligned dipoles produce their own field $\vec{E}_{dipole}$ that tends to cancel the external field $\vec{E}_{ext}$ that aligned them, producing a net field $\vec{E}_{net}$.

dipoles. When such a collection starts completely unaligned (Fig. 25–15a) and is exposed to an external field, the dipoles align with the field as in Fig. 25–15b. But once there is a set of aligned dipoles, the set of dipoles can make its own electric field, which as in Fig. 25–15c opposes the external field. The net field within the material is thereby decreased. It is helpful to keep this qualitative picture in mind as we turn to the experimental facts.

Michael Faraday is generally given credit for having performed the first experiments, in the early nineteenth century, that showed that the capacitance increases when insulating materials are placed between the two conductors of a capacitor. If C_0 is the capacitance of a given capacitor in a vacuum (or in air), then the capacitance C of the same capacitor with dielectric between its conductors is larger than C_0 by a factor called the **dielectric constant**, κ. We have

$$C = \kappa C_0; \tag{25–18}$$

CAPACITANCE MODIFICATION IN DIELECTRICS

$$\kappa \equiv \frac{C}{C_0}. \tag{25–19}$$

The dielectric constant κ, which is larger than unity for all materials, depends on the material as well as on external conditions such as temperature. The value of κ can run from only slightly larger than one—κ for air under normal conditions is 1.0005—to as large as several hundred. Table 25–1 gives a representative set of values of κ, but the temperature dependence of many of these values is so strong that the values must be used with care.

TABLE 25–1 • Dielectric Properties of Materials[†]

Material	Dielectric Constant, κ	Dielectric Strength, E_{max} (10^6 V/m)
Vacuum	1.0	
Air	1.00054	3
Paraffin	2.0–2.5	10
Teflon	2.1	60
Polystyrene	2.5	24
Lucite	2.8	20
Mylar	3.1	
Plexiglas	3.4	40
Nylon	3.5	14
Paper	3.7	16
Fused quartz	3.75–4.1	
Pyrex	4–6	14
Bakelite	4.9	24
Neoprene rubber	6.7	12
Silicon	12	
Germanium	16	
Water	80	
Strontium titanate	332	8

[†]Values for some materials depend strongly on temperature and the frequency of oscillating fields.

You may have seen a device that makes use of the modifications due to dielectrics, an electric stud finder (Fig. 25–16). A unit with a metal plate acting as a capacitor in a circuit slides along a wall. Unless the plate is over a stud, there is air behind the wall, but when a stud is encountered, the capacitance changes because wood is a dielectric, and this is detectable in the circuit.

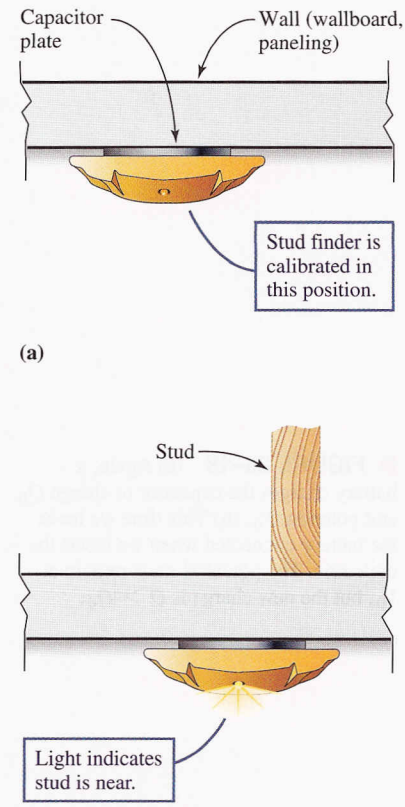
Experimental Evidence for the Behavior of Dielectrics

To simulate the experiment that led Faraday to his conclusions about dielectrics, let's first use a battery to charge a parallel-plate capacitor in air to a potential V_0 and a charge $Q_0 = C_0V_0$ (Fig. 25–17a). (By "air" we mean an approximate vacuum—air itself has a dielectric constant, but it is very close to unity.) Here, the subscripts refer to the quantity in air—for example, C_0 is the capacitance when there is air between the plates. We disconnect the battery and measure the voltage, or potential difference (Fig. 25–17b). We then slide a dielectric, such as Plexiglas, between the plates (Fig. 25–17c). *The voltage is reduced.* The charge is unchanged—Plexiglas is an insulator—and the reduction factor is what we called above the dielectric constant:

$$V = \frac{V_0}{\kappa}.$$

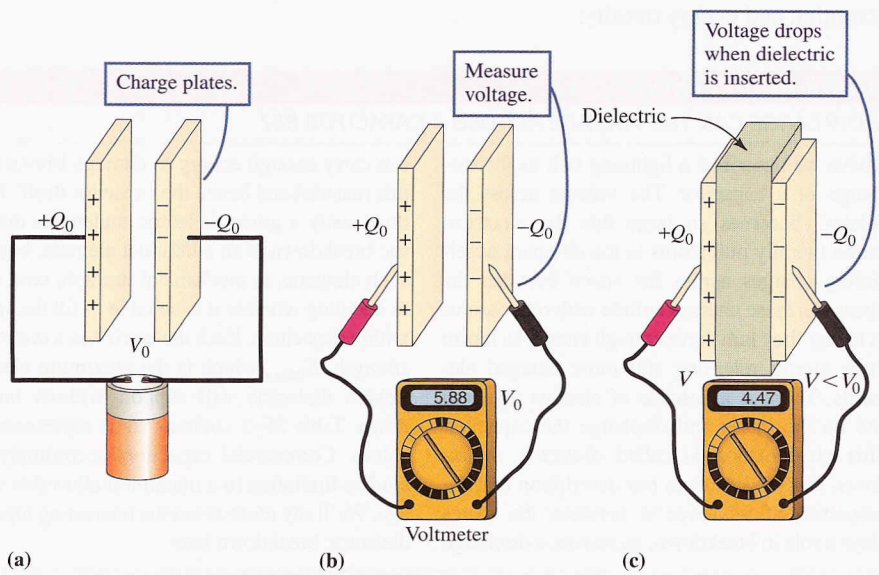
To see that κ is indeed the dielectric constant defined above, note that the charge did not change, so we can interpret the reduction of the voltage as due to a change in the capacitance from the original value C_0 to a new value C:

$$C = \frac{Q_0}{V} = \frac{Q_0}{V_0/\kappa} = \kappa\frac{Q_0}{V_0} = \kappa C_0.$$



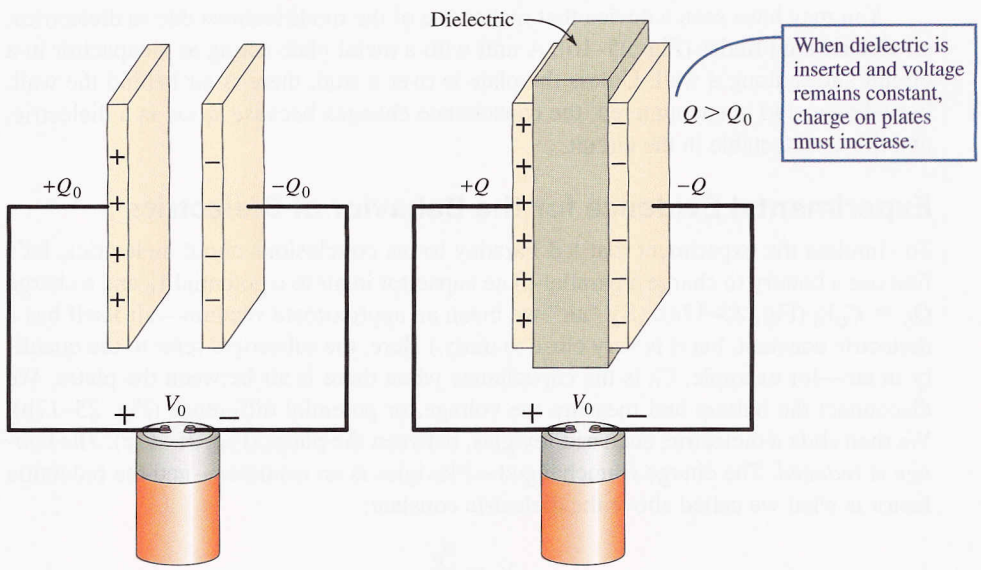
This verifies Eq. (25–18).

In another experiment we leave the battery connected to the capacitor after it is charged in air (Fig. 25–18a). After we insert the Plexiglas the potential remains the battery voltage V_0 (Fig. 25–18b). We observe, however, that *the charge on the conducting plates increases* by a factor of κ ($Q = \kappa Q_0$). Our experimental result remains in agreement with Eq. (25–18):



$$C = \frac{Q}{V_0} = \frac{\kappa Q_0}{V_0} = \kappa C_0.$$

Let's reinterpret these results in terms of permittivity. If we take a parallel-plate capacitor, for which $C_0 = \varepsilon_0 A/d$, we have



$$C = \kappa C_0 = \frac{\kappa\varepsilon_0 A}{d}. \qquad (25\text{–}20)$$

▲ **FIGURE 25–16** A schematic diagram of a stud finder, as seen from above the wall looking down. In (a) the stud finder is calibrated with no dielectric material (as for example a building stud) behind the wall. (b) The capacitance changes when the stud finder approaches a stud.

◀ **FIGURE 25–17** (a) A battery charges a capacitor to charge Q_0 and potential V_0. (b) If we take the battery away and measure the voltage with a voltmeter, we measure V_0 for the voltage. (c) If a dielectric is inserted into the capacitor, the voltage drops to $V < V_0$.

▶ **FIGURE 25–18** (a) Again, a battery charges the capacitor to charge Q_0 and potential V_0. (b) This time we leave the battery connected when we insert the dielectric. The potential must remain at V_0, but the new charge is $Q > Q_0$.

If the charge is held fixed, the new voltage is

$$V = \frac{V_0}{\kappa} = \frac{Q_0}{\kappa C_0} = \frac{\sigma_0 A}{\kappa C_0} = \frac{\sigma_0 d}{\kappa \varepsilon_0}. \tag{25–21}$$

The new electric field between the plates is reduced in magnitude to

$$E = \frac{V}{d} = \frac{\sigma_0}{\kappa \varepsilon_0} = \frac{E_0}{\kappa}, \tag{25–22}$$

where $E < E_0$. Note that in each of Eqs. (25–20) through (25–22) we can *replace the permittivity of free space, ε_0, by a new permittivity, ε*, which depends on the dielectric used and on external conditions:

$$\varepsilon = \kappa \varepsilon_0. \tag{25–23}$$

PERMITTIVITY MODIFICATION IN DIELECTRICS

Although we have shown this simple rule only for the parallel-plate case, the substitution of ε for ε_0 when a dielectric is involved applies to all geometries and to all equations in which the permittivity appears, such as the expressions for field strength, potential, and energy density.

THINK ABOUT THIS. . .

HOW LARGE CAN THE VOLTAGE ACROSS A CAPACITOR BE?

Above we described a lightning bolt as the discharge of a capacitor. The voltage across the "plates" becomes so large that the electrical forces literally pull atoms in the air apart, accelerating charges across the space between the plates. As these charges collide with other atoms in the air they may have enough energy to ionize these atoms, releasing still more charged elements. There is a cascade of charges that will end on the plates and discharge the capacitor. This phenomenon is called *dielectric breakdown*. It is evident from our description that the properties of whatever is between the plates plays a role in breakdown; moreover, a discharge can carry enough energy to damage irrevocably this material and hence the capacitor itself. Thus how easily a given dielectric undergoes dielectric breakdown is an additional element, beyond such elements as mechanical strength, cost, etc., in deciding whether it is suitable to fill the space within capacitors. Each dielectric has a *dielectric strength*, $E_{\max}$, which is the maximum electric field a dielectric will support without breakdown. Table 25–1 contains some representative values. Commercial capacitors accordingly include a limitation to a maximum allowable voltage. We'll say more about the interesting topic of dielectric breakdown later.

EXAMPLE 25–10 A parallel-plate capacitor has plate area 20.0 cm^2 and a plate separation 4.0 mm. (a) Find the capacitance in air and the maximum voltage and charge the capacitor can hold. (b) A Teflon sheet is slid between the plates, filling the entire volume. Find the new capacitance and maximum charge. (c) Before the insertion of the Teflon, the plates are set to a voltage of 24 V by a battery that is then disconnected. What are the energies in the capacitor before and after the Teflon is inserted?

Setting It Up We have a standard parallel-plate capacitor with known plate area A and separation d. We denote the unknown capacitance as C for air and C' for Teflon, according to what fills the space between the plates.

Strategy For parts (a) and (b), this is a matter of applying Eq. (25–4), but with ε_0 replaced by ε in part (b). We can look up the value of the dielectric constant of Teflon in Table 25–1 ($\kappa = 2.1$), and this gives us $\varepsilon = \kappa\varepsilon_0$; equivalently, $C' = \kappa C$. As for the maximum voltages, V_{max} and V'_{max} for air and Teflon respectively, that will be determined by the dielectric strengths of air and Teflon, also found in Table 25–1. Finally, the maximum charge that can be put on the plates is the capacitance multiplied by the maximum voltage.

For part (c), we fix the voltage across the capacitor in the two cases and use Eq. (25–9) to determine the energy given this voltage and the known capacitances.

Working It Out (a) For air we have

$$C = \frac{\varepsilon_0 A}{d} = \frac{(8.85 \times 10^{-12}\,\text{F/m})(2.00 \times 10^{-3}\,\text{m}^2)}{(4.0 \times 10^{-3}\,\text{m})} = 4.4 \times 10^{-12}\ \text{F} = 4.4\,\text{pF},$$

while for Teflon,

$$C' = \kappa C = (2.1)(4.4\,\text{pF}) = 9.2\,\text{pF}.$$

(b) From Table 25–1, the dielectric strength of air and Teflon are 3×10^6 V/m and 6.0×10^7 V/m respectively, so for air

$$V_{max} = E_{max} d = (3 \times 10^6\,\text{V/m})(4.0 \times 10^{-3}\,\text{m}) \cong 10^4\,\text{V} = 10\,\text{kV},$$

and

$$Q_{max} = CV_{max} = (4.4 \times 10^{-12}\,\text{F})(10^4\,\text{V}) \cong 4 \times 10^{-8}\,\text{C}.$$

For Teflon

$$V'_{max} = E'_{max}\, d = (6.0 \times 10^7\,\text{V/m})(4.0 \times 10^{-3}\,\text{m}) = 2.4 \times 10^5\,\text{V}$$

and

$$Q'_{max} = C'V'_{max} = (9.2 \times 10^{-12}\,\text{F})(2.4 \times 10^5\,\text{V}) = 2.2\,\mu\text{C}.$$

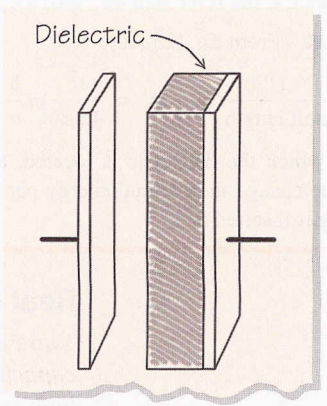
Both the maximum voltage and maximum charge are greatly increased after the Teflon is inserted.

(c) Before the Teflon is inserted, the energy is

$$U = \frac{CV^2}{2} = \frac{(4.4 \times 10^{-12}\,\text{F})(24\,\text{V})^2}{2} = 1.3 \times 10^{-9}\,\text{J}.$$

After the Teflon is inserted, C increases by the factor κ, whereas V decreases by the same factor. The product CV^2 thus *decreases* by a factor of κ:

$$U' = \frac{C'V'^2}{2} = \frac{(\kappa C)(V/\kappa)^2}{2} = \frac{U}{\kappa} = \frac{1.3 \times 10^{-9}\,\text{J}}{2.1} = 6.2 \times 10^{-10}\,\text{J}.$$



What Do You Think? Did the capacitor do work as the Teflon was inserted? If so, what was its sign?

Example 25–10 shows that when the material in the space between the plates of a capacitor is replaced by a dielectric of higher dielectric constant, the energy decreases. As we implied in the "What do you think?" question for that example, the capacitor therefore does positive work as the new dielectric is inserted. In turn, this means that there must be a force that pulls the dielectric into the space between the plates, and with sensitive instruments, the tug on the dielectric can be measured.

EXAMPLE 25–11 Suppose that the Teflon sheet inserted between the capacitor plates in Example 25–10 is only 2.0 mm thick and fills just half the volume. The capacitor is isolated, and both before and after the Teflon is inserted, the capacitor carries a charge of $Q = 1.0$ nC. Find the electric field everywhere inside the capacitor, and find the new capacitance.

Setting It Up We show the new configuration in Fig. 25–19. Although the Teflon sheet is on the right in Fig. 25–19, this choice is immaterial.

Strategy We previously found the electric field between the plates in air to be $E_0 = \sigma/\varepsilon_0$. Where Teflon is present rather than air, ε_0 is replaced by $\varepsilon = \kappa\varepsilon_0$, or equivalently the electric field is $E_{Tef} = E_0/\kappa$ [Eq. (25–22)]. In this case, we will have two successive values of electric field, and by integrating the field all the way across the space, we find the voltage between the plates. Given the known charge, we can then determine the capacitance from Eq. (25–4).

▲ **FIGURE 25–19** A dielectric inserted in a parallel-plate capacitor fills only half the volume.

(continues on next page)

Working It Out The electric field strengths in air and Teflon are

$$E_0 = \frac{\sigma}{\varepsilon_0} = \frac{Q}{\varepsilon_0 A} = \frac{1.0 \times 10^{-9}\ \text{C}}{(8.85 \times 10^{-12}\ \text{F/m})(2.0 \times 10^{-3}\ \text{m}^2)} \cong 5.6 \times 10^4\ \text{V/m},$$

$$E_{\text{Tef}} = \frac{E_0}{\kappa} = \frac{5.6 \times 10^4\ \text{V/m}}{2.1} \cong 2.7 \times 10^4\ \text{V/m}.$$

The direction of these fields is from the positively charged plate to the negatively charged one. To find the total voltage drop across the plates (which we need to find the capacitance), we integrate the electric field over the distance between the plates:

$$V = \int_0^d E\,dx = \int_0^{2\text{ mm}} E_0\,dx + \int_{2\text{ mm}}^{4\text{ mm}} E_{\text{Tef}}\,dx$$

$$= E_0 \int_0^{2\text{ mm}} dx + E_{\text{Tef}} \int_{2\text{ mm}}^{4\text{ mm}} dx = E_0(2\text{ mm}) + E_{\text{Tef}}(2\text{ mm})$$

$$= (5.6 \times 10^4\ \text{V/m})(2 \times 10^{-3}\ \text{m}) + (2.7 \times 10^4\ \text{V/m})(2 \times 10^{-3}\ \text{m}) \cong 170\ \text{V}.$$

This calculation makes it clear that it does not matter whether the Teflon sheet is on one side or the other, or even in the middle.

Finally, the capacitance is, by definition, $C = Q/V$:

$$C = \frac{1.0 \times 10^{-9}\ \text{C}}{170\ \text{V}} = 5.9\ \text{pF}.$$

This value is intermediate to the capacitances of the system empty or filled with Teflon. This capacitor is equivalent to two capacitors in series—one empty and of width $d/2$; the other filled with Teflon and of width $d/2$.

What Do You Think? If we used Bakelite instead of Teflon, would the new capacitance be smaller, larger, or unchanged?

EXAMPLE 25–12 Consider the system shown in Example 25–3—what we'll refer to here as a coaxial cable. (We ignore the necessary mechanical presence of a support for the structure.) With equal but opposite charges per unit length λ on the two elements of the cable, the latter acts as a capacitor. A plug of insulating material of dielectric constant κ is inserted between the wire and the sheath to a depth x from the end. What is the change in potential energy of the charged cable? What electric force, if any, acts on the material as it is inserted? Assume that the charge density on the cable is unchanged as the material is inserted.

Setting It Up We show the coaxial cable in Fig. 25–20 with the radii of the central wire and outer tube a and b, respectively.

Strategy In the presence of the dielectric the charge on the elements is unchanged, while the field and hence the potential drop across the elements will change. In Example 25–3 we found the potential difference between the conductors in the coaxial cable to be $V_b - V_a = V = \frac{\lambda}{2\pi\varepsilon_0} \ln\frac{b}{a}$. By using a charge per unit length λ in place of a total charge Q, Eq. (25–10) will give us an energy per unit length, and we will want to see if this changes as the dielectric is inserted—we can anticipate from previous examples that it will. A change in the energy will imply a force, and its sign will in turn depend on the sign of the energy change: A decrease in the energy in the cable as the dielectric is inserted means a force pulling the material in. More precisely, if U is the energy in the cable as a function of the insertion distance x, the force will be $-dU/dx$.

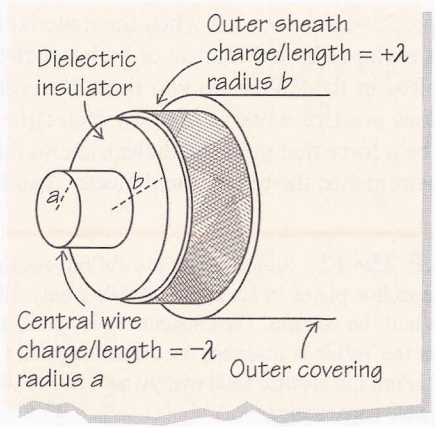
Working It Out From Eq. (25–10),

$$\frac{U}{\text{unit length}} = \frac{1}{2}\lambda V = \frac{\lambda^2}{4\pi\varepsilon_0} \ln\frac{b}{a}.$$

In the region in which the dielectric is located, ε_0 is replaced by $\varepsilon = \kappa\varepsilon_0$. Thus the change in potential energy per unit length when the dielectric plug is inserted is

$$\frac{\Delta U}{\text{unit length}} = \frac{U_{\text{dielectric}}}{\text{unit length}} - \frac{U_{\text{air}}}{\text{unit length}} = \frac{\lambda^2}{4\pi}\left(\frac{1}{\varepsilon} - \frac{1}{\varepsilon_0}\right) \ln\frac{b}{a}.$$

Thus if the plug penetrates to a depth x, the total change in potential energy is



$$\Delta U = \frac{x\lambda^2}{4\pi}\left(\frac{1}{\varepsilon} - \frac{1}{\varepsilon_0}\right) \ln\frac{b}{a} = \left(\frac{1}{\kappa} - 1\right)\frac{x\lambda^2}{4\pi\varepsilon_0} \ln\frac{b}{a}.$$

Because $\kappa > 1$, $\Delta U < 0$. The energy decreases when the plug is inserted, so we expect the plug to be pulled into the space between the conductors. The force exerted on the dielectric as it moves into the cable is

$$F = -\frac{dU}{dx} = \left(1 - \frac{1}{\kappa}\right)\frac{\lambda^2}{4\pi\varepsilon_0} \ln\frac{b}{a}.$$

F is positive because $\kappa > 1$. The plug is indeed pulled into position.

What Do You Think? The force on the plug is independent of the depth to which it is inserted. Why?

▲ **FIGURE 25–20** A coaxial cable.

Real Capacitors

Two types of capacitors comprise the bulk of modern capacitors. In *multilayer ceramic capacitors*, metal sheets separated by ceramic insulators with dielectric constants as high as 20,000 are folded into a compact form. The dielectric constant is so high that capacitances on the order of millifarads can be reached. *Electrolytic capacitors* can achieve capacitances of roughly the same size in even smaller volumes. In this case, the dielectric—a nonconducting metal oxide—is deposited in a thin layer on a sheet of

metal. The second conductor is a conducting paste or liquid that adheres well to the metal oxide. The dielectric layer between the conductors can be made quite thin—as thin as 10^{-8} m. Moreover, by etching the metal before the dielectric layer is deposited, a series of sharp valleys is created in the metal, greatly increasing its surface area. If we recall that the capacitance of parallel plates is inversely proportional to the distance between the plates and proportional to the area of the plates, we see that electrolytic capacitors can achieve large capacitances.

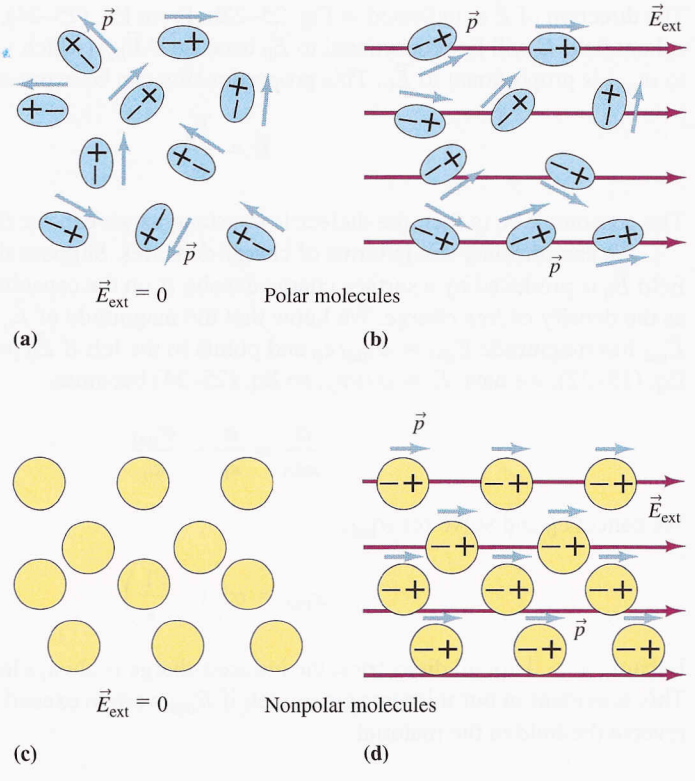
THINK ABOUT THIS. . .

HOW ARE CAPACITORS WITH VERY LARGE CAPACITANCES CONSTRUCTED?

Capacitors with large capacitance are potentially important in many applications, and this has encouraged extensive work. The technology now exists for making capacitors with capacitances on the order of farads, but such capacitors cannot be built with a couple of flat plates! With a suitable dielectric, a 6-V potential difference across a gap of as little as 0.25 μm is possible without breakdown of the dielectric material. A 1-F capacitor for this situation must therefore have an area $A = (0.25 \times 10^{-6}\ \text{m})(1\ \text{F})\,/\,(8.85 \times 10^{-12}\ \text{F}\cdot\text{m}^{-1}) = 2.8 \times 10^{4}\ \text{m}^2$; this corresponds to a square more than 100 m on a side, twice as large as a football field. One way to make capacitors with capacitances this large is to make one of the "plates" from a conducting powder which is compressed only enough to join the grains but not so much as to close the pores. The result is a piece of material with a huge surface area. A dielectric is deposited to make a very thin layer on the compacted powder, and the entire piece is then immersed in a conducting liquid that forms the second "plate." While such capacitors can hold a lot of charge, the paths that current follows through them is long and, in fact, the capacitor cannot be discharged very rapidly.

25–6 The Microscopic Description of Dielectrics

We briefly argued at the start of the previous section that the presence of dipoles within dielectrics explains their macroscopic behavior in electric fields. In this section we shall expand on these comments. We refer to molecules with permanent electric dipole moments, such as H_2O, as *polar* molecules. In the absence of an external electric field, the directions of the dipole moments of polar molecules in a material are randomly distributed (Fig. 25–21a). However, when the material is placed in an external electric field, as



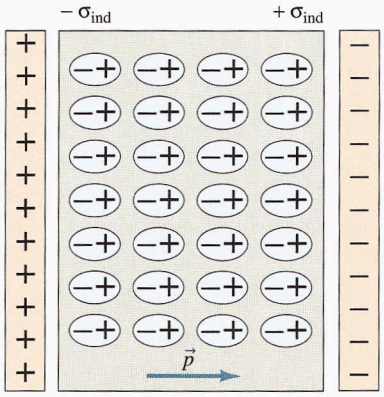


FIGURE 25–21 (a) In the absence of an external electric field, the dipole moments of polar molecules, here denoted $\vec{p}$, are randomly oriented. (b) In the presence of an external electric field, the dipole moments align themselves with the field. (c) In the absence of an external electric field, nonpolar molecules have no dipole moment. (d) In the presence of an external electric field, nonpolar molecules obtain an induced dipole moment aligned with the electric field.

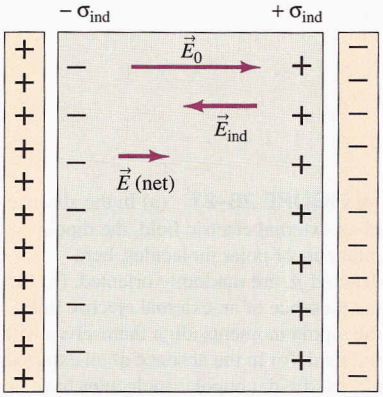


in Fig. 25–21b, the dipoles are subject to a torque and tend to align themselves with the field. Thermal agitation disturbs the individual alignments, leaving only an average alignment which will be more pronounced for stronger electric fields and lower temperatures. The average degree of alignment grows *linearly* with the external electric field over a wide range of values of the field.

Nonpolar molecules are those without a permanent dipole moment. In the absence of an external electric field, their charge distributions are symmetric; that is, no particular direction is apparent (Fig. 25–21c). As we discussed in Section 22–5, when these molecules are placed in an external electric field, their charge components separate, and they acquire an induced dipole moment that is fully aligned with the field (Fig. 25–21d). The magnitude of this dipole moment increases as the external field increases, and again there is an important range of values of the external electric field for which the dipole moment grows *linearly* with the field.

The effect of placing an insulating slab made of either polar or nonpolar molecules in a charged capacitor is shown in Fig. 25–22a. As opposed to a conductor, in an insulator there is no free charge to move through the material. However, the dipole moments, either permanent or induced, become aligned with the electric field. The inside of the dielectric remains electrically neutral, but the charge distribution is *polarized*, and *induced charge* appears on the two outside surfaces of the slab. We denote the induced surface charge density as σ_{ind}. The two dielectric surfaces have equal but opposite induced charge densities. The induced surface charge density is proportional either to the degree to which the permanent dipole moments of polar molecules are aligned, or, for a material consisting of nonpolar molecules, to the magnitude of the induced dipole moments. Both of these are linear in the external field over a large range of values of the external field, so there is an important range of values of the external field for which σ_{ind} *is proportional to the external field.*

(a)

(b)

▲ **FIGURE 25–22** (a) When a dielectric is inserted in a capacitor, induced charges appear on the surface. (b) The induced charges cause an induced electric field $\vec{E}_{\text{ind}}$ opposite to the external electric field $\vec{E}_0$ caused by the free charge on the capacitor plates. The net effect is a reduced electric field $\vec{E} = \vec{E}_0 + \vec{E}_{\text{ind}}$ within the dielectric.

By assuming that the induced charge is proportional to the external field, we can distinguish the electric fields that appear in dielectrics. There are three fields: The external field $\vec{E}_0$ is present whether the dielectric is present or not. An *induced electric field* $\vec{E}_{\text{ind}}$ is produced by the induced surface charge on the dielectric, and this is proportional to the external field. Because of the way the induced charge forms, $\vec{E}_{\text{ind}}$ is opposite to $\vec{E}_0$. Finally, the net electric field $\vec{E}$ inside the dielectric is

$$\vec{E} = \vec{E}_0 + \vec{E}_{\text{ind}}. \tag{25–24}$$

The direction of $\vec{E}$ is indicated in Fig. 25–22b. From Eq. (25–24), we can see that the resultant field $\vec{E}$ will be proportional to $\vec{E}_0$ because if $\vec{E}_{\text{ind}}$ (which we know is proportional to σ_{ind}) is proportional to $\vec{E}_0$. This proportionality can be expressed with the constant κ:

$$\vec{E} = \frac{\vec{E}_0}{\kappa}.$$

The constant κ is, in fact, the dielectric constant, as we can see from Eq. (25–22).

We can translate this in terms of charge densities. Suppose that the original electric field $\vec{E}_0$ is produced by a surface charge density σ on the capacitor plates. We refer to σ as the density of *free charge*. We know that the magnitude of $\vec{E}_0$ is $E_0 = \sigma/\varepsilon_0$ and that $\vec{E}_{\text{ind}}$ has magnitude $E_{\text{ind}} = \sigma_{\text{ind}}/\varepsilon_0$ and points to the left if $\vec{E}_0$ points to the right. From Eq. (25–22), we have $E = \sigma/\kappa\varepsilon_0$, so Eq. (25–24) becomes

$$\frac{\sigma}{\kappa\varepsilon_0} = \frac{\sigma}{\varepsilon_0} - \frac{\sigma_{\text{ind}}}{\varepsilon_0}. \tag{25–25}$$

We cancel ε_0 and solve for σ_{ind}:

$$\sigma_{\text{ind}} = \sigma\left(1 - \frac{1}{\kappa}\right). \tag{25–26}$$

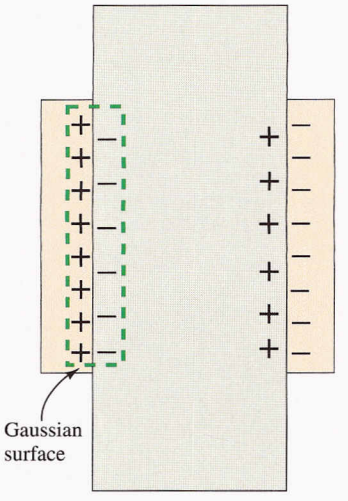
Because $\kappa > 1$ for all dielectrics, the induced charge is always less than the free charge. This is evident in our microscopic model; if E_{ind} were to exceed E_0, we would actually reverse the field in the material.

Gauss' Law and Dielectrics

How does the fact that ε_0 is replaced by ε in a dielectric affect Gauss' law? For the Gaussian surface drawn in Fig. 25–23, Gauss' law gives

$$\int_{\text{closed surface}} \vec{E} \cdot d\vec{A} = \frac{Q_{\text{encl}}}{\varepsilon_0} = \frac{Q - Q_{\text{ind}}}{\varepsilon_0}, \tag{25–27}$$

where Q is the free charge enclosed, the charge that sets up the original field $\vec{E}_0$. The enclosed charge is the free charge minus the induced charge. But from Eq. (25–25),



$$\frac{Q}{\kappa} = Q - Q_{\text{ind}},$$

and this gives us an alternative form of Gauss' law when dielectrics are present, namely

$$\int_{\text{closed surface}} \vec{E} \cdot d\vec{A} = \frac{Q}{\kappa\varepsilon_0} = \frac{Q}{\varepsilon}. \tag{25–28}$$

The constant ε_0 is replaced by $\varepsilon = \kappa\varepsilon_0$ *provided Q is the free charge*. This is a general result even if Fig. 25–23 refers to a parallel-plate capacitor. If the dielectric is not uniform throughout, κ will not have the same value throughout. In this case, κ should be brought under the integral, and Gauss' law reads

$$\int_{\text{closed surface}} \kappa\vec{E} \cdot d\vec{A} = \frac{Q}{\varepsilon_0}. \tag{25–29}$$

▲ **FIGURE 25–23** A dielectric fills the entire volume of a capacitor. A Gaussian surface surrounding the interface region between the dielectric and each plate surrounds both free and induced charges. The total charge enclosed by the Gaussian surface when Gauss' law is applied includes both charges.

Consequences of the Microscopic Model of Dielectrics

Our model of induced charges explains the experimental behavior of the dielectrics we have described to this point. This model is also the basis for a variety of testable experimental predictions:

1. There are two classes of dielectrics: those made of nonpolar molecules and those made of polar molecules. The dipole moments of induced dipoles are generally much smaller than those of permanent dipoles, so the value of κ for nonpolar dielectrics should be much closer to one than that for polar dielectrics. Water is an example of a polar dielectric, and you can see from Table 25–1 that its dielectric constant κ is large.
2. Thermal effects that disrupt the alignment are less strong, and polar dielectrics should line up more easily—have larger values of κ—at lower temperatures. Kinetic theory (see Chapter 19) shows that the dielectric constant takes the more precise form

$$\kappa = 1 + \frac{\text{a constant}}{T}. \tag{25–30}$$

   This temperature dependence, which is *Curie's law*, holds rather well. The mechanism by which nonpolar dielectrics react to external fields suggests that they should not obey Curie's law, and this is indeed the case.
3. The polarization of crystalline solids with a permanent dipole moment can change if the planes of their lattice structure are stressed by being twisted or pressed. Under such stress, the internal electric fields change, and the changing fields produce an electrical signal. This phenomenon, known as *piezoelectricity*, is the principle behind the operation of some microphones and strain gauges.

Summary

Capacitors are devices for storing electric charge and energy and typically consist of two conductors with equal and opposite charges of magnitude Q and potential difference V. Capacitance is defined as

$$C \equiv \frac{Q}{V}. \tag{25–2}$$

The capacitance of a parallel-plate capacitor in air is given by

$$C = \frac{\varepsilon_0 A}{d}. \tag{25–4}$$

where A is the plate area and d is the plate separation. The SI unit of capacitance is the farad: 1 F = 1 C/V.

The potential energy of a capacitor can be written as

$$U = \frac{Q^2}{2C} = \frac{CV^2}{2} = \frac{QV}{2}. \tag{25–8, 25–9, 25–10}$$

The energy density, or energy per unit volume, of an electric field is

$$u = \frac{\varepsilon_0 E^2}{2}. \tag{25–12}$$

Capacitors connected in parallel can be replaced by an equivalent capacitor with capacitance

$$C_{\text{eq}} = C_1 + C_2 + \cdots + C_n. \tag{25–14}$$

Capacitors connected in series can be replaced by an equivalent capacitor according to the relation

$$\frac{1}{C_{\text{eq}}} = \frac{1}{C_1} + \frac{1}{C_2} + \cdots + \frac{1}{C_n}. \tag{25–17}$$

Dielectrics are insulators with a characteristic property called the dielectric constant, κ, $\kappa > 1$. When a dielectric fills the space between the two conducting plates of a capacitor, the value of the capacitance is increased:

$$C = \kappa C_0, \tag{25–18}$$

where C_0 is the capacitance of the capacitor with a vacuum (or air) between its conductors. Our previous results can be modified for the presence of dielectrics by replacing the permittivity of free space, ε_0, by the permittivity ε given by

$$\varepsilon = \kappa\varepsilon_0. \tag{25–23}$$

Each insulator also has a characteristic property called the dielectric strength, which gives the approximate maximum electric field that the insulating material can withstand before it breaks down and ionizes.

The behavior of capacitors can be understood by considering the molecular structure of matter. Polar and nonpolar molecules of a dielectric become aligned with the external electric field, reducing the effects of that field. An alternative form of Gauss' law when dielectrics are present in a capacitor is

$$\int_{\text{closed surface}} \vec{E} \cdot d\vec{A} = \frac{Q}{\varepsilon}, \tag{25–28}$$

where Q is the free charge.

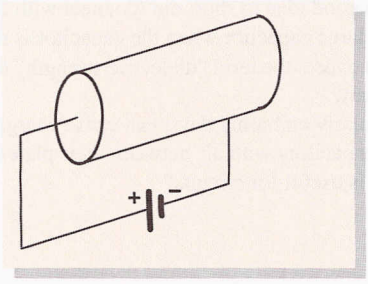
Understanding the Concepts

1. There are two common ways to write SI units of permittivity. Does the fact that there is more than one way present a problem?
2. You have two parallel plates, a battery, a voltmeter, and a piece of unknown plastic. Devise a method to determine the dielectric constant of the plastic.
3. What argument can you give to show that the electric field of a parallel-plate capacitor cannot drop abruptly to zero as we pass outside the region between the plates? Recall the fact that the voltage drop around any closed path must be zero.
4. What is the meaning of a capacitor with zero capacitance?
5. If the radius of the inner wire of the coaxial cable in Example 25–3 approaches zero, the capacitance per unit length of the coaxial cable also approaches zero. What is the physical significance of that?
6. It is not possible to break up every combination of capacitors into a sequence of parallel and series capacitors. Find an example of a combination that cannot be decomposed in this way.
7. We say that a capacitor has a charge Q. But is that what we really mean? Is the total charge on a capacitor actually Q?
8. From our discussion of the physical nature of dielectrics, can you imagine a physical system in which the dielectric constant is less than one?
9. The plates of a charged parallel-plate capacitor are disconnected from the charging battery and are pushed together. What happens to the potential difference, the capacitance, and the stored energy?
10. The plates of a parallel-plate capacitor, still connected to a battery with potential difference V, are pushed together. What happens to the charge on the plates, the capacitance, and the stored energy?
11. You are given a thin metal sheet of area A. You can make it into a spherical shell, roll it into two concentric cylinders, or cut it to make a parallel-plate capacitor. Which arrangement would give the largest possible capacitance?
12. What happens if you short out (connect with a conductor) the two plates of a large, charged capacitor? Could this be dangerous?
13. For finite parallel plates there is a fringe field (see Fig. 25–4). What effect would you expect this phenomenon to have on the capacitance of a parallel-plate capacitor?

14. Is it possible for a pair of nonconductors carrying equal but opposite charges to act as a capacitor? In what ways would such an arrangement differ from, or be similar to, the capacitors treated in this chapter?
15. Consider Example 25–5. Do you think you could charge more than one 12-V capacitor with a car battery? What about a thousand?
16. Why is it a good idea to short out (connect with a conductor) the plates of a large capacitor when the capacitor is not in use?
17. Would you expect the term "dielectric strength" to have meaning for a vacuum?
18. Air, particularly on humid days, can cause charge leakage. Why, then, can capacitors with air between their plates hold charge in a way that is useful for circuits?

Problems

25–1 Capacitance



1. (I) (a) What is the capacitance of two square metal plates, each 50 cm^2 in area, separated by 1 mm? (b) What is the radius of a conducting sphere with the same capacitance?
2. (I) A coaxial cable has an inner wire of radius 0.8 cm and an outer sheath of radius 1.2 cm. What is the capacitance of a kilometer of the cable?
3. (I) At different times, a 4-μF capacitor has a charge of (a) 4 μC, (b) 10 μC, and (c) 1 mC. What is the voltage across the capacitor in each case?
4. (I) How much charge can be stored on the plates of a 1-μF capacitor if the plates are attached to a battery that can give a potential difference of (a) 2 V? (b) 12 V?
5. (I) You must design a capacitor to store 2×10^{-6} C of charge, but you have only a 3-kV power supply and two metal plates of area 250 cm^2 each. What limits do you put on the separation between the plates?
6. (I) What is the capacitance of a piece of coaxial cable 180 cm long for which the radius of the inner conductor is 1.0 cm and the radius of the outer conducting sheath is 1.5 cm?
7. (II) Calculate the capacitance of two concentric spherical conductors of radii r and R, respectively. Discuss the limits of (a) finite r, $R \rightarrow \infty$; (b) $(R - r) \ll r$.
8. (II) Two concentric conducting spheres have radii of 3.0 cm and 15 cm, respectively, and an equal but opposite charge of 1.4×10^{-7} C. What is the potential difference between them? [*Hint*: Use the results of Problem 7.]
9. (II) A parallel-plate capacitor of area 0.040 m^2 carries a charge $q = 4.0 \times 10^{-8}$ C. The potential across the plates increases with time t according to the equation $V = 50.0\text{ mV} + (0.10\text{ mV/s})t$, as a result of a time-dependent increase of the separation between the plates. Find the function of time that describes the separation.
10. (II) A parallel-plate capacitor has square plates 6 cm on a side, separated by 0.3 mm. The capacitor is charged to 3 V, then disconnected from the charging power supply. What is the charge density on the plates? The total charge on each plate?
11. (II) The capacitance of a variable capacitor used in a radio varies from 0.2 μF to 0.01 μF. The capacitor is charged to a potential difference of 300 V at maximum capacitance and then isolated. At minimum capacitance, what is the voltage?

25–2 Energy in Capacitors

12. (I) A thundercloud has a charge of 900 C and a potential of 90 MV with respect to the ground 1 km below it. (a) What is the capacitance of the system? (b) How much energy is stored in the thundercloud system?
13. (I) A capacitor holds a charge of 0.068 C at a potential of 2900 V. How much energy was required to charge the capacitor?
14. (I) A capacitor in a computer with a capacitance of 0.7 pF has 2 V across it. How much energy is contained within the electric field of the capacitor?
15. (I) A fully charged flash attachment for a camera has electrical energy of 27 J. The potential across it is 300 V. What is the capacitance of the flash attachment?
16. (I) How much energy is stored on a metal sphere of radius 35 cm when a charge of 3.0×10^{-5} C is placed on it?
17. (II) A coaxial cable with an inner wire of diameter 3 mm and an outer sheath wire of diameter 8 mm has a potential of 1 kV between the wires. (a) What is the capacitance of 10 m of the cable? (b) How much energy is stored in the 10-m piece of cable? In a 1-km piece?
18. (II) Two concentric conducting spheres of radii 4.0 cm and 12.0 cm, respectively, are given equal but opposite charges of 6.0×10^{-8} C. How much energy is stored in the system?
19. (II) A capacitor consists of two parallel plates, each of area A. It is charged using a battery of potential V_0, which is then disconnected. (a) How much does the energy of the capacitor change if the separation of the plates is changed from d_0 to d_1? (b) How much work is done by the external force used to move the plates? (c) Suppose that the plates of the capacitor remain connected to the battery as they are moved. How much does the energy stored in the capacitor change under these conditions? (d) Is this change related to the work done by the force moving the plates?

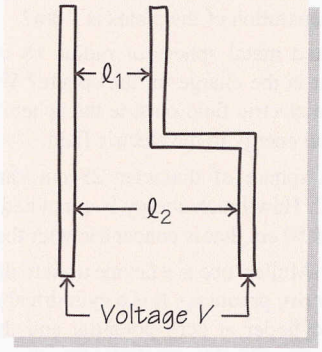
25–3 Energy in Electric Fields

20. (I) The electric field in a large thunderstorm is 125,000 V/m. How much energy is contained in 1 m^3? In 1 km^3?
21. (I) The electric field due to an infinitely long, uniformly charged wire is calculated in Example 23–5. What is the electrical energy density in the space around the wire as a function of the distance from the wire?
22. (I) A Van de Graaff accelerator with a spherical dome of radius 0.75 m has a potential of 20,000 V in air. Assume that the accelerator is, in effect, a charged sphere. How much energy is stored in its electric field?
23. (I) Approximately how much energy is stored in a cube of sides 5 cm that is 1.0 m from a point charge of magnitude 5×10^{-4} C?
24. (I) The energy density in the space between the plates of a parallel-plate capacitor is 10^{-6} J/m^3. What is the voltage between the plates if the separation of the plates is 1 cm?
25. (II) An isolated metal sphere of radius 18 cm is at potential 8300 V. What is the charge on the sphere? What is the energy density of the electric field outside the sphere? Integrate this to obtain the total energy in the electric field.
26. (II) A metal sphere of diameter 25 cm carries a charge of 6.0×10^{-7} C. How much energy is contained in a spherical region of radius 50 cm that is concentric with the sphere?
27. (II) A Geiger–Muller tube is a device used to detect ionizing particles (radioactive products). It is a cylindrical capacitor with the outer metal cylinder at zero potential and the central wire at about 500 V (Fig. 25–24). (a) Calculate the capacitance of the tube if its length is 15 cm, the radius of the outer cylinder is

▲ **FIGURE 25–24** Problem 27.

2 cm, and that of the central wire is 0.02 cm. (b) When an ionizing particle enters the detector, it creates free electrons and ions, the gas breaks down, and the capacitor discharges. How much energy is needed to recharge the Geiger–Muller tube?

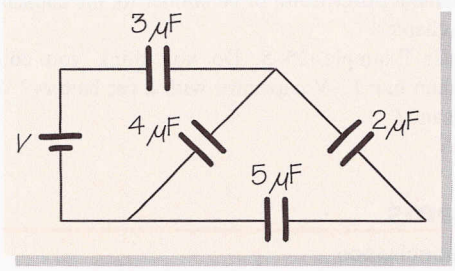
28. (III) A nonconducting sphere of radius 0.070 m carries a uniformly distributed charge of 7.3×10^{-6} C. How much energy is contained in a spherical region of radius 25 cm that is concentric with the sphere?



29. (III) The plates of a parallel-plate capacitor are 400 cm^2 in area and 0.5 cm apart. The potential difference between the plates is 1500 V. (a) What is the field between the plates? (b) the charge on each plate? (c) the force exerted by the field on one of the plates? (d) Suppose that the plates are pulled apart so that the separation increases by 20 percent. What is the change in the stored energy? Is this consistent with the answer to part (c)? [If not, you probably answered (c) incorrectly.]

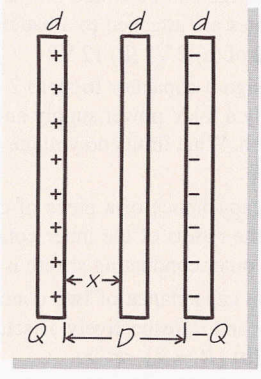
30. (III) Assume that an electron consists of a sphere of radius R with its charge distributed uniformly on the surface. (a) What is the electric field outside of the radius R? (b) What is the total electrostatic energy stored in the electric field? (c) Assume that all the energy of part (b) is solely responsible for the rest energy of the electron. (Rest energy is the energy associated with an object's mass, according to the theory of special relativity, even if the object is at rest. It takes the form mc^2, where in this case m is the electron's mass, 0.9×10^{-30} kg, and c is the speed of light, 3×10^8 m/s.) What must the radius R of the electron be?

25–4 Capacitors in Parallel and in Series



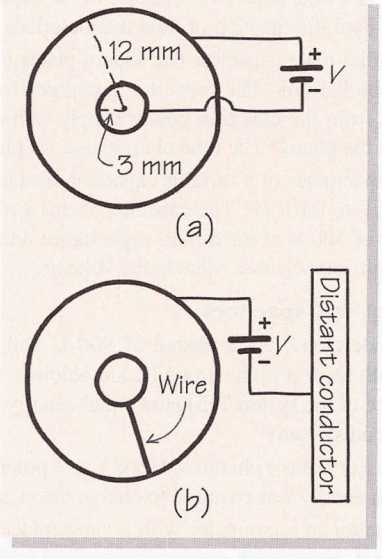
31. (I) When two capacitors are connected in parallel, the resulting combination has capacitance 6.5 μF. When the same two capacitors are connected in series, the resulting combination has capacitance 1.4 μF. What are the capacitances of the two capacitors?

32. (II) Find the capacitance of the parallel-plate system in Fig. 25–25. Can this system be represented by two pairs of parallel plates of half the total area connected in series or in parallel?



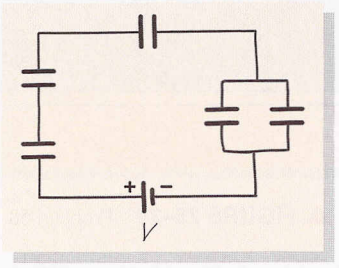
▲ **FIGURE 25–25** Problem 32.

33. (II) Find the equivalent capacitance of the circuit shown in Fig. 25–26.



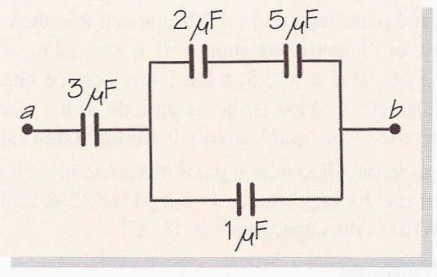
▲ **FIGURE 25–26** Problem 33.

34. (II) Two large, thin metal plates of area A and thickness d, carrying charges Q and $-Q$, respectively, are placed a distance D apart (Fig. 25–27). Suppose that an uncharged, thin metal plate of the same area and thickness is placed between them, such that the distance between the uncharged plate and the positively charged plate is x. What is the capacitance of the combined system as a function of x?



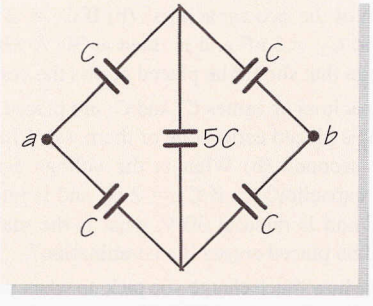
▲ **FIGURE 25–27** Problem 34.

35. (II) What is the capacitance of the two concentric, spherical conductors of radii 3.0 mm and 12 mm, respectively, connected as shown in Fig. 25–28a? Suppose that the conductors are connected as shown in Fig. 25–28b. What is the capacitance now?



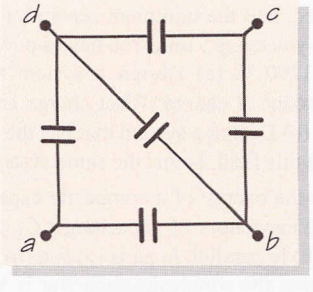
▲ **FIGURE 25–28** Problem 35.

36. (II) Find the equivalent capacitance of the circuit shown in Fig. 25–29. The capacitance of each capacitor is 18 μF.



▲ **FIGURE 25–29** Problem 36.

37. (II) (a) Find the equivalent capacitance of the combination of capacitors shown in Fig. 25–30. (b) Assume that the potential difference between b and a is 300 V and find the charge on each of the capacitors in the figure.



▲ **FIGURE 25–30** Problem 37.

38. (II) Figure 25–31 illustrates a set of five capacitors connected together across the points a and b. What is the value of a single capacitor that could replace this system and collect the same total charge for a given voltage drop V_{ab}?

▲ **FIGURE 25–31** Problem 38.

39. (II) Figure 25–32 shows a network of identical capacitors. What is the equivalent capacitance between the points a and b? What is it between a and c? Between b and d?

▲ **FIGURE 25–32** Problem 39.

40. (II) Capacitor C_1 has a capacitance of 175 μF; capacitor C_2 has a capacitance of 18 μF. A charge of $q = 4$ μC is placed on C_1, whereas C_2 is brought to a potential difference between its plates of 3 V. (a) What is the total energy stored in the two capacitors? (b) The negatively charged plate of C_1 is connected to the positively charged plate of C_2. What will change in the system, if anything? Neglect the fringe fields at the ends of the capacitors.

41. (II) Consider the capacitors of Problem 40, with C_2 modified so that it holds a charge of 25 μC at a potential difference of 5 V between the plates. (a) How is the capacitance of C_2 modified? (b) What is the charge on the capacitor equivalent to the whole system when the negatively charged plate of C_1 is connected to the positively charged plate of C_2?

42. (II) You have four capacitors whose capacitances are 2 μF, 3 μF, 4 μF, and 5 μF, respectively. Describe a circuit with an equivalent capacitance smaller than the 5-μF capacitor by 0.032 μF.

25–5 Dielectrics

43. (I) Consider a parallel-plate capacitor in which the space between the plates is filled with Teflon. With the charge held fixed, the Teflon is replaced by Plexiglas. If the voltage across the capacitor was 600 V in the first case, what is it after the change?

44. (I) You have a piece of plastic whose dielectric constant you want to measure with two parallel plates, a 4-V battery, and a voltmeter. You charge the plates with the battery and then disconnect them. After you slide the plastic into the full volume between the plates, the voltmeter indicates a voltage drop from 4 V to 3.6 V. What is the dielectric constant?

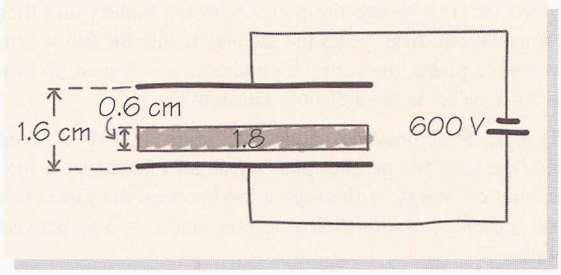
45. (I) A 12-V automobile battery can store 4×10^6 J of energy. Find the area of a parallel-plate capacitor that can store the same amount of energy, if the separation between the plates is 1 mm and a dielectric with dielectric constant $\kappa = 3$ is between the plates.

46. (II) Repeat Problem 17 for polystyrene placed between the wires of the coaxial cable.

47. (II) A homemade capacitor is constructed out of two sheets of aluminum foil 20 cm by 15 cm in size. The foil is placed on either side of a single page of a telephone book. One hundred pages of the telephone book are 7.7 mm thick. (a) If the paper has $\kappa = 2.9$, what would the capacitance be? (b) The capacitance was measured to be 4.6 nF. What would you estimate for the actual value of the dielectric constant? (c) Make a plot of the capacitance for 1, 2, 4, 10, and 20 telephone pages between the foils. What does this curve look like? (Such low capacitances can be measured with a typical undergraduate physics laboratory multimeter. However, one does have to take account of the capacitance of the multimeter leads themselves.)

48. (II) Electrolytic capacitors involve a very thin coating of a dielectric between two conducting plates that are very close together. Let's imagine such a capacitor with plates of area 2 cm^2, but an insulating layer (and hence a separation) only 1 atom thick. If an atom is approximately 0.1 nm in diameter and has a dielectric constant of 10, what capacitance could we attain? Such a capacitor would have to operate at a relatively low voltage.

49. (II) Calculate the change in capacitance of an isolated sphere that becomes embedded in a dielectric with dielectric constant κ. If the capacitance change is due to a charge induced on the surface of the dielectric, what is the ratio of the induced charge density to that of the original surface charge density?



50. (II) Two large, parallel metal plates have a potential difference of 12 kV, and the electric field between them has a magnitude of 0.90×10^6 V/m. A material with a dielectric constant of 1.5 is inserted between the plates, with the plate separation adjusted so that the capacitance is unchanged. Calculate the new plate separation.

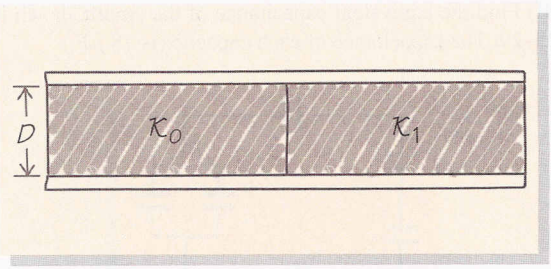
51. (II) A parallel-plate capacitor carrying charge q_0 is modified by the insertion of a dielectric with $\kappa = 1.8$ between the plates. As a consequence, the energy stored in the capacitor triples. What will the charge be after the dielectric is inserted?

52. (II) A coaxial cable has an inside wire of radius 3.5 mm and an outside metal sheath of radius 5.0 mm. The intermediate region is filled with a material of dielectric constant 2.2. (a) What is the capacitance of such a cable 100 m long? (b) If the potential difference between the inner and outer conductors is 500 V, what is the charge on the inner conductor, and how much energy is stored in 100 m of cable?

53. (II) A dielectric slab of thickness d and dielectric constant κ is inserted in the middle of a parallel-plate capacitor of plate separation D. What is the new capacitance of the capacitor, given that the area of each plate is A?

54. (II) A parallel-plate capacitor of dimensions 20 cm × 28 cm and separation distance 1.6 cm contains a dielectric slab of thickness 0.6 cm and dielectric constant 1.8. The potential difference between the plates is 600 V (Fig. 25–33). What are the electric fields in the empty space and inside the dielectric?

▲ **FIGURE 25–33** Problem 54.



55. (II) A parallel-plate capacitor of area 10 cm^2 and plate separation 5 mm holds how much free charge if the voltage between its plates is 300 V, and the following materials are inserted between its plates: air, paper, neoprene, Bakelite, and strontium titanate? (Use Table 25–1.)

56. (II) Two parallel plates of area 0.80 cm^2 with Plexiglas inserted between them break down when a voltage of 6 kV is applied to the plates. How much charge will the plates hold when the Plexiglas is removed? (Use Table 25–1.)

57. (II) A capacitor consists of two concentric spherical shells of radii r_1 and r_2, respectively. Calculate the capacitance if the space between the shells is filled with a dielectric of dielectric constant κ. If the capacitor starts out with air between the shells and carries a charge Q, and if the space is then filled with the dielectric, what is the change in energy?

58. (II) A parallel-plate capacitor has area $L \times L$ and separation $D \ll L$. One-half the space between the plates is filled with a dielectric for which $\kappa = \kappa_0$, and the other half with a dielectric for which $\kappa = \kappa_1$ (Fig. 25–34). Find the capacitance of this capacitor.

59. (II) A capacitor consists of 10 plates attached alternately to a positive and negative terminal. The plates are 6.0 cm × 8.0 cm in size and are 1.2 mm apart. What is the capacitance? Suppose that the region between the plates is filled with material of dielectric constant 2.8. What will the capacitance be?

▲ **FIGURE 25–34** Problem 58.

25–6 The Microscopic Description of Dielectrics

60. (I) By measuring the capacitance and voltage of a capacitor containing a dielectric with dielectric constant 4.5, the free charge on the capacitor is measured to be 18 μC. What is the induced charge?

61. (II) Use Gauss's law and Eq. (25–24) to show, from Fig. 25–23, that $E_{\text{ind}} = \sigma_{\text{ind}}/\varepsilon_0$.

62. (II) A charge Q is placed on a parallel-plate capacitor of area $L \times L$ and plate separation d. The capacitor is then filled with a dielectric of dielectric constant κ. If $L = 0.22$ m, $d = 1.8$ mm, $Q = 0.3$ μC, and $\kappa = 3.5$, what is the surface charge induced on the dielectric? What is the magnitude of the electric field in the dielectric? How much energy is stored in this capacitor?

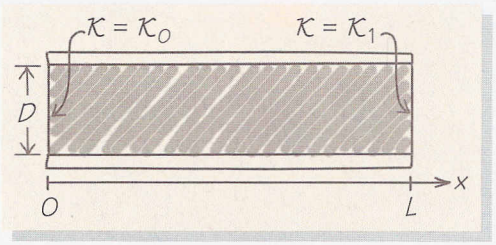
63. (II) A capacitor filled with a polar dielectric is used as a temperature sensor. Its capacitance is 3.2 μF at 23°C and 2.65 μF at 87°C. What is the capacitance at 48° C?

General Problems

64. (I) An uncharged metal plate is inserted midway between the plates of a parallel-plate capacitor carrying charges Q and $-Q$ on the plates. Will the plate be sucked in or will it have to be pushed in? Give a simple explanation for your result.

65. (I) Two capacitors of values C_1 and C_2 are placed in series, and a voltage V is placed across the total. (a) What is the total voltage across each of the two capacitors? (b) If $C_1 = 2$ nF and is rated at 10 V, and $C_2 = 3$ nF and is rated at 30 V, what is the maximum voltage that should be placed across the combination?

66. (I) Two capacitors of values C_1 and C_2 are placed in parallel, and a voltage V is placed across one of them. (a) What is the voltage across the second? (b) What is the voltage across the single equivalent capacitor? (c) If $C_1 = 2$ nF and is rated at 10 V, and $C_2 = 3$ nF and is rated at 30 V, what is the maximum voltage that should be placed across the combination?

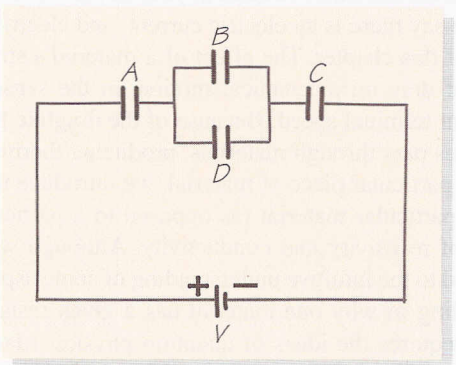


67. (II) *Estimate* how much charge you pick up when you walk across a carpet on a dry winter day. [*Hint*: View yourself as a good conductor, spherical in shape, and notice how close your hand has to come to a doorknob before the inevitable spark occurs. Use Table 25–1.]

68. (II) You have 300 cm^2 of aluminum plate (which you can cut into pieces) and a 500-cm^2 sheet of 5-mm-thick Bakelite (which you can also cut). Neither material can be sliced into thinner sheets or rolled, and the minimum separation between any aluminum plates you cut is 5 mm. You have a power supply of a single voltage, 1200 V. (a) Design a system that will hold the maximum amount of charge. What charge and energy can this system hold? (b) Design a system that has the maximum electric field, and find this field. Is this the same system as part (a)?

69. (II) Calculate the energy of a composite capacitor that consists of N identical capacitors of capacitance C_1 that are connected (a) in series; (b) in parallel. In parts (a) and (b), the total potential difference across the composite capacitor is V. (c) Assume that the total charge is Q, and repeat the calculation.

70. (II) A capacitor consists of two flat metal plates of area 0.28 m^2 and plate separation of $d = 1.5$ cm. A flat metal plate of the same area and of thickness 0.5 cm is inserted midway between the plates of the capacitor, leaving two spaces of thickness 0.5 cm each. (a) Find the new capacitance. (b) If the original capacitor has charge Q, what is the surface charge density induced on the intermediate plate? (c) Suppose that the original charge on the external plates remains the same. How does the energy of the new system compare to the energy of the system without the inserted plate? (d) Compare the capacitor with the metal inserted to the same capacitor with a dielectric of the same dimensions inserted.

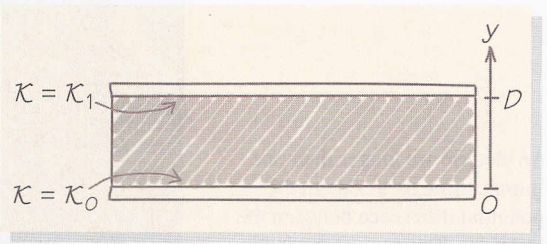


71. (II) A parallel-plate capacitor has an area of $L \times L$ and a plate separation of $D \ll L$. It is filled with a nonuniform dielectric whose dielectric constant varies linearly across the capacitor (Fig. 25–35). At $x = 0$, $\kappa = \kappa_0$, and at $x = L$, $\kappa = \kappa_1$. We can express κ as a function of x: $\kappa = \kappa_0 + [(\kappa_1 - \kappa_0)x/L]$. Treat the capacitor plates as broken into a set of capacitors connected in parallel with plates that are strips of width dx, and calculate the capacitance.

▲ **FIGURE 25–35** Problem 71.

72. (II) A thunderstorm is a fairly complicated phenomenon in terms of the distribution of charges, but we can estimate that there is a voltage drop of as much as 10^8 V between Earth and the bottom of a thundercloud, and the charges involved may run into the hundreds of coulombs. Estimate the capacitance of the Earth–cloud system and the energy contained in the space between the cloud and Earth.

73. (II) Consider the arrangement of the four initially uncharged capacitors shown in Fig. 25–36. Capacitors *A*, *B*, *C*, and *D* have capacitances 5.4 μF, 4.3 μF, 3.2 μF, and 2.1 μF, respectively. Suppose that a battery applies a potential difference of 3000 V across the circuit, which is then disconnected from the battery. What is the potential difference across each capacitor?



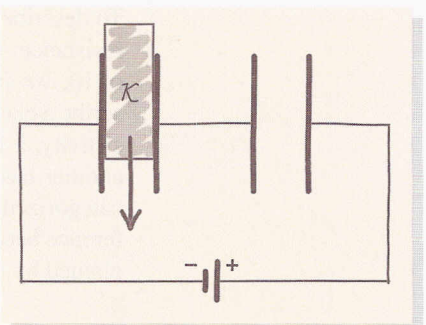
▲ **FIGURE 25–36** Problem 73.

74. (II) Consider a parallel-plate capacitor of plate area 0.40 m^2 and plate separation 3.0 mm. (a) Assume that the maximum electric field strength (before breakdown) in air is 2.7×10^6 V/m. What are the capacitance and the charge stored at the maximum voltage? (b) Suppose that the capacitor is immersed in oil of dielectric constant $\kappa = 6.0$, and the maximum charge that can be stored is a factor of 10 larger than that without the oil. What is the maximum field strength the oil can maintain?

75. (II) A parallel-plate capacitor has a capacitance of 3.0 μF. The plates are charged to 1500 V. What is the energy stored in the capacitor? How much work is required to insert a dielectric of $\kappa = 2.8$ between the plates? Assume that the capacitor is disconnected from the voltage source before the dielectric is inserted.

76. (II) A dielectric of dielectric constant κ is inserted a distance x into a parallel-plate capacitor with square plates of area A and plate separation d. What is the capacitance as a function of x? Calculate the amount of energy stored in the capacitor for a potential difference V.

77. (II) A parallel-plate capacitor has an area of $L \times L$ and a plate separation of $D \ll L$. It is filled with a nonuniform dielectric whose dielectric constant varies linearly from one plate to another (Fig. 25–37). At the bottom plate, the dielectric constant is κ_0; at the upper plate, it is κ_1. If y is the distance measured up from the bottom plate to the top plate, then $\kappa = \kappa_0 + [(\kappa_1 - \kappa_0)y/D]$. Treat the capacitor as a set of capacitors connected in series, and calculate the capacitance.



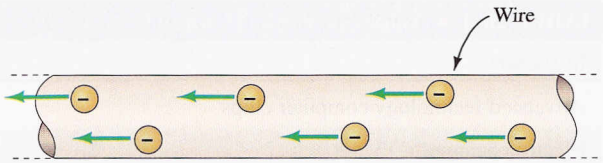
▲ **FIGURE 25–37** Problem 77.

78. (II) Three capacitors of strengths 2 μF, 4 μF, and 9 μF, respectively, can be connected in various ways between two points. What arrangement gives the smallest equivalent capacitance, and what arrangement gives the largest equivalent capacitance?

79. (II) Show that when capacitors are arranged in series, the total capacitance is less than any of the individual capacitances.

80. (III) Two identical capacitors of capacitance C are connected in series across a total potential V. A dielectric slab of dielectric constant κ can fill one of the two capacitors and is slowly inserted into that capacitor (Fig. 25–38). Compute the changes in the total electric energy of the two capacitors, in the charge on each capacitor, and in the potential drop across each capacitor. Account for any energy change by a corresponding change in energy in some other part of the system.

▲ **FIGURE 25–38** Problem 80.



Chapter 26

▶ An electric arc longer than one meter jumps through air due to the large potential difference between the two electrodes. The current carried in such an arc can be quite large.

Currents in Materials

In the last few chapters we have been discussing electrostatics, but we also encountered some examples of charge movement, such as the charging and the rapid discharge of a capacitor in Chapter 25, and of the motion of electrons as an electron beam in Section 22–4. In fact the motion of charge within conducting materials—for example, within the wiring, appliances, and other circuits in your home—is everywhere around us. When charges move, we say there is an electric current, and electric currents within conductors form the topic of this chapter. The effect of a material's structure on electric current is like the effect of drag on mechanical motion, in the sense that the charges move on average at constant terminal speed. Because of the draglike forces, we must expend energy to make charges pass through materials, producing thermal energy. To describe these phenomena for a particular piece of material, we introduce the idea of resistance; to describe them for a particular material (as opposed to a particular piece of it), we introduce the concepts of resistivity and conductivity. Although we can describe a classical model that is an aid to the intuitive understanding of some aspects of resistivity, a fundamental understanding of why one material has a given resistivity and another has a different resistivity requires the ideas of quantum physics. Materials are categorized according to how easy it is for a current to move through them, and the difference between conductors, insulators, semiconductors, and superconductors also is explained by quantum physics.

◀ **FIGURE 26–1** Charges move in a cross section of wire, meaning that a current is flowing.

26–1 Electric Current

Electric current (or just **current**) is defined as the total charge that passes through a given cross-sectional area per unit time. Current can be composed of moving negative charges such as electrons or positive charges such as protons; it may occur within an overall-neutral material such as a conductor, or it may occur as a charged beam such as the electron beam of a television tube. Here, we concentrate on the general notions of current—whether that current describes the motion of charges within free space or within conducting materials. In Fig. 26–1, we have drawn the charge that passes through a conducting wire. Recall that *charge is conserved* (see Chapter 21), meaning that unless charge accumulates within a region, as much charge enters that region as leaves it.

A simple picture may be helpful to you in thinking about electric current within the metals that conduct electric current easily. In this picture, electrons under the influence of the potential that makes them move are like the balls that pass through a pinball machine impelled by gravity. The parent ions that form the lattice structure of the material are like the pins of the pinball machine, and multiple collisions with these fixed ions introduce a random element in the motion of the electrons, slowing them down, giving them a terminal velocity on average. While this picture "explains" many features of electric current, don't take it too seriously; we'll see later in the chapter that it is quite incomplete!

If ΔQ is the amount of charge passing through the cross sectional area of a wire in a time interval Δt, then the *average current*, I_{av}, through the wire is defined as

$$I_{\text{av}} \equiv \frac{\Delta Q}{\Delta t}. \tag{26–1}$$

If the current changes with time, we define the *instantaneous* current, I, by taking the limit $\Delta t \to 0$, so that the current is the instantaneous rate at which charge passes through an area:

$$I \equiv \frac{dQ}{dt}. \tag{26–2}$$

DEFINITION OF ELECTRIC CURRENT

The unit of current is the coulomb per second; this unit is also called the *ampere* (A, or, frequently, "amp"), after André Marie Ampère, who performed pioneering work in electricity and magnetism early in the nineteenth century. While the ampere will be defined more precisely in Chapter 28, that definition is equivalent to the simple relation

$$1\ \text{A} \equiv 1\ \text{C/s}.$$

The ampere is a fairly large unit, and it is also convenient to express current in milliamps (mA, 10^{-3} A); microamps (μA, 10^{-6} A); or even nanoamps (nA, 10^{-9} A). You might note that since an electron has a charge magnitude 1.6×10^{-19} C, some 0.6×10^{19} electrons pass each second in a 1 A current.

Currents occur over a wide range of values (Table 26–1). When the current has no time dependence we refer to a direct current (DC). Currents that have a harmonic time dependence, alternating currents (AC), are commonplace; we shall study them in more detail in Chapter 33. The values in Table 26–1 that refer to AC represent the average magnitude of the oscillating current.

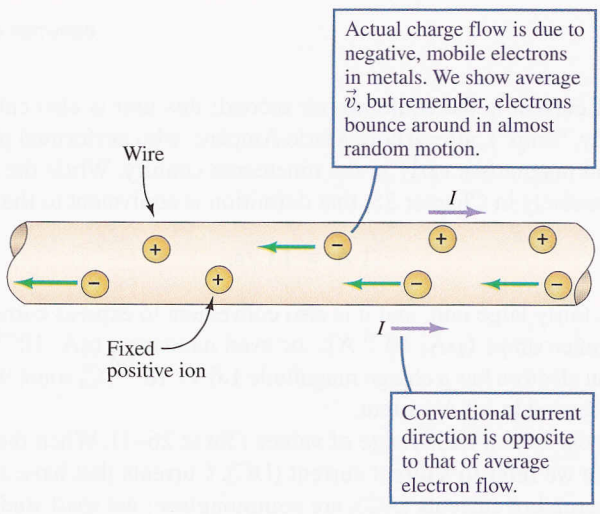


TABLE 26–1 • Values of Various Currents

Situation	Current (A)
Advanced-technology computer chips	10^{-12} to 10^{-6}
Electron beam of a TV set	10^{-3}
Minimum current that is dangerous when it passes through the human body (AC or DC)	10^{-2} to 10^{-1}
Proton beam of the Fermilab accelerator	0.3
Flashlight bulb	0.3
Household lightbulb (AC)	1
Automobile starter	200
Peak current in a lightning strike	10^{4}
Maximum current carried by a superconducting niobium wire of 1 cm^2 cross section	10^{7}

The Direction of Current

Current is a scalar quantity, as both charge and time are scalars, but it has a sign associated with it. It is useful to indicate the sign of the current by a directional arrow. Figure 26–2 depicts the direction of current flow within a conductor. By historical convention we associate the direction of current flow with the direction of "flow" of positive charges—even though it is actually the negative charges that move in conducting materials such as metals. In a conductor the positive charges—the atomic ions left behind by the electrons—are fixed in an ordered crystal lattice. In an ionized gas or a chemical solution, the charges that actually move and create the current may be positive or negative. This arbitrary convention for current direction causes no real problem, because a flow of positive charge to the right and a flow of the same amount of negative charge to the left represent the same current. By simply measuring the current, it is *not possible* to determine the sign of the charges that move (the *charge carriers*). By convention:

> **The direction of the current is the direction in which positive charge carriers would move, even if the actual charge carriers are negative charges moving in the opposite direction.**

▲ **FIGURE 26–2** By convention, the current direction is the direction in which positive charge effectively moves, even though in conductors it is the negative charge, electrons, that actually moves.

EXAMPLE 26–1 An accelerator used for medical research emits protons at the rate of 2.0×10^{13} protons per second. What is the current carried by this beam of protons?

Setting It Up Let us call N the number of protons emitted per unit time. We will need to use the charge per proton, $e = 1.6 \times 10^{-19}$ C.

Strategy The current I is defined as the rate at which charge passes, i.e. the charge per unit time. Here that is simply given by $I = Ne$.

Working It Out

$$I = Ne = (2.0 \times 10^{13} \text{ protons/s})(1.6 \times 10^{-19} \text{ C/proton})$$
$$= 3.2 \times 10^{-6} \text{ A}.$$

What Do You Think? In what way does this current differ from a current in a wire described above? *Answers to **What Do You Think?** questions are given in the back of the book.*

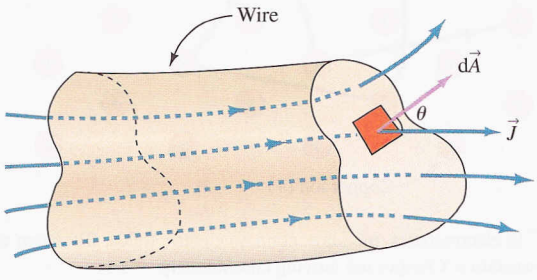
CONCEPTUAL EXAMPLE 26–2 A colliding beam experiment at the accelerator at the Fermi National Laboratory involves a beam of protons moving in the positive x-direction, and a beam of antiprotons moving in the opposite direction. Is there a net current here, and what is its sign? (For our purpose it is enough to know that antiprotons are particles with the same mass as protons, but with a charge of equal magnitude and opposite sign.)

Answer Suppose that the number of protons (charge e) that pass a given point each second is N, and the number of antiprotons (charge $-e$) per second is N'. Then the current associated with the protons is Ne in the positive x direction. The current of antiprotons is $N'(-e)$ in the *negative* x direction, and this is equivalent to a current of $N'e$ in the positive direction. Thus the total current is $(N + N')e$ in the positive x-direction. As far as current-carrying capacity is concerned, the antiprotons are equivalent to electrons.

What Do You Think? Consider also the fact that an antiproton and a proton can collide and annihilate each other, with the result that both disappear. Suppose that $N = N'$ and that all the antiprotons annihilate all the protons in some region where they can collide. Will this violate current conservation?

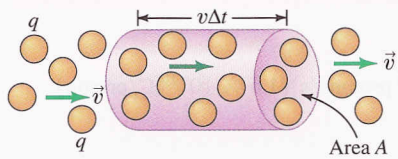
Current Density

Sometimes we must deal with the *details* of charge motion, not just an overall movement of charge, as for example within nonuniform materials, or even gases and plasmas. In that case we work with **current density**, $\vec{J}$, which is the rate of charge flow per unit area through an infinitesimal area. To define the current density, we must take into account the *local* magnitude and direction of the charge flow. Unlike current, which is a scalar, current density is a *vector*, with units of amperes per square meter. The direction of $\vec{J}$ is defined to be the direction of the net flow of positive charges at that particular infinitesimal element of area—since the area is tiny, it forms a plane and its direction is unambiguous.



What is the relation between current density and current? We determine this relation in a wire by dividing the finite area A through which the charge flows into infinitesimal areas $d\vec{A}$ (Fig. 26–3). This procedure is analogous to one we followed in treating fluid flow (in Chapter 16) or electric flux (in Chapter 23). The differential current dI flowing through $d\vec{A}$ is

$$dI = \vec{J} \cdot d\vec{A} = J\, dA \cos\theta, \tag{26–3}$$



where θ is the angle between $\vec{J}$ and the area element $d\vec{A}$. From Eq. (26–3), we see that dI is a maximum when $\vec{J}$ and $d\vec{A}$ are parallel and dI is zero when $\vec{J}$ is perpendicular to $d\vec{A}$. The total current passing through the area A is a sum over the differential currents dI:

$$I = \int_{\text{surface } A} \vec{J} \cdot d\vec{A}. \tag{26–4}$$

If the current density is uniform across a wire, the current through the wire is just the product of the wire's cross-sectional area with the magnitude of the current density.

◀ **FIGURE 26–3** The area of a finite wire is divided up into differential areas $d\vec{A}$ with the current density, $\vec{J}$, whose direction is the direction of the local current, defined at every point. The direction of $d\vec{A}$ is normal to the differential area.

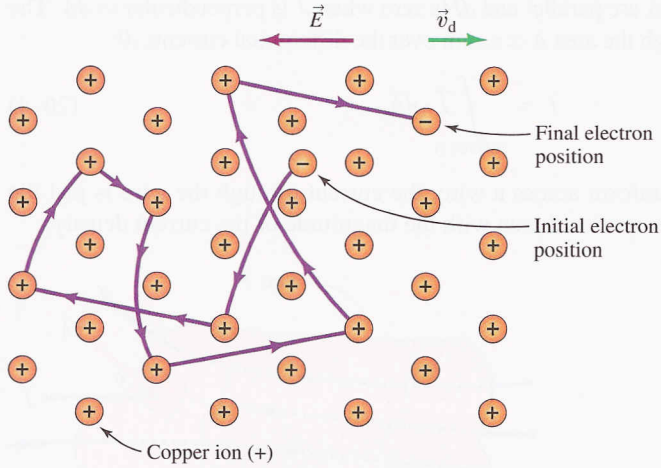
▲ **FIGURE 26–4** A collection of particles (each with charge q) with number density n_q all move to the right with velocity $\vec{v}$. The total charge passing through an area A in time Δt is $\Delta Q = n_q q v A\, \Delta t$.

Current Density of Moving Charges

Let us now connect current density to the microscopic motion of individual charges. Consider a collection of moving charges each of charge q, as in Fig. 26–4. In some small region, the number of charged particles per unit volume—the *number density*—is n_q. Suppose also that these particles all move with velocity $\vec{v}$. Then in a time interval Δt, the amount of charge passing through a given area A perpendicular to $\vec{v}$ is ΔQ, the charge contained in the volume $A(v\ \Delta t)$ swept out by the moving charges. We have

$$\Delta Q = \left(\frac{\text{charge}}{\text{volume}}\right)(\text{volume}) = (n_q q)(Av\ \Delta t) = n_q q v A\ \Delta t, \qquad (26\text{–}5)$$

where we have used the fact that the charge per unit volume is the number density of the charge carriers times the charge per particle. Thus the current is given by



$$I = \frac{\Delta Q}{\Delta t} = n_q q v A. \qquad (26\text{–}6)$$

Finally, the current density is I divided by A in the limit of *small* A, or $J = I/A$. The direction of $\vec{J}$ is specified by the direction of $\vec{v}$ with a sign determined by the sign of q:

$$\vec{J} = n_q q \vec{v}. \qquad (26\text{–}7)$$

26–2 Currents in Materials

We have referred to *conductors* as materials through which charge moves easily, *insulators* as materials through which charge does not move easily, *semiconductors* as materials intermediate to conductors and insulators, and *superconductors* as materials that under certain circumstances—in particular, at sufficiently low temperatures—carry current with no opposition whatsoever. How materials carry charge is of central interest for technology and of fundamental scientific importance. In Section 26–1 we mentioned a simple guiding picture (to be developed further in Section 26–5) in which electrons within conductors behave as though they were free to move, except for the presence of the stationary ions that form the crystal lattice of the metal, which form a set of obstacles for the electron motion. In this scenario electrons, constantly moving because the metal is at a finite temperature, undergo frequent collisions with the positive ions that form the crystal lattice of the metal whether the field is present or not (Fig. 26–5). When there is no field, the electrons do not, *on average*, move in any particular direction, and there is no macroscopic current. The motion of the electrons is random, like the motion of air molecules. In the presence of an electric field $\vec{E}$ each "free" electron experiences a force $\vec{F} = -e\vec{E}$ and thus accelerates between collisions in a direction opposite to the electric field.† In this case there is a *net* movement of electrons in

▶ **FIGURE 26–5** In one picture of current flow in a metal, an electron collides frequently with the ions and impurities and scatters randomly from the ions, here indicated with circles enclosing plus signs. When an electric field is present, the electron picks up a component of velocity opposite the field. The electron's path in the electric field is slightly parabolic. The extra component of velocity present due to the electric field is, on average, much less than the average speed of the electrons when no field is present.

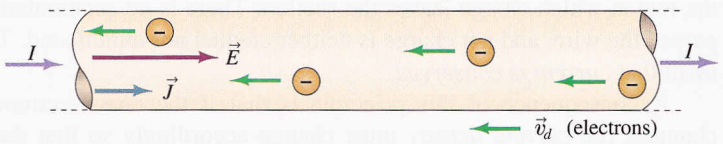
†In electrostatics, metals contain no electric fields. But when we deal with currents, we are no longer in electrostatics: Charges are moving continuously.

the direction of the electric force they experience. The collisions, in effect, give rise to a drag force on the flow of electrons. As with the fall of a parachute, drag acts to settle the motion to a steady flow in the direction of the force. The electrons move on average with a constant terminal velocity called the **drift velocity**, $\vec{v}_d$—this is the velocity indicated in Figs. 26–4 and 26–5. Equation (26–6) gives the relation between drift speed and current. Here the charge carriers are the electrons, so that n_q equals n_e, the density of free electrons in the metal, and Eq. (26–6) then gives

$$I = n_e q v_d A, \tag{26–8}$$

where A is the cross-sectional area of a metal wire.

We can solve Eq. (26–8) to find the drift speed in terms of the current:



$$v_d = \frac{I}{n_e q A}. \tag{26–9}$$

Equations (26–8) and (26–9) show the relations between current and drift speed. Remember that the direction of the electron's drift velocity is opposite to the defined direction of the current density because of the positive charge-carrier convention.

In Fig. 26–6, we show the relationships among the external electric field $\vec{E}$, the current I, the current density $\vec{J}$, and the electron's drift velocity $\vec{v}_d$. For the case of the wire, $J = I/A$, and from Eq. (26–9), we have

$$\vec{J} = n_e q \vec{v}_d. \tag{26–10}$$

Note the formal confirmation that $\vec{J}$ is opposite to the direction of $\vec{v}_d$: A negative sign is introduced when we recognize that $q = -e$.

◀ **FIGURE 26–6** Electrons drift in the direction opposite that of the current, I, current density, $\vec{J}$, and electric field, $\vec{E}$.

EXAMPLE 26–3 Estimate the drift speed v_d for electrons in a copper wire of diameter $d = 1.0$ mm that carries a current $I = 100$ mA. Copper has about one free electron per atom available to carry charge and has a mass density of 8.92 g/cm^3 and a molecular weight of 63.5 g/mol.

Setting It Up We refer to Fig. 26–6 for a pictorial representation.

Strategy The drift speed can be calculated from Eq. (26–10) if the current density and electron density are known. The current density involves the total current and the area of the wire, both obtainable from the data given. We have for the magnitude of the current density $J = \frac{I}{A} = \frac{I}{\pi r^2} = \frac{I}{\pi (d/2)^2}$, where d is the diameter of the wire and I is the total current. To calculate the free electron density, we make use of the fact that there is one free electron per atom, so that the free electron density equals the density of copper atoms. Here we proceed as follows:

(No. of atoms)/m^3 = [(No. of atoms)/kg][mass density in kg/m^3]

= [(No. of atoms/mole)/(No. of kg/mole)][mass density in kg/m^3].

In the last step, the number of atoms per mole is Avogadro's number N_A. To get the number of kg in 1 mole, we use the fact that the molecular weight of Cu is 63.5 g/mol = 63.5×10^{-3} kg/mol, and the mass density is 8.92 g/cm^3 = 8.92×10^3 kg/m^3. With all this information in hand we can then use Eq. (26–10) to find v_d.

Working It Out With the number of free electrons per atom denoted by n (here $n = 1$), we have

$$\begin{aligned} n_e &= n N_A \frac{1}{M} \rho_{\text{Cu}} \\ &= (1 \text{ electron/atom})(6.02 \times 10^{23} \text{ atoms/mol}) \\ &\quad \times \frac{1}{63.5 \times 10^{-3} \text{ kg/mol}} (8.92 \times 10^3 \text{ kg/m}^3) \\ &= 8.46 \times 10^{28} \text{ electrons/m}^3. \end{aligned}$$

A calculation of the current density gives

$$J = \frac{I}{\pi (d/2)^2} = \frac{4(100 \times 10^{-3} \text{ A})}{\pi (1.0 \times 10^{-3} \text{ m})^2} = 1.3 \times 10^5 \text{ A/m}^2,$$

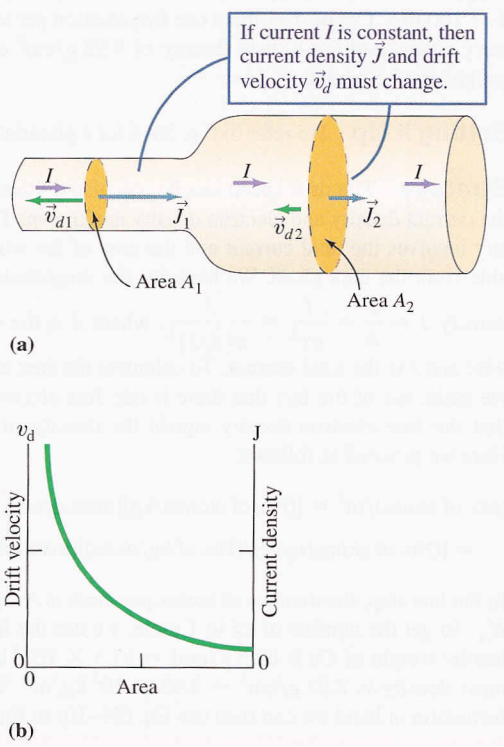
from which we calculate

$$\begin{aligned} v_d &= \frac{J}{n_e q} = \frac{1.3 \times 10^5 \text{ C/s} \cdot \text{m}^2}{(8.5 \times 10^{28} \text{ electrons/m}^3)(1.6 \times 10^{-19} \text{ C/electron})} \\ &= 9.6 \times 10^{-6} \text{ m/s}. \end{aligned}$$

Does this seem like a small value to you? See the "Think about this . . . " box below.

What Do You Think? If the current is increased by a factor of 4 in this problem, by how much would the radius of the wire have to change to keep the current density constant?

THINK ABOUT THIS. . .



WHY DOES THE LIGHT APPEAR THE MOMENT YOU THROW THE LIGHT SWITCH?

In Example 26–3, we saw that the drift speed in a realistic wire carrying a realistic current is only a tiny fraction of a centimeter per second. Certainly you don't have to wait for hours for the electrons to drift to the lightbulb you want to put to use. In fact, household circuits carry alternating current (the subject of Chapter 33), in which there is no net flow of electrons in one direction or another! So what happens when we switch on a light in our house? When the switch is thrown, the electric field that influences the electrons to move in the wire is set up throughout the wire at speeds approaching the speed of light. The free electrons are spread throughout the wire, and they are each affected by the electric field almost simultaneously. They start moving at once in response to this field—those nearest the switch as well as those nearest the electrical appliance. A similar effect occurs in fluid flow, and we can compare an electric wire with free electrons to a garden hose full of water. If you want to move a sprinkler while you water the lawn, you turn the water off, move the sprinkler, and then turn the water back on. Because the hose is already full of water, the sprinkler starts immediately: The force of the water at the faucet end is quickly transmitted all along the hose, and the water at the sprinkler end of the hose flows from the sprinkler almost the moment the faucet is opened. Similarly, the electrons that move within the filament of the lightbulb are already present when the switch is thrown. When this happens the electric field and hence the current that it drives, are set up almost instantaneously.

Current and the Conservation of Charge

How does the conservation of charge affect currents in materials? The current in a wire describes the flow of charge along the wire. For steady flow (constant current), the rate at which charge enters a section of the current-carrying wire in a given time must equal the rate at which charge leaves the section: There is no accumulation of charge in any part of the wire, and net charge is neither created nor annihilated. This is just the statement that *current is conserved.*

A consequence of this principle is that if the cross-sectional area of the wire changes, the *current density* must change accordingly so that the product JA is unchanged (Fig. 26–7a). Equation (26–10) in turn implies that *for a fixed current*, the drift speed, like the current density J, is inversely proportional to the area of the wire (Fig. 26–7b). The conservation of current will continue to act as a constraint if the wire

▶ **FIGURE 26–7** (a) A steady current is the same in all parts of a wire, even if the area of the wire varies. This means that the current density and drift speed will vary with the area: Both are larger when the wire cross section is smaller. (b) More precisely, the drift speed and current density are inversely proportional to the wire area.

splits into two or more wires, even if, as we will learn in Section 26–4, the currents in the individual wires are determined by the properties of these wires. The situation is analogous to the flow of water along a pipe. As we learned in Chapter 16, for water in steady flow the conservation of mass implies the conservation of flux of the water. The rate at which water enters a pipe is equal to the rate at which water leaves. If the pipe narrows, the speed of the flow increases, while if the pipe widens, the speed of the flow decreases. If the pipe splits, the rate of flow in each section adjusts itself in a way that is consistent with conservation of the total flow rate.

26–3 Resistance

We have seen that a current flows when an electric field is applied to a conductor. We can equally consider the flow to be due to a potential difference V, with the current flowing from a higher to lower potential. The amount of current that flows through a material for a given potential difference across that material depends on the material's properties and its geometry.

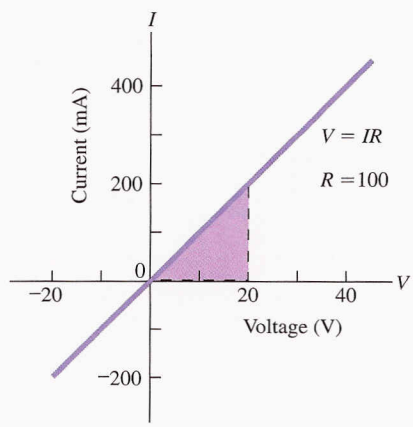
The **electrical resistance** of a piece of material is a measure of how easily charge flows within that material. The resistance R is defined to be the ratio of the voltage (potential difference) across the material to the current that flows through it:

$$R \equiv \frac{V}{I}. \tag{26–11}$$

DEFINITION OF RESISTANCE

If a material has a low resistance, then more current will flow for a given voltage than it will for a higher resistance. The units of resistance are volts per ampere, but a separate SI unit called the **ohm** (Ω) has been defined as the resistance through which a current of 1 A flows when a potential difference of 1 V is applied:

$$1\ \Omega \equiv 1\ \text{V/A}.$$

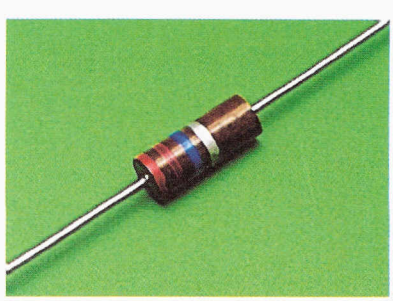


Units of kilohms (kΩ or $10^3\ \Omega$) or megohms (MΩ or $10^6\ \Omega$) are also commonly used.

Georg Simon Ohm was the first to study the resistance of different materials systematically. In 1826, he published his experimental result that, for many materials including most metals, *the resistance is constant over a wide range of potential differences*. This statement is called *Ohm's law*. It is not, properly speaking, a law, but rather an empirical statement about the behavior of materials. When the resistance of a material is constant over a range of potential differences, we say that the material is *ohmic*. We shall continue the traditional practice of referring to this linear relation between voltage and current for these materials as a "law" and writing it as

$$V = IR, \tag{26–12}$$

OHM'S LAW

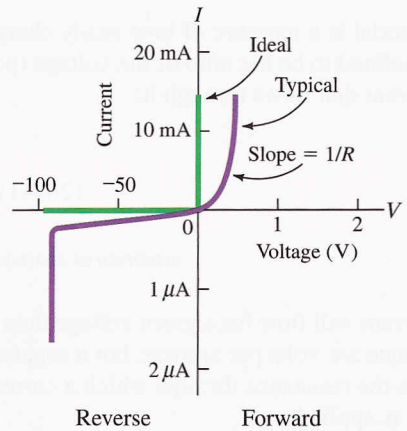


where R *is independent of* V. Figure 26–8 illustrates the consequence of the independence of V and R.

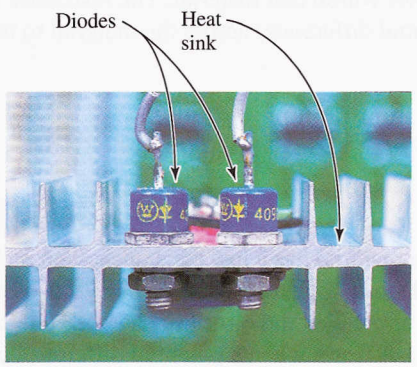
▲ **FIGURE 26–8** For ohmic materials, Ohm's law states that the ratio V/I is a constant.

Resistors

A **resistor** is a piece of ohmic material with a specific value of resistance. It forms a part of many circuits; indeed, since all circuit elements through which current flows have some resistance, it is ubiquitous in circuits. Common resistors have resistances that range from fractions of an ohm to millions of ohms (Fig. 26–9). A resistor of given resistance R with a given potential V between its terminals allows the flow of a current $I = V/R$. Resistors are represented in circuit diagrams by zigzag lines, ⁓⁓⁓. They are connected to each other and to other elements such as capacitors or batteries by conducting wires that are generally assumed to have negligible resistance.



▲ **FIGURE 26–9** Resistors are color coded to indicate the value of their resistance.



THINK ABOUT THIS. . .

CAN NONOHMIC MATERIAL BE USEFUL IN CIRCUITS?

There are many *nonohmic materials*: materials for which the voltage and current do not obey the linear relation of Ohm's law. In fact, if you look closely enough, there are no perfectly ohmic materials, so this is partly just a question of degree. But some materials have conduction properties that differ spectacularly from Ohm's law (see Section 26–6). Moreover, one can tailor these conduction properties through precise control of the relative proportions of different atoms. Such materials and devices play an enormous role in computing and other electronic applications. Figure 26–10a shows current-versus-voltage curves (ideal and typical) for a **diode**. A diode is a device that transmits current easily when the voltage difference has one sign, but prevents charge flow (that is, it has a very high resistance) when the voltage difference has the other sign. The curve is very far from the linear curve demanded by Ohm's law. Diodes are used in many electric devices (Fig. 26–10b). They may be used to charge a battery while preventing it from discharging, or, more interestingly, they prevent the "backflow" in AC and therefore are important in devices that convert AC to DC.

(a)

(b)

▲ **FIGURE 26–10** (a) Plot of current versus voltage for an ideal diode (green) and a typical real diode (purple). Note that, for the ideal diode, there is no current when the voltage is negative: The diode allows current to flow in only one direction. (b) Two (blue) diodes used to convert AC voltage to DC are bolted to an aluminum plate to dissipate thermal energy (heat sink).

Resistivity and Conductivity

The resistance of a conducting wire of a given material depends both on the shape (length and cross-sectional area) of the wire, and on the intrinsic properties of the material. Our guiding picture for resistance ascribes the difference between the acceleration of a charge in free space and the steady flow in a conductor to the effect of collisions with the ions within the material. These provide a retarding force that opposes the electric field E. This retarding force will clearly vary from material to material. Since the effect of the collisions is a local one—that is, it does not depend on the precise shape or size of the piece of material—we expect that it is $J = I/A$ that will depend on E and the properties of the material. If we define the intrinsic (geometry- and size-independent) **resistivity** ρ of a material by E/J, we see that this can be expressed in terms of I/A and the voltage V, which is related to the electric field by $E = V/L$, where L is the length of the wire. We write

$$\rho \equiv \frac{E}{J}. \qquad (26\text{–}13)$$

DEFINITION OF RESISTIVITY

Using $E = V/L$ and $J = I/A$, and recalling $R = V/I$, Eq. (26–13) reads $\rho = R(A/L)$, or

$$R = \rho\frac{L}{A}. \tag{26–14}$$

The reciprocal of the resistivity is the **conductivity**, σ.

$$\sigma \equiv \frac{1}{\rho}. \tag{26–15}$$

DEFINITION OF CONDUCTIVITY

Typical values of conductivity are listed in Table 26–2. The resistivities and conductivities of the materials shown in Table 26–2 vary over many orders of magnitude. The conductivity of a metal such as aluminum is a factor of 10^{21} higher than that of a good insulator such as Teflon. It is worthwhile noting here that while our guiding model—acceleration of free electrons with drag due to collisions—may provide us with a concrete picture to work with, it is not remotely adequate to explain the huge range of values for conductivity observed in nature. Only quantum mechanics can do that, and we shall discuss this a little in Section 26–6.

In the basic relation that defined the resistivity in Eq. (26–13), both the electric field and the current density are vectors, and a better version of this relation is

$$\vec{E} = \rho\vec{J}. \tag{26–16}$$

RELATION BETWEEN FIELD AND CURRENT DENSITY

TABLE 26–2 • Resistivities, Conductivities, and Temperature Coefficients (at 20°C)

Material	Resistivity, ρ ($\Omega \cdot m$)	Conductivity, σ $(\Omega \cdot m)^{-1}$	Temperature Coefficient, α $(°C)^{-1}$
Conductors			
Elements			
Aluminum	2.82×10^{-8}	3.55×10^{7}	0.0039
Silver	1.59×10^{-8}	6.29×10^{7}	0.0038
Copper	1.72×10^{-8}	5.81×10^{7}	0.0039
Iron	10.0×10^{-8}	1.0×10^{7}	0.0050
Tungsten	5.6×10^{-8}	1.8×10^{7}	0.0045
Platinum	10.6×10^{-8}	1.0×10^{7}	0.0039
Alloys			
Nichrome	100×10^{-8}	0.1×10^{7}	0.0004
Manganin	44×10^{-8}	0.23×10^{7}	0.00001
Brass	7×10^{-8}	1.4×10^{7}	0.002
Semiconductors			
Carbon (graphite)	3.5×10^{-5}	2.9×10^{4}	−0.0005
Germanium (pure)	0.46	2.2	−0.048
Silicon (pure)	640	1.6×10^{-3}	−0.075
Insulators			
Glass	10^{10} to 10^{14}	10^{-14} to 10^{-10}	
Neoprene rubber	10^{9}	10^{-9}	
Teflon	10^{14}	10^{-14}	

Equivalently, from the definition of conductivity, Eq. (26–15), we have

$$\vec{J} = \sigma\vec{E}. \tag{26–17}$$

The reason for writing out these equations is that Eqs. (26–16) and (26–17) are general results—not limited to ohmic materials. It is only for ohmic materials that ρ and σ do not vary with V or $\vec{E}$.

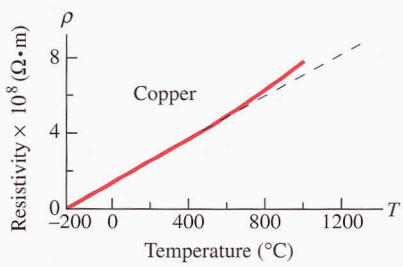
EXAMPLE 26–4 Determine the current density, resistance, and electric field for the copper wire of Example 26–3 if the wire is 10 m long.

Setting It Up In addition to the quantities given in the problem statement, we will want to use data for copper in Table 26–2.

Strategy Given the current and the wire's cross section, the current density is $J = I/A = I/(\pi r^2) = 4I/(\pi d^2)$. We are also given the length of the wire, so that the resistance can be calculated—$R = \rho L/A$—and we can look up $\rho = 1.72 \times 10^{-8}\ \Omega \cdot \text{m}$ for copper. Finally we find the desired field using $E = \rho J$.

Working It Out We calculate in order

$$J = \frac{4I}{\pi d^2} = \frac{4(100 \times 10^{-3}\ \text{A})}{\pi(1.0 \times 10^{-3}\ \text{m})^2} = 1.3 \times 10^5\ \text{A/m}^2.$$



Next we have

$$R = \rho\frac{L}{A} = \frac{(1.72 \times 10^{-8}\ \Omega \cdot \text{m})(10\ \text{m})}{\pi(0.50 \times 10^{-3}\ \text{m})^2} = 0.22\ \Omega.$$

Finally

$$E = \rho J = (1.72 \times 10^{-8}\ \Omega \cdot \text{m})(1.3 \times 10^5\ \text{A/m}^2) = 2.2 \times 10^{-3}\ \text{V/m}.$$

What Do You Think? If the electric field we calculated above acts within an iron wire of the same size as the copper wire in this example, how will the current differ, if at all?

▲ **FIGURE 26–11** The resistivity of copper as a function of temperature.

The Temperature Dependence of Resistivity

Resistivities of some materials, copper for example, have a strong temperature dependence (Fig. 26–11). We can represent the temperature dependence with a linear approximation that is sufficiently accurate for most purposes:

$$\rho \cong \rho_0[1 + \alpha(T - T_0)]. \tag{26–18}$$

The parameter α is the *temperature coefficient of resistivity*, and ρ_0 is the resistivity at the reference temperature T_0, normally 20°C. Values of ρ, σ, and α are given in Table 26–2 for $T = 20°\text{C}$. Resistivities for most metals increase with temperature, as Fig. 26–11 shows for copper, and we'll discuss this further in the next section.

EXAMPLE 26–5 Find the resistance of a coil of platinum wire of diameter 0.5 mm and length 20 m at 20°C and at 1000°C.

Setting It Up The numbers for resistivity as well as for temperature dependence can be found in Table 26–2.

Strategy Calculation of resistance in terms of the dimensions of the wire and of the resistivity involves a simple application of Eq. (26–14). We are given the diameter d of the wire, and the area is then $A = \pi(d/2)^2$. The resistance is then given in terms of the resistivity. The latter has a well-defined temperature dependence, given by Eq. (26–18). If we take that into account, then

$$R = \rho\frac{L}{A} = \rho\frac{4L}{\pi d^2} = \rho_0[1 + \alpha(T - T_0)]\frac{4L}{\pi d^2}.$$

Here ρ_0 for platinum is $10.6 \times 10^{-8}\ \Omega \cdot \text{m}$, and the coefficient $\alpha = 3.9 \times 10^{-3}\ °\text{C}^{-1}$. All we need to do is to evaluate the above formula for two different values of T.

Working It Out For $T = T_0 = 20°\text{C}$,

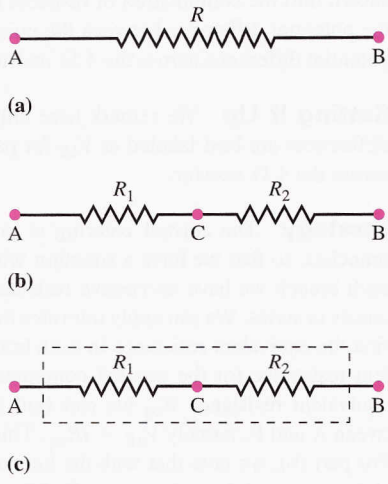
$$R = \rho\frac{L}{A} = (10.6 \times 10^{-8}\ \Omega \cdot \text{m})\frac{4 \times 20\ \text{m}}{\pi(0.5 \times 10^{-3}\ \text{m})^2} = 11\ \Omega.$$

For $T = 1000°\text{C}$, we multiply the above result by the factor $[1 + \alpha(T - T_0)]$ to get

$$R = (11\ \Omega)[1 + (3.9 \times 10^{-3}\ °\text{C}^{-1})(1000°\text{C} - 20°\text{C})] = 53\ \Omega.$$

This large spread in values suggests that, depending on the materials used for resistors, the operation or design of a circuit must account for temperature dependence. This is particularly true since energy is dissipated within resistors in the form of thermal energy (see Section 26–7).

What Do You Think? The melting temperature of platinum is over 1700°C, while that of copper is a little over 1000°C. Consider their temperature coefficient of resistivity and decide which would be more useful for a lightbulb filament. (Real filaments are made of tungsten.)

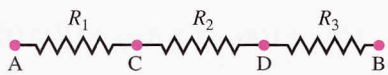


26–4 Resistances in Series and in Parallel

In the previous chapter we studied capacitors, and we saw that a set of capacitors connected in a combination within an electric circuit could sometimes be replaced by a single "equivalent" capacitor, i.e. one that could replace the combination and leave the relevant circuit characteristics external to the combination unchanged. Resistors can be treated similarly, and in this section we develop the rules that tell us how to find equivalent resistors. As for capacitors, so long as any particular configuration of resistors can be reduced to a sequence of series and parallel connections, it is possible to find a single equivalent resistance. This can be helpful in any number of contexts, starting with the most direct: simplifying a circuit that has been "overdesigned."

Resistors in Series

Current conservation allows us to calculate the effective resistance when a number of resistors are connected in series. Figure 26–12a shows a wire connecting two points A and B, with a resistor of resistance R in between. If the current flowing through the resistor R is I, then the potential difference between the points A and B is $V_{AB} = IR$. Suppose we now put two resistors along the same wire—we have connected them in series—and take a point C that lies on the wire between the two resistors (Fig. 26–12b). Current conservation demands that the current I is the same all along the wire. If the first resistor has resistance R_1, then the potential difference between A and C must be $V_{AC} = IR_1$. If the second resistor between C and B has resistance R_2, then the potential difference between these points is $V_{CB} = IR_2$. Let us now put a box around the two resistors in series, as in Fig. 26–12c. We see that the potential difference between the points A and B is given by $V_{AB} = V_{AC} + V_{CB}$. This sum, however, is $V_{AB} = IR_1 + IR_2 = I(R_1 + R_2)$. We may now ask for the resistance R_{eq} equivalent to the two resistors in series, by which we mean that $V_{AB} = IR_{\text{eq}}$. It follows that



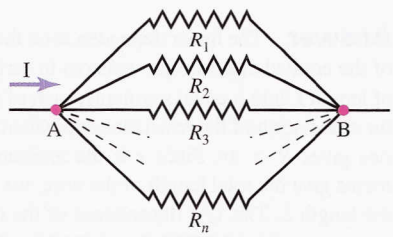
$$R_{\text{eq}} = \frac{V_{AB}}{I} = R_1 + R_2. \tag{26–19}$$

▲ **FIGURE 26–12** (a) A single resistor between points A and B on a wire, with potential difference V_{AB} between the points. (b) Two resistors in series between points A and B. (c) Two resistors in series act as a single equivalent resistor.

A repeat of the exercise with three resistors R_1, R_2, R_3 between the points A and B, with intermediate breaks at the points C and D, as in Fig. 26–13, shows that the equivalent resistance is

$$R_{\text{eq}} = \frac{V_{AB}}{I} = \frac{V_{AC} + V_{CD} + V_{DA}}{I} = R_1 + R_2 + R_3. \tag{26–20}$$

▲ **FIGURE 26–13** Three resistors in series, acting as a single equivalent resistor.



This is easily generalized to n resistors in series:

$$R_{\text{eq}} = R_1 + R_2 + R_3 + \cdots + R_n. \tag{26–21}$$

Resistors in Parallel

Like capacitors, resistors can be placed in parallel, as in Fig. 26–14. A current I flows into a junction point A, from which n wires sprout, carrying resistors of resistance $R_1, R_2, \ldots R_n$. These wires come together again at the junction point B, out of which the original (*conserved*) current I flows. The potential difference between the points A and B is given as V_{AB}, and *this is the same as the potential difference across any of the resistors*. The current flowing out of the junction point A breaks up into parts that flow through the different resistors. How big these partial currents are is determined by the resistors that they flow through. Thus $I_1 = V_{AB}/R_1$, $I_2 = V_{AB}/R_2$, and so on. The equivalent resistance is given by rewriting the conserved current I as a sum of the partial currents, all of which is written in terms of the potential difference V_{AB} and the individual resistances. In other words, the equivalent resistance R_{eq} is defined by V_{AB}/I, so that $I = V_{AB}/R_{\text{eq}}$. Current conservation then implies that

$$I = \frac{V_{AB}}{R_{\text{eq}}} = I_1 + I_2 + \cdots + I_n = \frac{V_{AB}}{R_1} + \frac{V_{AB}}{R_2} + \cdots + \frac{V_{AB}}{R_n}$$
$$= V_{AB}\left(\frac{1}{R_1} + \frac{1}{R_2} + \cdots + \frac{1}{R_n}\right).$$

▲ **FIGURE 26–14** An arrangement of n resistors in parallel, carrying current from A to B, with potential difference V_{AB} from A to B.

Dividing out V_{AB} yields the relation that holds for resistors **in parallel**,

$$\frac{1}{R_{\text{eq}}} = \frac{1}{R_1} + \frac{1}{R_2} + \cdots + \frac{1}{R_n}. \tag{26–22}$$

EXAMPLE 26–6 Consider a current $I = 3.0$ A flowing as shown into the combination of resistors in Fig. 26–15. (a) Calculate the potential difference between the points A and B. (b) What is the potential difference across the 4 Ω resistor?

Setting It Up We remark here only that the desired potential differences are best labeled as V_{AB} for part (a), and for part (b), V_{CB} across the 4 Ω resistor.

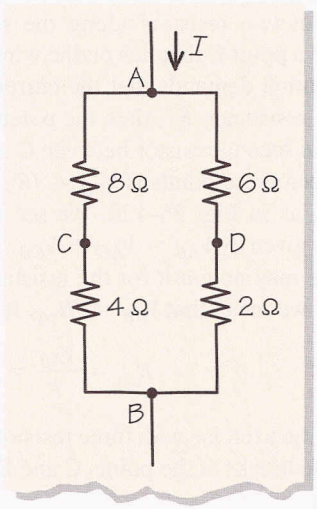
Strategy The current entering at point A divides up into two branches, so that we have a situation with resistances in parallel. In each branch we have successive resistances, so there are also resistances in series. We can apply our rules to find equivalent resistances: first the equivalent resistance in each branch, then an overall equivalent resistance for the parallel combination. By finding the overall equivalent resistance R_{eq} we can find the potential difference between A and B, namely $V_{AB} = IR_{\text{eq}}$. This gives us the answer to (a). For part (b), we note that with the known V_{AB} and the equivalent resistance in each branch, we can find the current in each branch. The potential difference V_{CB} is then the current in the left branch times the resistance 4 Ω.

Working It Out The equivalent resistance in the left branch (the ACB path), which contains two resistors in series, is $R_{ACB} = 8\ \Omega + 4\ \Omega = 12\ \Omega$. The equivalent resistance in the right branch is similarly $R_{ADB} = 6\ \Omega + 2\ \Omega = 8\ \Omega$. Finally we want the overall equivalent resistance,

$$1/R_{\text{eq}} = 1/R_{ACB} + 1/R_{ADB} = 1/(12\ \Omega) + 1/(8\ \Omega) = 5/(24\ \Omega),$$

or $R_{\text{eq}} = (24\ \Omega)/5 = 4.8\ \Omega$. With these values we can proceed to the potential differences.

(a) We have immediately



$$V_{AB} = R_{\text{eq}}I = (4.8\ \Omega) \times (3\ \text{A}) = 14\ \text{V}.$$

(b) The current through the branch ACB is $I_{ACB} = V_{AB}/R_{ACB} = (14\ \text{V})/(12\ \Omega) = 1.2$ A. In turn,

$$V_{CB} = I_{ACB} \times (4\ \Omega) = (1.2\ \text{A}) \times (4\ \Omega) = 4.8\ \text{V}.$$

As a check we can calculate the potential difference between A and C, $V_{AC} = (1.2\ \text{A}) \times (8\ \Omega) = 9.6$ V, which when added to the 4.8 V yields the total potential difference of 14 V.

What Do You Think? In what way would the calculation be simpler if we were to interchange the 8 Ω and 6 Ω resistors?

▲ FIGURE 26–15

CONCEPTUAL EXAMPLE 26–7 Equation (26–14) tells us that the resistance of a wire is proportional to its length L and inversely proportional to its cross-sectional area A. Is this consistent with the results obtained within this section?

Answer The linear dependence on the length is just an application of the equivalence rule for resistors in series. If we cut a uniform wire of length L into n equal segments, each of resistance r, then the rule for the calculation of the resistance equivalent to n identical resistors in series gives $R = nr$. Since r is the resistance per segment, and n segments give the total length of the wire, we find that R is proportional to the length L. The $1/A$ dependence of the resistance is a direct application of the equivalence rule for resistors in parallel. We may view a wire of total cross-section A as a total of N wires in parallel, each of cross-sectional area A/N. Suppose each of these N wires has a resistance r. Then the rule for calculating the equivalent resistances yields $1/R_{\text{eq}} = N(1/r)$, or $R_{\text{eq}} = r/N$. Now according to Eq. (26–14), $r = \rho\dfrac{L}{(A/N)} = N\rho\dfrac{L}{A}$. This gives us $R_{\text{eq}} = r/N = \rho L/A$, a consistent result. (Another way to see this is to note that R should be independent of N—of how many pieces you cut the original resistor into—and the only way that can happen is for r to be *inversely proportional* to the area A/N; this leaves R_{eq} inversely proportional to the area A.)

*26–5 Free-Electron Model of Resistivity

A more fundamental understanding of resistivity requires quantum mechanics. Nevertheless, there is a simple classical model of electrons and resistivity that is consistent with Ohm's law. It was first proposed in 1900 by Paul Drude and is known as the **free-electron model**, or the **Drude model**. Although the model has fundamental deficiencies, its study is worthwhile for two reasons: First, the model allows us to focus on the physics of resistivity. Second, the model illustrates how model-building in the physical sciences proceeds, and how we can judge the success or failure of a model.

We start with the idea that solids contain "free" electrons, which can move within the material and carry charge. The density of free electrons n_e depends on the material, and this is the factor responsible for the differences among conductors, insulators, and semiconductors (which we shall discuss in Section 26–6). In metals, the number of loosely attached electrons per atom (these are the electrons that behave as though they were free) lies on average in the range 1.0 to 1.3, although it can be as large as 3.5 (for aluminum).

The model postulates that free electrons form a "gas" of independent particles at temperature T. The electrons move erratically due to collisions with the atoms or ions that form the crystal lattice when there is no electric field, but when there is an applied field, they are accelerated by it in between the collisions. The result is an on-average movement that forms the current. The effect of the collisions, in other words, is to produce a drag force that results in a constant drift velocity, producing the steady current. As we saw in Chapter 5, one of the simplest drag forces is proportional to the electrons' speed. If we assume this form, then Newton's second law for the component of electron motion that is parallel to the applied field is

$$ma = -eE - (\text{a constant})v,$$

where m is the mass of an electron. The constant must have dimensions of mass/time, and we write it as m/τ, where τ is a quantity with dimensions of time. From the kinetic theory of Chapter 19 one can establish that τ is the *collision time*, the average time between successive collisions of an electron with the lattice ions. The acceleration drops to zero when the speed of the electrons reaches the drift speed, v_d, meaning that $ma = -eE - (m/\tau)v_d = 0$, or

$$v_d = -\frac{eE\tau}{m}. \tag{26–23}$$

The minus sign indicates that the direction of the drift velocity is opposite to that of the electric field, as must be the case with electrons in motion. When this expression is inserted into Eq. (26–10) for the current density, we find

$$J = n_e(-e)v_d = \frac{n_e e^2 \tau}{m} E. \tag{26–24}$$

Comparison with Eq. (26–17) yields

$$\sigma = \frac{n_e e^2 \tau}{m}, \quad \text{or} \quad \rho = \frac{1}{\sigma} = \frac{m}{n_e e^2 \tau} \tag{26–25}$$

for the conductivity σ and the resistivity ρ. The quantities e and m are independent of the type of material. The average time between collisions may be expressed in terms of the *mean free path* λ and the average speed v_{av} of the electrons in the free-electron "gas" by using Eq. (19–51), $\tau = \lambda/v_{\text{av}}$.

For electric fields not so large that the material itself is disrupted, none of the quantities in Eq. (26–25) depend on E, and thus the resistivity (or conductivity) is constant over a wide range of applied electric fields. This was the basis of Drude's (and independently Hendrik Lorentz's) claim to understand Ohm's law at an atomic level, dating from 1900.

EXAMPLE 26–8 What is the free-electron model's prediction for the collision time of current-carrying electrons in copper, given that the resistivity of copper is $1.7 \times 10^{-8}\ \Omega \cdot \text{m}$? You may use the parameters of Example 26–2.

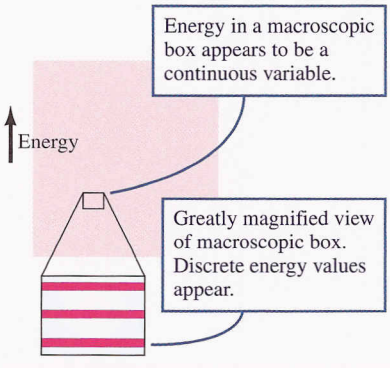
Setting It Up The collision time τ is related to the resistivity ρ given above by Eq. (26–25). The other parameters in the equation are the known charge $e = 1.6 \times 10^{-19}\ \text{C}$, the known electron mass $m = 0.91 \times 10^{-30}\ \text{kg}$, and the electron density $n_e = 8.5 \times 10^{28}$ electrons/m^3, a number calculated in Example 26–3.

Strategy A rearrangement of Eq. (26–25) gives us the desired quantity, $\tau = \dfrac{m}{n_e e^2 \rho}$.

Working It Out We have

$$\tau = \frac{0.91 \times 10^{-30}\ \text{kg}}{(8.5 \times 10^{28}\ \text{electrons/m}^3)(1.6 \times 10^{-19}\ \text{C})^2(1.7 \times 10^{-8}\ \Omega \cdot \text{m})}$$
$$= 2.5 \times 10^{-14}\ \text{s}.$$

The Failure of the Free-Electron Model



The free-electron model assumes electrons moving among a lattice of ions. A closer look at the predictions of this model reveals significant discrepancies with experiment. In particular:

- The measured average speed of electrons in metals is *more than a factor of 10* higher than the model predicts for copper at room temperature.
- We know from Chapter 19 [see Eq. (19–33)] that the rms speed of the particles of a gas is proportional to $\sqrt{T}$, where T is the temperature. However, experimental values for the mean speed of conduction electrons are essentially independent of temperature.
- The mean free path—the average distance an electron travels between collisions [see Eq. (19–15)]—should be independent of temperature according to the model. Experimentally, this quantity is much larger than expected and has a $1/T$ dependence.

Although the free-electron model is *qualitatively* correct in many aspects, it cannot be taken too literally, because it is a classical model in what turns out to be the domain of quantum mechanics. A correct model of electrical conduction *requires* the use of quantum mechanics. Indeed, quantum physics comes in at several levels, the major ones as follows:

- Conduction electrons do not act as a classical gas of noninteracting electrons; rather, they obey a velocity-distribution law based on quantum physics.
- Quantum physics requires us to treat electrons as though they were waves scattering from the lattice structure of the material. In particular, this treatment leads to a surprise: Quantum physics predicts that *there would be no resistance to electron flow in a fixed, perfectly ordered crystal with no impurities*. Finite conductivities result from departures from the perfect lattice structure. These departures occur in two ways: impurities are present in real materials, and the positions of lattice atoms vibrate at finite temperatures due to thermal excitation. At high temperatures, resistivity to electron flow is caused primarily by thermal vibrations. At low temperatures, resistivity is due to electrons being scattered by impurities.

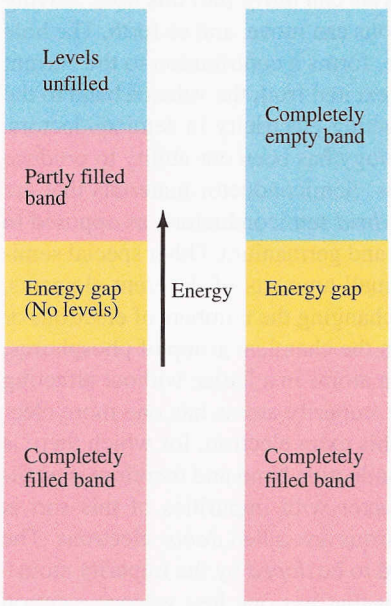
There is ample evidence that the quantum physics ideas are correct. Indeed, *all* the properties described are correctly explained with these ideas. We'll discuss them in more detail in the following optional section and then later in Chapter 43.

▲ **FIGURE 26–16** Energy diagram that shows the possible energy levels of an electron in a solid. (It takes no account of the crystalline structure formed by the parent ions of the electrons, whose presence has a strong effect on the possible energy levels—see Fig. 26–17). Classical physics predicts a continuum of possible energies, but quantum mechanics shows that the possible levels are actually discrete but so closely spaced that they are hard to distinguish.

*26–6 Materials and Conductivity

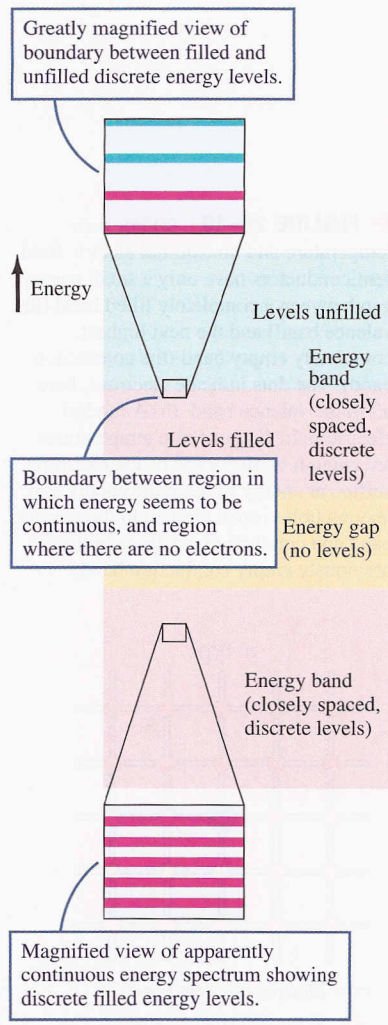
Materials differ in their ability to conduct electricity over an enormous range. A good conductor might have a resistivity of $10^{-8}\ \Omega \cdot \text{m}$; a good insulator, about $10^{14}\ \Omega \cdot \text{m}$. The resistivity of semiconductors ranges from 10^{3} to $10^{-5}\ \Omega \cdot \text{m}$ and depends sensitively on temperature. Superconductors have no measurable resistance at all below a so-called critical temperature, a quantity that is specific to the material. We argued in the previous section that a proper quantitative explanation of the resistivity of all materials requires quantum physics. In this section, we employ a minimal amount of the ideas that explain quantum physics to describe the critical properties that distinguish conductors, insulators, semiconductors, and superconductors.

In classical physics, the energy of a "free" electron within a metal can take on any value; we say that the energy values form a *continuum*. In contrast, a quantum description of electrons confined to the interior of a metal but otherwise free shows that the possible energy values of such electrons are *quantized*; that is, the possible energies have discrete values. In other words, an electron cannot have *any* energy value, much as the frequencies of standing waves on a string cannot have any value, just a set of discrete values. In a sample of material whose size is large compared with atomic sizes (10^{-10} m), these energy values are so close together that they appear to be continuous, just as the separate dots in a newspaper photograph are not distinguishable from a large distance. Figure 26–16, an energy diagram, illustrates the allowed energy levels. It is important to keep in mind that this diagram illustrates only the *possible* energy levels.



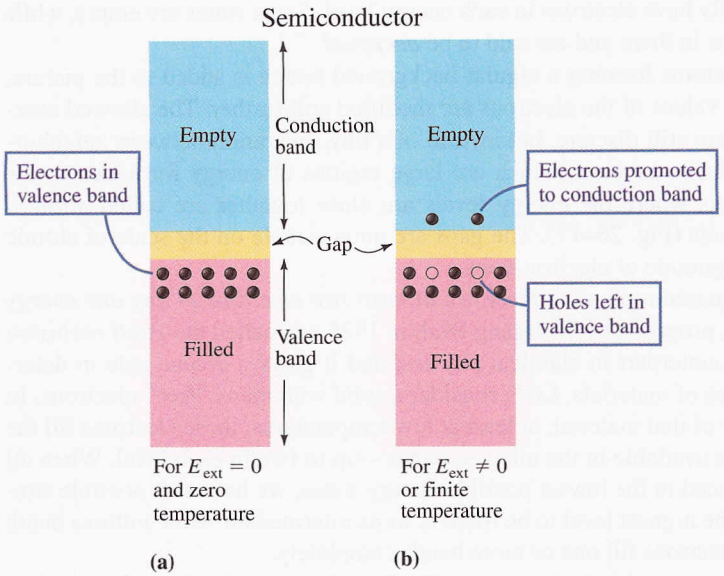
We do not necessarily have electrons in each energy level. Some states are empty, while others have electrons in them and are said to be *occupied*.

When a set of atoms forming a regular background lattice is added to the picture, the possible energy values of the electrons are modified still further. The allowed energies of an electron are still discrete, but instead of a tiny separation between neighboring levels, there are *energy gaps*, which are large regions of energy forbidden to the electron. The regions where the energy levels are close together are called *allowed bands* of energy levels (Fig. 26–17). The gaps are quite sizable on the scale of atomic physics—of the magnitude of electron-volts.

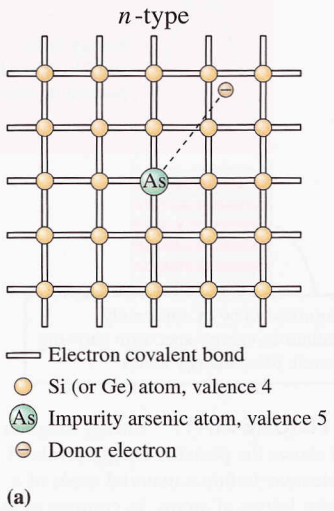


According to quantum physics, *there are at most two electrons in any one energy level*. This property, proposed by Wolfgang Pauli in 1925 and called the *Pauli exclusion principle*, has no counterpart in classical physics, and it plays a crucial role in determining the properties of materials. Let's consider a solid with many "free" electrons. In an equilibrium state of that material, at least at low temperatures, these electrons fill the lowest energy levels available in the allowed bands—up to two in each level. When all the electrons are placed in the lowest possible energy states, we have two possible situations. In the first, the highest level to be filled is some intermediate level within a band; in the second, the electrons fill one or more bands completely.

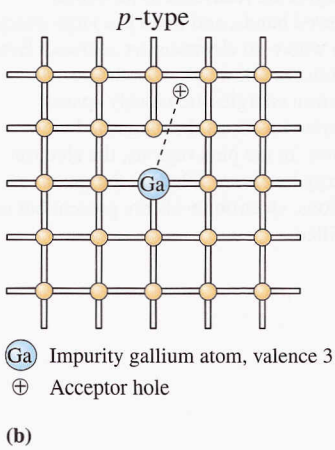
Suppose that we now add some energy to the free electrons—by imposing an electric field, for example. The electrons in the lower energy levels cannot accept that energy, because they cannot move into a higher energy level that already has its quota of two electrons. The only electrons that can accept energy are those that lie in the top levels, and then only if there are nearby unoccupied levels into which they can move. This will be quite easily done with a small input of energy if the topmost occupied levels are in a partially filled band, but difficult if the topmost occupied levels fill out a band. Materials with a partially filled band are *conductors*. When the electrons in the highest occupied energy levels move freely into the empty energy levels immediately above, a current is produced. The electrons that jump from a lower level to a higher level are said to be *excited*. The energy-band structure for conductors is shown in Fig. 26–18a. *Conductors are characterized by having a highest-energy band with levels only partly occupied.*



If the highest-energy electrons of a material fill a band completely, then a small electric field will not give these electrons enough energy to jump the large energy gap to the bottom of the next (empty) band. We then have an *insulator* (Fig. 26–18b). An example of a good insulator is diamond (a form of carbon), whose energy gap is 6 eV.



◀ **FIGURE 26–18** (a) Conductors have electrons in partly filled bands, whereas (b) insulators have an energy gap between a completely filled band and the next completely empty band. The pink and blue regions indicate where the allowed energy levels are filled and unfilled, respectively. Within each of the allowed bands, the possible energy levels form a set of closely spaced discrete levels.



▲ **FIGURE 26–17** Energy diagram that shows the possible energy levels of an electron within a material made of a regular lattice of atoms. In contrast to the possibilities of Fig. 26–16, the electron energies are restricted to lie within allowed bands, and there is a large energy gap where no electrons are allowed. Even within the allowed bands, the possible electron energies are closely spaced discrete levels, as the magnified view shows. In the pink regions, the electron energy levels are filled; in the green regions, electron levels are present but are unfilled.

▶ **FIGURE 26–19** (a) For zero temperature and no external electric field, semiconductors have only a small energy gap between a completely filled band (the valence band) and the next highest, completely empty band (the conduction band). The dots indicate electrons, here all in the valence band. (b) A modest electric field $\vec{E}_{ext}$ or finite temperatures are enough to give some of the electrons sufficient energy to jump the energy gap, leaving holes (open circles) in the valence band and conduction electrons in the previously empty conduction band.

▲ **FIGURE 26–20** An (a) *n*-type and a (b) *p*-type semiconductor are created by doping the original lattice with atoms that have, respectively, more and less valence electrons than the atoms of the original lattice have.

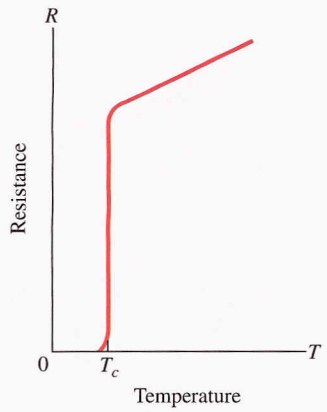
In semiconductors, the highest-energy electrons fill a band (the *valence band*) at $T = 0$, as in insulators. However, semiconductors have only a small energy gap between that band and the next, the *conduction band* (Fig. 26–19a). Silicon and germanium have energy gaps of 1.1 eV and 0.7 eV, respectively, and are semiconductors. Because the energy gap is so small, increasing the temperature or applying a modest electric field will allow some electrons to jump the gap, and electric current will flow (Fig. 26–19b). A semiconductor with an electric field too small to boost conducting electrons to the next energy band will act as an insulator; once the field increases above the strength necessary to allow electrons to "jump the gap," the material acts as a conductor. In other words, there is a minimum electric field under the influence of which a material changes from an insulator to a conductor. In addition, an increase in temperature will give a fraction of the electrons enough thermal energy to jump the gap in semiconductors and thus *lowers* the resistivity. For a conductor, a rise in temperature *increases* the resistivity because the atoms, which are obstacles to electron flow, vibrate more vigorously.

When an electron in the valence band of a semiconductor crosses the energy gap and conducts electricity, it leaves behind what is known as a **hole**. Other electrons in the valence band near the top of the stack of energy levels can move into this hole, leaving behind their own holes, into which still other electrons can move, and so forth. The hole behaves as a positive charge and, since it can move, forms a contribution to the current on its own as a positive charge carrier. An electron excited from the valence band to the conduction band is thus doubly effective at conducting electricity in semiconductors.

One of the major advances in materials technology has been our ability to produce new semiconductors, those with tailored properties. Semiconductor materials that are compounds, such as gallium arsenide, are called *hybrid* semiconductors, as opposed to *intrinsic* elemental semiconductors, such as silicon and germanium. Other special semiconductors are made by introducing impurities, small amounts of different elements, into the lattice. These impurities have the effect of changing the numbers of electrons or holes available to conduct. For example, an atom in the chemical group of phosphorus, arsenic, and antimony can replace one of the silicon atoms in a lattice without affecting the lattice itself too much. However, each of these impurity atoms has one more electron in its valence level than does a silicon atom; this extra electron, for which there is no room in the valence band, takes a place in the conduction band and therefore is available to carry current (Fig. 26–20a). A semiconductor with impurities of this sort is called an *n*-type semiconductor, and the extra electrons are called *donor* electrons. The semiconducting material, silicon in this case, is said to be *doped* by the impurity atoms.

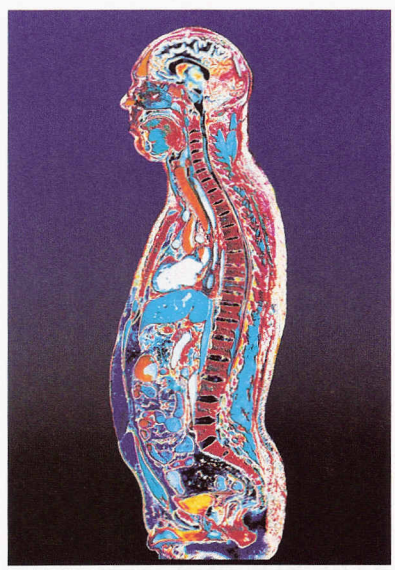
We can alternatively add atoms of an element that has one less valence electron than silicon, such as boron, aluminum, or gallium. Figure 26–20b shows that in this

case we are one electron short of what is needed to form the atomic-level bond that holds the lattice together. This electron must be provided by the electrons of the valence band of the lattice material, and so holes are created in this band. These holes act as positive charge carriers. The impurity atoms are called *acceptors*, and a semiconductor with impurities of this sort is called a *p*-type semiconductor.



Many electronic devices, such as the diode mentioned in Section 26–3, depend heavily on the properties of semiconductors. Probably the best known and most widely used of these devices are transistors, which can amplify electronic signals, and form the basic building blocks of logic devices.

Superconductors



In 1911, H. Kammerlingh Onnes found that mercury abruptly loses *all* of its resistance—at least as far as he could tell—at a *critical temperature* T_c of 4.1K (Fig. 26–21a). This state of zero resistance persists at temperatures below T_c. A material that exhibits zero resistance at some critical temperature is called a *superconductor*. An experiment on a superconducting ring in which a current had been induced showed that there was no observable decrease in the current after a full year. From the measurements in this experiment, it was possible to deduce that if there were any resistive decrease of the current, it had to occur over a period of at least 10^9 years!

The prospect of having an *electric current that lasts forever* is an enticing one. It implies, among other things, the cheap transmission of electricity. The phenomenon of superconductivity cannot be understood as an extension of ordinary conductivity. The abruptness with which resistance disappears completely suggests that an ordinary conductor makes a transition to a totally different state of matter at T_c, much as liquid water turns into a crystal (ice) at 273K. In 1957, John Bardeen, Leon Cooper, and Robert Schrieffer satisfactorily explained the *superconducting phase* with quantum physics in what is now known as the BCS theory.

Until 1986, the materials with the highest-known values of T_c became superconducting at 23K. Helium is liquid at such temperatures and is thus used for cooling superconductors. However, liquid helium is a relatively expensive medium, as is the equipment that keeps it cold. That limited the uses of superconductors to scientific applications, such as magnets for particle accelerators (see Chapter 28) or to important situations such as nuclear magnetic resonance imaging machines in hospitals (Fig. 26–21b). In 1986, however, K. Alex Muller and J. George Bednorz discovered a new class of materials for which T_c is much higher; superconductors are now known that have a T_c above 120K ($-153°C$). This discovery has great technological implications because such materials can be cooled relatively cheaply with nitrogen (which is liquid at 77K). Research in both the basic physics behind these materials and their technological applications is of active interest.

(b)

▲ **FIGURE 26–21** (a) For superconductors the resistance drops to zero at the critical temperature T_c. (b) An MRI image of a human made using a superconducting magnet.

26–7 Electric Power

Electric energy is sent to our homes and workplaces and composes much of the energy used in our society. Efficient delivery of this energy is of paramount importance, and in this section, we shall look at the ways in which resistance affects the delivery of electric energy.

We have compared electrical resistance to mechanical drag. When there is drag in mechanical motion, mechanical energy is converted to thermal energy. The second law of thermodynamics (Chapter 20) shows that some of this thermal energy is irretrievably lost in the sense that it cannot all be converted to mechanical work. Similarly, just as mechanical friction generates heat, the passage of a current through a resistor generates heat, and in this way some electric energy is lost due to resistance. While sometimes we want to use the thermal energy, as in the heating element of an electric stove, it cannot all be converted to useful mechanical work, and in the transmission of electricity the thermal energy created is lost energy.

To calculate the energy lost per unit time (the power lost) when a charge moves in a material, consider a small charge dq that moves through a potential difference V. The change in the potential energy of the charge (dU) is equal to the work done (dW)

by the electric force due to the potential difference, and is given by $dU = V\,dq$. It follows that the power, the rate at which energy is expended by the force that pushes the charge, is

$$P = \frac{dW}{dt} = V\frac{dq}{dt}. \tag{26–26}$$

Because the current $I = dq/dt$, the electric power lost, which is the power that must be delivered to move I through the potential V, is

$$P = VI. \tag{26–27}$$

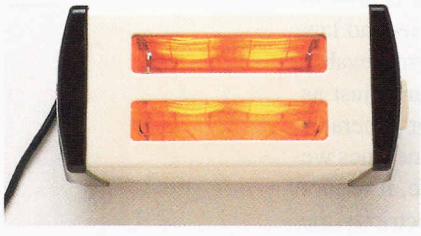
POWER LOST IN RESISTANCE

This result is a general one, independent of the type of material—in particular, whether the material is ohmic or nonohmic—and of the nature of the charge movement. Power has SI units of watts (W), with 1 W = 1 J/s. By using Eq. (26–27), we have another unit for power:

$$1\ \text{W} = 1\ \text{V}\cdot\text{A}. \tag{26–28}$$

For ohmic materials, $V = IR$, where R is a constant. Thus the power expenditure for ohmic materials is

$$P = VI = V\left(\frac{V}{R}\right) = \frac{V^2}{R}. \tag{26–29}$$



Equivalently, we can use $V = IR$ in Eq. (26–29) to find that

$$P = I^2R. \tag{26–30}$$

Whether we use Eq. (26–29) or Eq. (26–30) depends on what is known in a particular application. The power lost (rate of energy loss) in a resistor appears in the form of thermal energy and is variously called *ohmic heating, Joule heating*, and I^2R loss.

EXAMPLE 26–9 Nichrome is an alloy of nickel, chromium, and iron often used as a heating element in electrical devices. A nichrome wire (1.0 m in length) is crisscrossed along the interior of a toaster (Fig. 26–22) that can carry a maximum current of 8 A when there is a 120-V potential difference from one end of this wire to the other[†]. If the resistivity of nichrome is $1.0 \times 10^{-6}\ \Omega\cdot\text{m}$, what is the radius of the wire? What power does the toaster use?

Setting It Up We call the given current I, the given voltage V, the given wire length L, and the given resistivity $\rho = 1.0 \times 10^{-6}\ \Omega\cdot\text{m}$. The desired wire radius will be labeled r. The current and resistance are known, so the power can be calculated.

▲ **FIGURE 26–22** The glowing nichrome wires of a toaster.

Strategy With the help of Eq. (26–14) we can calculate the cross-sectional area A once the resistance is determined: $A = \rho L/R$, and given A the wire radius follows from $A = \pi r^2$. Thus the first step is to calculate the resistance using $R = V/I$. The power can be calculated using $P = V^2/R$.

Working It Out We have

$$R = \frac{V}{I} = \frac{120\ \text{V}}{8\ \text{A}} = 15\ \Omega.$$

It follows from $A = \rho L/R$ that

$$r = \sqrt{\frac{A}{\pi}} = \sqrt{\frac{\rho L}{\pi R}} = \sqrt{\frac{(1.0 \times 10^{-6}\ \Omega\cdot\text{m})(1.0\ \text{m})}{\pi(15\ \Omega)}}$$
$$= 0.15 \times 10^{-3}\ \text{m}.$$

Finally, the power is

$$P = \frac{V^2}{R} = \frac{(120\ \text{V})^2}{15\ \Omega} = 960\ \text{W}.$$

What Do You Think? Suppose the toaster is accidentally connected into a 240-V outlet. With the voltage doubled, by how much will the power consumed change? (Assume that the toaster doesn't burn out, and don't try this!)

[†]Real household electricity involves an oscillating voltage difference and an oscillating (or alternating) current. Ignore these effects here and in Example 26–10.

We described the commercial units of electric energy in Section 6–5: The energy unit in the electric power industry is the kilowatt-hour (kWh), 3.6×10^6 J. When electric energy is delivered to a home, the energy delivered per unit time is also called the electric power.

EXAMPLE 26–10 A 100-W bulb is left on in an outdoor storage room to keep paint from freezing. The 100-W rating refers to the power dissipated in the bulb's filament, which is a resistor. If electricity costs 8 cents/kWh, about how much does it cost to burn the lightbulb for three months during winter?

Setting It Up The given power of 100 W expresses an energy consumed per second. We know the total time that the bulb burns, as well as the cost per kWh of energy.

Strategy The number of joules of energy used over three months is found by converting three months to seconds, then multiplying the power, 100 W, by the number of seconds the bulb is on. Since the cost rate is given in dollars per kWh, we'll want to convert the energy units to kWh.

Working It Out The number of seconds the bulb is lit is

$$(3 \text{ months})(30 \text{ days/month})(24 \text{ h/day})(3600 \text{ s/h}) = 7.8 \times 10^6 \text{ s}.$$

The energy used is

$$(100 \text{ W})(7.8 \times 10^6 \text{ s}) = 7.8 \times 10^8 \text{ J}$$
$$= (7.8 \times 10^8 \text{ J}) \times [1 \text{ kWh}/(3.6 \times 10^6 \text{ J})] = 220 \text{ kWh}.$$

From this we find the cost, $(8 \times 10^{-2}\ \$/\text{kWh}) \times (220 \text{ kWh}) = \$17.60$.

Although the primary purpose of a lightbulb is to produce light, most of the electric energy it dissipates is converted into heat, not light.

What Do You Think? Assuming the voltage is fixed, will it be more or less expensive to have *two* of these bulbs in (a) series, (b) parallel?

EXAMPLE 26–11 As we described in Eq. (17–17), a piece of metal such as a wire heated to a temperature T (in units of degrees kelvin) radiates energy in the form of electromagnetic waves, with the power emitted per unit surface area given by Stefan's formula, $P_{\text{Stefan}} = \sigma T^4$, where the constant σ is roughly 5.7×10^{-8} W/(K$^4 \cdot$ m^2). A bus-stop shelter is heated by a 1-m-long metallic coil that is 1 mm in diameter. The temperature of the coil is 2000K. If the resistivity of the coil material at that temperature is given by $5 \times 10^{-7}\ \Omega \cdot \text{m}$, estimate the current that must flow through the wire to maintain its temperature. (We are assuming that at this temperature the fraction of the power dissipated due to convection of the air around the coils is small.)

Setting It Up In addition to knowing the temperature T, we are given the diameter d of the wire and its length L. These will suffice to find the power emitted in radiation, and since we are given the resistivity ρ, we can match this power emission to a resistive power loss in terms of the unknown current.

Strategy The first step is to use Stefan's formula to calculate the power P radiated by the wire, given that the temperature is $T = 2000$K. This will give for the total radiated power $P = P_{\text{Stefan}} \times A$, where A is the surface area of the wire. This power must come from resistive loss in the wire, because that is what heats the wire to high temperatures. Therefore we calculate the resistance R of the wire in terms of the resistivity of the material, using Eq. (26–14) and the wire dimensions, and match P to the resistive loss RI^2, a relation that allows us to solve for the desired current I.

Working It Out With the wire's surface area $A = \pi d \times L$, the emitted power is

$$P = \sigma T^4 \times (\pi d \times L) = [5.7 \times 10^{-8} \text{ W}/(\text{K}^4 \cdot \text{m}^2)] \times$$
$$(2 \times 10^3 \text{ K})^4 \times \pi \times (10^{-3} \text{ m}) \times (1.0 \text{ m}) = 3 \times 10^3 \text{ W}.$$

The resistance of the wire is

$$R = \rho \frac{L}{A_{\text{cross section}}} = \rho \frac{L}{\pi (d/2)^2}$$
$$= (5 \times 10^{-7}\ \Omega \cdot \text{m}) \frac{1.0 \text{ m}}{\pi (0.5 \times 10^{-3} \text{ m})^2} = 0.6\ \Omega.$$

Finally we use $P = RI^2$, with P the radiated power, so that

$$I = \sqrt{\frac{P}{R}} = \sqrt{\frac{3 \times 10^3 \text{ W}}{0.6\ \Omega}} = 70 \text{ A}.$$

What Do You Think? Suppose you would like to keep the material and the temperature of the radiating coil the same but at the same time reduce the current. Could this be done by changing the diameter d of the wire, and if so, how?

Resistors used in circuits are characterized not only by their resistance, but also by a power rating. This power rating states the maximum power that the resistor can dissipate without being damaged due to overheating. The power rating is measured in watts. According to Eq. (26–30), which states that the power dissipated in a resistor is $P = I^2R$, we can deduce the maximum allowed current from the power rating. One class of relatively inexpensive resistors, so-called carbon film resistors, is limited to about 2 W; a second more expensive type known as wire-wound resistors have a power rating up to 50 W.

Summary

Electric current is the rate at which charge passes. The instantaneous current is given by

$$I \equiv \frac{dQ}{dt}. \tag{26–2}$$

The unit of current is the ampere (A), 1 C/s. Currents in wires are depicted as though the positive charges are moving, but it is actually electrons (negative charge) that are mobile.

The current density $\vec{J}$ is a vector quantity representing the current that passes through an area per unit time. The current is related to the current density by

$$I = \int_{\text{surface } A} \vec{J} \cdot d\vec{A}. \tag{26–4}$$

The free-electron model of conduction is useful as a qualitative description of current in a solid. The average, or drift, speed of the electrons that pass through the material is

$$v_d = \frac{I}{n_e q A}, \tag{26–9}$$

where n_e is the density of free electrons and q is the charge of an electron.

Electrical resistance R is the ratio of voltage to current

$$R \equiv \frac{V}{I}. \tag{26–11}$$

Many conducting metals show a linear relationship between voltage and current. The resistance is then constant over a wide range of voltages. This relation is called Ohm's law, $V = IR$.

Resistivity ρ is the quantity that distinguishes the part of the resistance that is intrinsic to each particular type of material. For wires of length L and cross-sectional area A, we have

$$R = \rho \frac{L}{A}. \tag{26–14}$$

The inverse of the resistivity is the conductivity σ which expresses how well a type of material conducts current:

$$\sigma \equiv \frac{1}{\rho}. \tag{26–15}$$

Both ρ and σ depend on temperature.

The electric field and current density are related by

$$\vec{E} = \rho \vec{J} \tag{26–16}$$

and by

$$\vec{J} = \sigma \vec{E}. \tag{26–17}$$

When a number of resistors of resistance $R_1, R_2, \ldots R_n$ are placed in series, then they act together as a single resistor of equivalent resistance

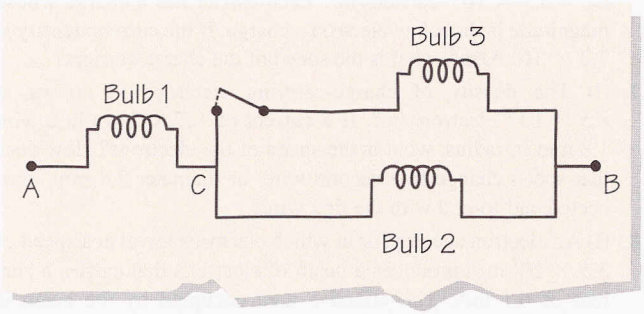
$$R_{\text{eq}} = R_1 + R_2 + R_3 + \cdots + R_n. \tag{26–21}$$

When a number of resistors of resistance $R_1, R_2, \ldots R_n$ are placed in parallel, then they act together as a single resistor of equivalent resistance given by

$$\frac{1}{R_{\text{eq}}} = \frac{1}{R_1} + \frac{1}{R_2} + \cdots + \frac{1}{R_n}. \tag{26–22}$$

The free-electron model, which provides a classical model for Ohm's law and the mechanism of electrical conduction, cannot fully account for the observed behavior of conductors, and the correct explanation of electrical conduction in metals is dependent on how electrons fill allowed energy bands and on the energy gap between these bands. Materials that conduct current easily have electrons in partially filled bands. Semiconducting materials, such as silicon and germanium, can be doped by impurity atoms to increase the density of charge carriers. The explanation of superconductivity requires both quantum mechanics and the presence of a new phase of matter in which electrons collectively transport electric current.

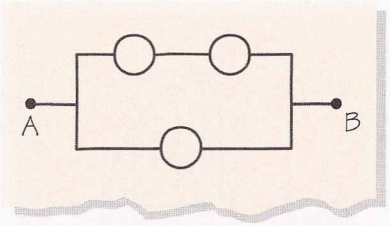
When a current moves through a potential difference, electric power P is dissipated (or produced), given by



$$P = VI. \tag{26–27}$$

For resistive materials, the power is also given by

$$P = \frac{V^2}{R} = I^2R. \qquad (26\text{–}29, 26\text{–}30)$$

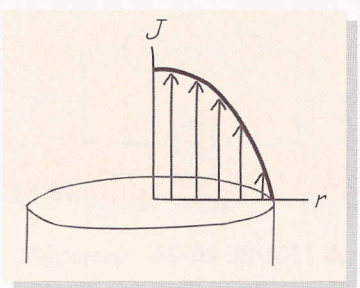


Understanding the Concepts

1. Consider the electron beam in a cathode-ray tube. The velocity of the electrons in the beam changes as the electrons are accelerated. Is the current the same everywhere in the beam?
2. How does the free-electron model for electrical resistance account for power dissipation? Does our microscopic picture agree with the voltage/current result?
3. The same current passes through two similar wires of unequal areas. Which wire will get hotter, and why?
4. The same current passes through two wires of the same area. One of the wires is made of aluminum, whereas the other is made of brass. Which wire will get hotter, and why?
5. What factors determine the differences in drift velocity of electrons in wires if the dimensions and current are the same?
6. Knowing what you now know about parallel and series resistance, why does the potential drop linearly along the length of a resistor that is a uniform cylinder?
7. If the movement of charges in a wire is similar to the flow of water in a hose, why, when a new hose is hooked up to a faucet, do we have to wait for a while until the water comes out, but when we hook a new wire up to a circuit, we do not have to wait for charge to come out the other end when the switch is turned on?
8. According to the discussion of Section 26–5, the resistivity in the free-electron model should vary with the square root of the temperature and thus should be zero at $T = 0$. Is this reasonable? How would you interpret this result?
9. We know that the resistivity of a metal is temperature dependent, and so therefore is the resistance of a wire. In Chapter 17, we saw that the dimensions of a piece of metal—such as a wire—change when the wire is heated. Does this provide an additional reason to change the resistance of a wire as it undergoes Joule heating? Would you expect the effect to be large?
10. When you throw a switch and charge flows in a household wire, does the wire become charged?
11. Suppose that we orient a wire between the plates of a charged capacitor so that there is an electric field along the cross section of the wire. Will the resistance of the wire change because all the charge-carrying electrons crowd to one side of the wire, thus effectively reducing the wire's cross section?
12. Gauss' law states that free charge in a conductor moves to the surface of the conductor. Does this mean that the current flowing through a wire is actually on the wire's surface?
13. The resistivity of most metals is on the order of $10^{-8}\ \Omega \cdot \text{m}$. Discuss why this might be so in terms of the result given by Eq. (26–25).
14. Is it possible to break up any combination of resistors into a sequence of parallel and series resistances? If not, give an example of a combination that cannot be so decomposed.
15. What is likely to happen when a current is so large that the power dissipation in a resistor through which the charge flows exceeds the resistor's power rating? What mechanism is responsible for such a disaster scenario?
16. What considerations would you have to take into account in designing a lightbulb filament with trade-off between the length of filament and the diameter of the filament?
17. The resistance of a wire is proportional to the length of the wire. Think of a wire as consisting of a series of shorter wires placed together in series. Can you use this information to predict the effective resistance of two different resistors of resistance R_1 and R_2 when they are placed in series in a circuit?
18. In Fig. 26–7a the drift velocity is smaller in area A_2 than in A_1, yet the current is the same. How is that possible?
19. Consider three identical bulbs between points A and B as shown in Fig. 26–23. The potential difference between A and B is fixed. The switch between C and bulb 3 may be open or closed. Will bulb 2 be brighter when the switch is open, or if it is closed? Will bulb 1 be brighter when the switch is open or if it is closed?

▲ **FIGURE 26–23** Question 19.

20. A copper rod of a given length and diameter has resistance R. Suppose the same rod is drawn into a wire with diameter 1/10 of what it was before. By what factor will the resistance change? Will it be larger or smaller?
21. Suppose all the resistors in Fig. 26–14 have the same resistance and the potential difference V_{AB} is held fixed. If the number of resistors is changed from n to $n + 1$, will the total current flowing between A and B increase or decrease?
22. Three resistors of resistance 1 Ω, 2 Ω and 4 Ω are placed in a network shown in Fig. 26–24. Can you decide in which places the resistors are to be put so as to minimize the overall resistance between A and B? What arrangement would maximize the overall resistance?



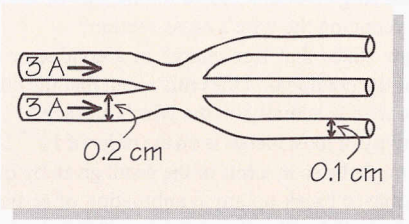
▲ **FIGURE 26–24** Question 22.

23. In high wattage lightbulbs, the filament is typically coiled. Why?

Problems

26–1 Electric Current

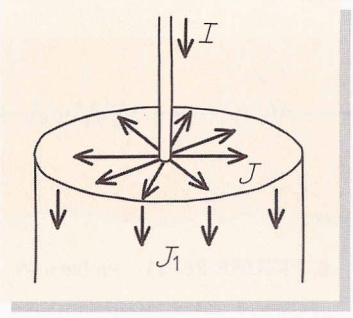
1. (I) A wire of diameter 2.2 mm carries a current of 0.46 A. What is the average current density? How much charge crosses a fixed point in the wire per second?
2. (I) There is a 1.2-A current in a wire of cross-sectional area $4.2 \times 10^{-5}\ \text{m}^2$. The drift speed of the electrons that carry the current is 0.32×10^{-5} m/s. Find the density of current-carrying electrons.
3. (I) A jumper cable used to start a car carries a current of 100 A and has a cross-sectional area of 36 mm^2 and a length of 2 m. The free-electron density in the cable is 8.5×10^{28} electrons/m^3. How long does it take a free electron to pass from one end of the cable to the other?
4. (I) Three straight wires of area 0.02 mm^2, 0.2 mm^2, and 2 mm^2, respectively, are aligned along the x-axis. They carry current densities along the x-axis of magnitude $3 \times 10^5\ \text{A/m}^2$, $13 \times 10^4\ \text{A/m}^2$, and $15 \times 10^4\ \text{A/m}^2$, respectively. Find the current in each wire.
5. (I) A wire of radius 1.6 mm carries a current of 0.092 A. How many electrons cross a fixed point in the wire in 1 s?
6. (I) Charge carriers in a semiconductor have a number density $n_q = 3.5 \times 10^{24}$ carriers/m^3. Each carrier has a charge whose magnitude is that of an electron's charge. If the current density is $7.2 \times 10^2\ \text{A/m}^2$, what is the speed of the charge carriers?
7. (I) The density of charge-carrying electrons in copper is 8.5×10^{28} electrons/m^3. If a current of 1.2 A flows in a wire 1.8 mm in radius, what is the speed of the electrons? How does that speed change in a second wire, of diameter 2.4 mm, connected end-to-end with the first wire?
8. (I) An electron accelerator in which electrons travel at a speed of 3.5×10^7 m/s produces a beam of electrons that carries a current of 6.1 mA. The effective area occupied by the beam is 0.50 cm^2. What is the density of electrons in the beam? Ignore all relativistic effects.
9. (II) In the National Synchrotron Light Source x-ray device at Brookhaven National Laboratory, there is an electron beam with an average current of 200 mA. The electrons have a kinetic energy of 2.5 GeV and a speed extremely close to the speed of light. How many electrons pass a given point in the accelerator per hour? How many electrons are contained in a 1-m length of the beam? Ignore all relativistic effects (a poor approximation, in this case).
10. (II) A cube of material is placed with one corner at the origin of a coordinate system; its sides, 1 cm long, are parallel to the three axes. The current density is $A\hat{i} + B\hat{j} + C\hat{k}$ throughout the cube. The units of A, B, and C are mA/cm^2. What are the currents along the x-axis, y-axis, and z-axis?
11. (II) The current density in a cylindrical wire of radius R is $J = J_0(1 - r^2/R^2)$, parallel to the axis of the wire (Fig. 26–25). Calculate the total current across a section perpendicular to the axis.



▲ FIGURE 26–25 Problem 11.

12. (II) In a plasma containing equal densities n of electrons and (positive) ions, the ions move to the right. Their speed is a factor of 1.5×10^{-3} smaller than the speed with which the electrons move to the left. What is the (net) current density? Give its direction and magnitude.
13. (II) An aqueous solution contains 0.1 mol/L of NaCl. The NaCl is dissolved in the form of Na^+ and Cl^- ions. Calculate the velocities of the Na^+ and Cl^- ions, respectively, if there is a measured total current density of 40 A/m^2. Assume that the velocity of the Cl^- ions is about 50 percent greater than that of the Na^+ ions.

26–2 Currents in Materials



14. (I) Calculate the drift speed of electrons in the conduction cables of an automobile starter cable, which is made of copper and has a diameter of 4 mm, if you suppose that the cable carries 100 A. How would this speed change if the diameter of the wire were doubled? [*Hint*: Useful data are contained in Example 26–2.]
15. (I) A single charged elementary particle ($q = 1.6 \times 10^{-19}$ C) travels with a speed very close to that of light in a circular accelerator of diameter 5 km. What is the current represented by the particle, taking into account multiple traversals of the charge past a given point?
16. (I) How many particles like that described in Problem 15 must be present at a given time to give rise to a current of 42 mA?
17. (II) An aluminum wire of area 50 mm^2 placed along the x-axis passes 10,000 C in 1 h. Assume that there is one free electron for each aluminum atom. Determine the current, current density, and drift speed. The mass density of aluminum is 2.7 g/cm^3.
18. (II) Gold has one electron per atom available to carry charge. Given that the mass density of gold is $19.3 \times 10^3\ \text{kg/m}^3$ and that its molecular weight is 197 g/mol, calculate the drift speed of the electrons in a gold wire that carries 0.3 A and has a circular cross section 0.5 mm in radius.
19. (II) Two parallel metal wires of diameter 0.2 cm and a charge-carrier density $n_e = 7 \times 10^{22}$ electrons/cm^3 carry a current of 3 A each. The wires join and then split into three identical but separate wires, each with a radius one-half that of the original wire (Fig. 26–26). All the wires are made of the same material. What are the drift speeds in both the larger and smaller wires? Can you explain the difference in speeds in terms of the speeds of water flow in pipes?

▲ FIGURE 26–26 Problem 19.

20. (II) The charge carriers in a certain wire of circular cross section and radius R have a drift speed down the wire that is not constant across the wire. Instead, the drift speed rises linearly from zero at the circumference ($r = R$) to v_0 at the center ($r = 0$). Compare the total current carried by this wire with the current carried by a wire of the same radius, same density of charge carriers, and a constant drift speed of $v_0/2$.

21. (II) A thin copper wire carrying a current I is welded to the center of a circular copper plate capping a copper tube (Fig. 26–27). The radius of the tube is R, the thickness of its wall and the top plate is d, and $d \ll R$. What is the current density in the tube and in the top plate?

▲ **FIGURE 26–27** Problem 21.

22. (III) Charges q move longitudinally down a rod of circular cross section and radius R. The density of the charge carriers n decreases as a function of the radial distance r from the center of the rod according to $n = n_0 - n'r$. The speed v of the charge carriers varies with r according to $v = v_0 - v'r^2$, where n_0, n', v_0, and v' are constants. Calculate the current that passes through the rod.

26–3 Resistance

23. (I) You have two solid cylinders of the same material. Piece 2 has half the length and half the diameter of piece 1. What is the ratio of the resistances of the two pieces?

24. (I) The conductivity of silver is 1.5 times that of gold. What is the ratio of the diameter of a silver wire to that of a gold wire of the same length if both wires are designed to have the same resistance?

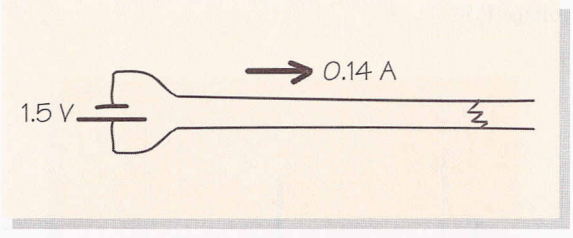
25. (I) An underground wire made of aluminum is 528 m long and has an area of 0.12 cm^2. (a) What is its resistance? (b) What is the radius of a copper wire of the same length and resistance?

26. (I) An old house is wired with AWG #18 copper wire, which has a diameter of 0.0403 in. (a) What is the wire's resistance per 100 ft? (b) One circuit consists of only one wire behind walls and has a resistance of 7.5 Ω. How long is this wire?

27. (I) The resistivity of copper is $1.72 \times 10^{-8}\ \Omega \cdot m$. What is the resistance of a section of gauge #10 wire (diameter 0.2588 cm) that is 10 m long?

28. (I) A carbon rod used in a welding machine is 5.0 mm in diameter and 20.0 cm in length. What is its resistance and how much current will pass through it if the welding machine puts a voltage of 380 V across it?

29. (I) Cables used to jump an automobile can get hot if used for more than a few seconds. Calculate the resistance at 20°C of a 2-m-long copper cable of cross-sectional area 36 mm^2. By how much does the resistance increase as the temperature rises from 20°C to 100°C?



30. (I) In the text, we refer to a power line with a total resistance of 10 Ω. Suppose that the power line is made of copper with a resistivity of $1.72 \times 10^{-8}\ \Omega \cdot m$, and is 175 km long. What is the radius of the wire?

31. (I) How long would a tungsten wire have to be if it is to be used in a toaster at 120 V and the current to be carried is 15 A? The cross-sectional area of the wire is $0.20 \times 10^{-6}\ m^2$.

32. (I) The electron current densities of copper and aluminum are $9 \times 10^{28}\ m^{-3}$ and $18 \times 10^{28}\ m^{-3}$, respectively. A wire of copper is joined to a wire of aluminum of the same diameter. If the same current is passing through the wires, compare the electron drift velocities and the resistances per unit length.

33. (II) A current passes through a tungsten wire in an appliance. If you assume that there is a fixed potential drop from one end of the wire to the other, what is the fractional change in the power consumed as the temperature of the tungsten wire changes from 800°C to 1200°C? Ignore any effects due to the change in the wire's length by thermal expansion.

34. (II) An electrician tests for a short circuit by putting a potential difference of 1.5 V across two neighboring parallel wires that would be independent of each other if there were no short. A current of 0.14 A then flows in the wires. The wires consist of material with a resistivity of $1.7 \times 10^{-8}\ \Omega \cdot m$ and have a diameter of 0.24 mm (Fig. 26–28). Given that the short effectively makes the wires act like a single wire, how far away is the short?

▲ **FIGURE 26–28** Problem 34.

35. (II) A nichrome wire of diameter 0.5 mm and length 50 cm is connected to a 50-V battery. What current passes through the wire at room temperature (25°C) and after the wire heats up to 400°C?

36. (II) The change in the resistance of a thin platinum wire can be used to measure temperature. Suppose that a constant 6.0 mA current passes through a platinum wire and that the potential drop measured at room temperature is 8.5 mV. What is the temperature of the wire when the potential drop is 8.7 mV?

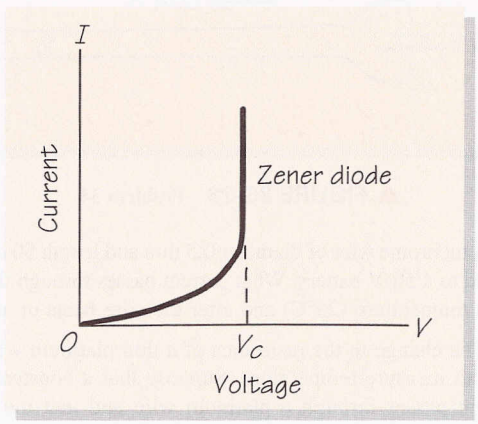
37. (II) An aluminum wire of length L and a copper wire of length $5L$ have precisely the same resistance. Given that the resistivity of aluminum and copper are $2.8 \times 10^{-8}\ \Omega \cdot m$ and $1.7 \times 10^{-8}\ \Omega \cdot m$, respectively, what is the ratio of the radii of the two wires?

38. (II) You have a 100-m-long wire of area 0.5 mm^2 with a thin coating of insulation, but you cannot identify the type of material that makes up the wire. You have a 12.0-V battery and a device to measure current. When the battery is placed across the two ends of the wire, you measure a current of 1.07 A. What is the wire material? (Use Table 26–2.)

39. (II) A coil used to produce a magnetic field is made of copper wire of area 1.5 mm^2 wound many times around a spool of diameter 20 cm. The resistance of the wire is 1.35 Ω. We must know the number of turns of wire to know the magnetic field. How many turns of wire are there on the spool?

40. (II) You wish to double a current that flows through a wire of fixed length, but you can increase the voltage that drives the current by only a factor of 1.8. You have other wires made of the same material but of different radii. What is the smallest factor by which the radius of a replacement wire should differ from the radius of the original wire?

41. (II) Aluminum has a density of $2.7 \times 10^3\ kg/m^3$. What is the resistance of an aluminum wire 0.12 cm in diameter and 80 m long? What is the mass of the wire? What is the mass of a copper wire, of density $8.9 \times 10^3\ kg/m^3$, with the same length and same total resistance?



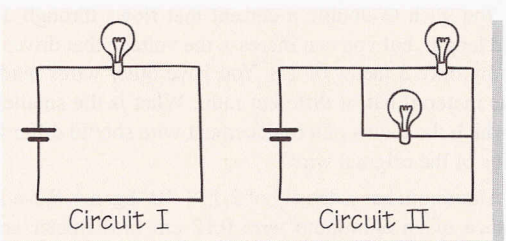
42. (II) What are the length and the radius of a copper wire (of circular cross section) whose resistance is 2 Ω and whose mass is 1.5 kg?

43. (II) How much silver (of density 10.5×10^3 kg/m^3) would be needed to make a wire 1 km long, with a resistance of 5 Ω?

44. (II) A copper pipe has an inside diameter of 2.75 cm and an outside diameter of 2.45 cm. What length of copper pipe will have a resistance of 3.5 Ω?

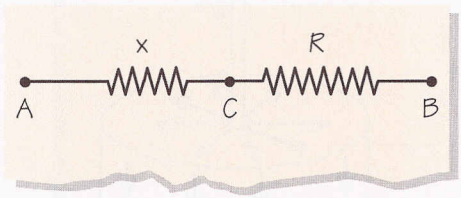
45. (II) A copper resistor has the shape of a cylindrical shell. What is the resistance of this resistor if its length is 1 m, its inner radius is 0.1 cm, and its outer radius is 0.2 cm? What is the radius of a solid wire of circular cross section with the same length and the same resistance? Compare the masses of the two resistors.

46. (II) A *zener diode*, named for Clarence Zener, has the *I–V* curve shown in Fig. 26–29. Sketch the resistance of the diode versus both current and voltage. What is special about the critical voltage V_c?



▲ FIGURE 26–29 Problem 46.

26–4 Resistances in Series and in Parallel



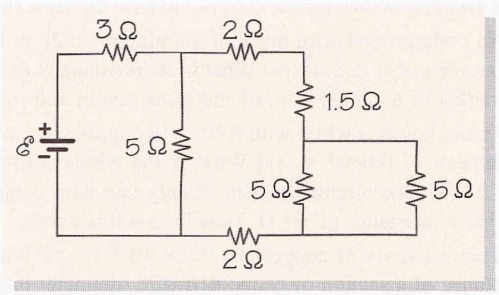
47. (I) We have three identical lightbulbs available to us. Two of them are connected in series to a battery. What is the relative brightness of the two bulbs? If the third bulb is connected in parallel with the second of the above bulbs, what are the relative brightnesses of the three bulbs?

48. (I) Consider the circuits shown in Fig. 26–30. The lightbulbs in all circuits are identical and the batteries are the same in the two circuits. Before working with these circuits, you are asked to make some predictions: (a) What is the brightness of the bulbs in circuit II relative to each other and to the bulb in circuit I? (b) If one of the bulbs is removed in circuit II, how will the brightness of the other bulb be affected? Does it matter which bulb is removed?

▲ FIGURE 26–30 Problem 48.

49. (I) Consider the circuit in Fig. 26–31 in which there are two resistors in series. The resistance of one of them, x, is unknown. If the resistor R is 10 Ω, the voltage drop across x is 8 V. If R is 5 Ω, the voltage drop across x is 12 V. What is the resistance of x, and what is the total potential drop across the two resistors in the case that R is 10 Ω?

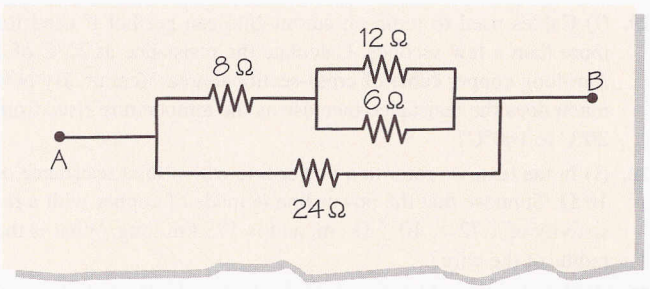
▲ FIGURE 26–31 Problem 49.



50. (I) Suppose we have two resistors in parallel. Their values are 20 Ω and 12 Ω respectively. What resistance placed in parallel with these will make the total effective resistance equal to 4 Ω?

51. (I) Five resistors of 18 Ω each are connected in series. If the potential difference between the ends of this set of resistors is 16 V, what current flows through the resistors? What is the power expended in the circuit?

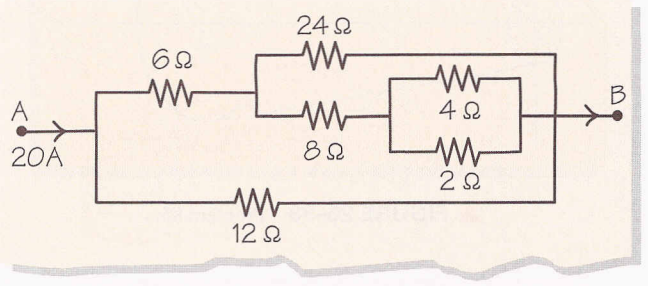
52. (I) Two 60-Ω resistors are placed in series across two terminals whose potential difference is 120 V. What is the total power dissipated?



53. (I) Two resistors are placed in parallel. One of the resistors has twice the resistance of the other; the lesser of the two resistances is 150 Ω. What is the resistance of the parallel combination?

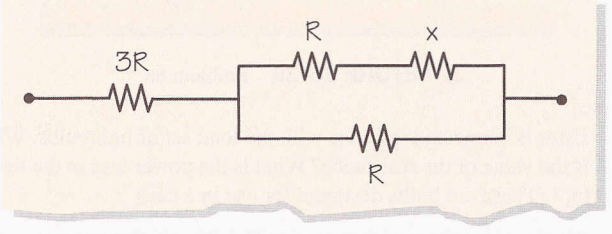
54. (I) Find the equivalent resistance of the circuit shown in Fig. 26–32.

▲ FIGURE 26–32 Problem 54.



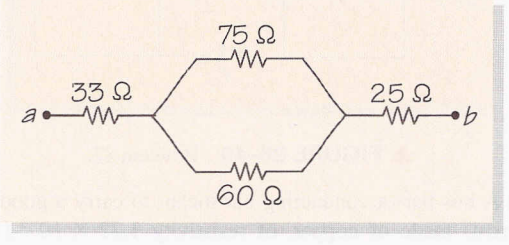
55. (II) Consider the combination of resistors shown in Fig. 26–33. Calculate the current in each resistor, given that $V_{AB} = 16$ V.

▲ FIGURE 26–33 Problem 55.



56. (II) Take the resistor combination in Fig. 26–33. What is the power dissipated in each of the resistors?

57. (II) Consider the network of resistors shown in Fig. 26–34. If a total current of 20 A flows through the network from A to B, what is the current in each of the resistors, and what is the voltage across each of the resistors?



▲ **FIGURE 26–34** Problem 57.

58. (II) Consider the circuit shown in Fig. 26–35. What must the value of the resistance x of the unknown resistor be so that the total equivalent resistance of the network is also x?

▲ **FIGURE 26–35** Problem 58.

59. (II) Points a and b are connected by the system of resistors shown in Fig. 26–36. A battery of 12 V and negligible internal resistance is connected across points a and b. (a) What is the equivalent resistance between points a and b? (b) The potential difference across the 75-Ω resistor? (c) The current flowing through the 33-Ω resistor?

▲ **FIGURE 26–36** Problem 59.

*26–5 Free-Electron Model of Resistivity

60. (I) Using the average time between collisions as calculated in Example 26–5, determine the drift speed of charge carriers for a material in which the electric field is 2.0×10^{-3} V/m.

61. (I) Assuming the collision time from Example 26–8 and an average speed of 2.7×10^6 m/s, estimate the mean free path for an electron in copper.

62. (I) Recall Eq. (19–46), which relates the collision cross section to the mean free path of a particle. Use that result together with the results of Problem 52 to estimate the collision cross section of an electron with an ion in a copper lattice.

63. (II) In Problem 20, we described a wire of radius R within which the drift speed of charge carriers varies with the distance from the center of the wire as $v_d = v_0[1 - (r/R)]$. Supposing that this wire is made of ohmic material, describe how the resistivity must vary with r to produce this drift-speed profile.

*26–6 Materials and Conductivity

64. (II) If you treat electrons as a gas of independent particles, at what temperatures would an average electron have sufficient energy to cross the energy gap for silicon (1.1 eV), germanium (0.7 ev), and carbon (6 eV)?

26–7 Electric Power†

65. (I) What is the resistance of a 65-W headlight used on a 12-V car battery?

66. (I) What is the maximum voltage that can be applied to a 1000-Ω resistor rated at 1.5 W?

67. (I) Your little sister leaves a 100-W lightbulb burning for an unnecessary hour. Assuming that electric power costs 10 cents per kilowatt-hour, what is the cost of her inaction?

68. (I) A graduate student in engineering has a collection of 100-Ω resistors with different power ratings of 1/8, 1/4, 1/2, 1, and 2 W. What is the maximum current that the student should use in each resistor?

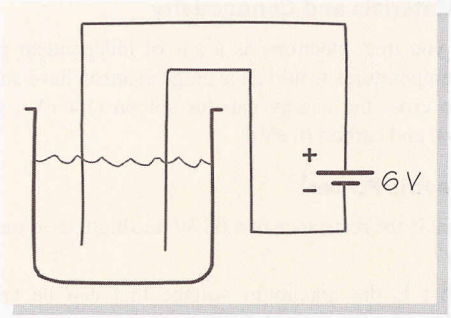
69. (I) What is the maximum allowable current for (a) a 160-Ω, 5-W resistor? (b) A 2.5-kΩ, 3-W resistor?

70. (I) An electrostatic accelerator has a maximum attainable voltage of 8×10^6 V. If a current of 100 μA is produced by accelerating charges in this potential difference, what is the nominal power required to operate the accelerator? Assume that this power can be converted to the accelerator voltage with 100 percent efficiency.

71. (I) Consider a resistor of resistance R. If the maximum allowed power dissipation is P, what is the maximum allowed operating voltage?

72. (I) An electric heater draws a current of 10 A from a 120-V circuit. What is the cost per hour of operating the heater if electrical energy costs 7 cents per kWh?

73. (I) A 2-m-long copper cable with cross-sectional area 36 mm^2 draws 100 A when it is used to jump start an automobile. It takes 20 s to start the engine. Given the resistance is 9×10^{-4} Ω, calculate how much energy is dissipated in the cable during this operation.



74. (II) A heater uses nichrome wiring ($\rho = 10^{-6}\ \Omega \cdot m$) and generates 1250 W when connected across a 110-V line. How long must the wire be if its cross-sectional area is 0.2×10^{-6} m^2?

75. (II) Consider the terminals of a 12-V battery connected by a copper wire. How long must the wire be if its cross-sectional area is 8×10^{-6} m^2 and if the power dissipated is 0.8 kW?

76. (II) Buildings have circuit breakers, devices that switch the current off when it exceeds a critical value, to protect the electrical system from damage. One circuit for a building's lights has a 15-A breaker. (a) What is the maximum power that can be delivered by a 110-V line to this circuit? (b) How many lightbulbs, each requiring 75 W, can this circuit handle?

†When we refer to household electricity applications, assume in each case that their currents and voltage differences are of the simple, constant type discussed in this chapter.

77. (II) A 6-V battery is connected to two metal wires dipped in a pot of water (Fig. 26–37). A current of 50 mA flows for 18 h. How much energy is taken out of the battery during that time?

▲ **FIGURE 26–37** Problem 77.

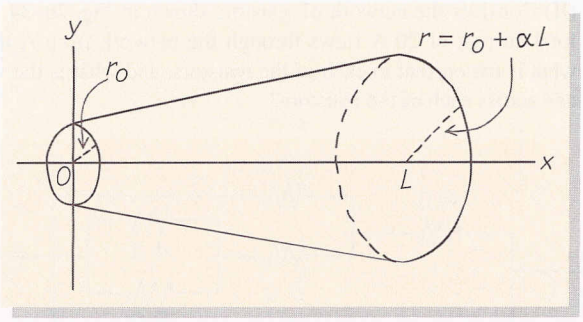
78. (II) A 500-W electric heater is designed to operate on a line of 115 V. As the result of a brownout (a partial interruption of electrical power) the line voltage drops to 105 V. Assuming that the heating unit has a fixed resistance, what is the power of the heater now?

79. (II) Consider the bus stop in Example 26–11. If it were necessary to reduce the current in the heater by a given factor, one could proceed by decreasing the temperature T of the wire or the wire's diameter (see "What do you think?" for that example). What changes would be preferable and why? Ignore the change of the resistivity with temperature—this is typically a smaller effect than the others that you will deal with here.

General Problems

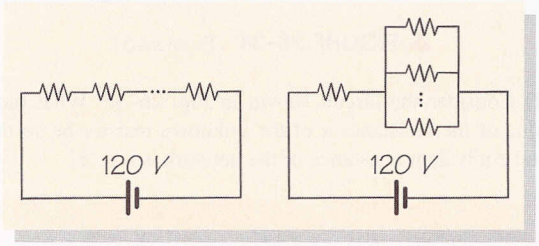
80. (I) The power dissipated in a resistor through which a current I passes is P_0. What is the power dissipated if the same current passes through three such resistors connected in series?

81. (II) An electric hot plate is used to boil water. The current drawn by the hot plate is 4 A. Calculate the voltage and resistance, based on a rough estimate of how long it takes to make a pot of tea.



82. (II) One month's electricity bill for an apartment is \$25.33, and the cost of electricity is 8 cents/kWh. All appliances used in this apartment work at 120 V. How many electrons passed through the apartment's electrical meter that month?

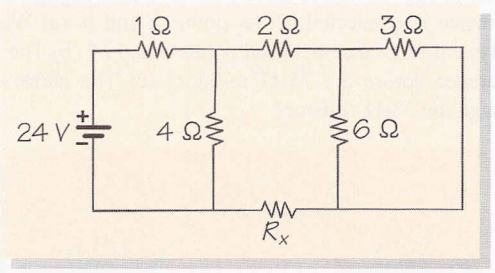
83. (II) A wire of resistance r is drawn—pulled like taffy—to double its length. Assuming a constant voltage and a fixed volume, by how much does the power dissipation change?



84. (II) A Van de Graaff accelerator delivers 4-MeV protons at a current of 5 μA through a target onto a piece of tungsten that serves to stop the proton beam. (a) How many protons stop in the tungsten in 1 h? (b) How much energy is delivered to the tungsten in 1 h? (c) What is the power of the proton beam?

85. (II) A piece of brass is machined into a long, tapering cylinder. Its radius is expressed by $r = r_0 + \alpha x$, where α is a constant and x is measured from the narrow end of the tapering cylinder and runs from 0 to L (Fig. 26–38). Find an expression for the resistance of this piece.

86. (II) The voltage at an electrical outlet is a constant 120 V. You have 10 identical lightbulbs whose maximum power consumption is 5 W (Fig. 26–39). (a) What is the resistance in each bulb if the power consumption is 50 W when the bulbs are connected in series? (b) If the 10 bulbs are connected in parallel, an additional resistor is needed so that the bulbs do not burn out. The resistor is connected in series with the total set of lightbulbs. What is the value of the resistance? What is the power loss in the resistor? (These are bulbs designed for use in a car.)



▲ **FIGURE 26–38** Problem 85.

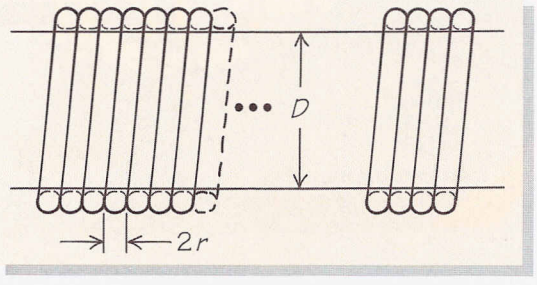
▲ **FIGURE 26–39** Problem 86.

87. (II) Consider the circuit shown in Fig. 26–40. Calculate the current and the power dissipated in the 4-Ω resistor as a function of the unknown resistance R_x.

▲ **FIGURE 26–40** Problem 87.

88. (II) A bus bar (a conducting bar meant to carry a good deal of current) made of copper, of resistivity $1.72 \times 10^{-8}\ \Omega \cdot \text{m}$, is meant to carry 100 A over a distance of 0.25 m at a temperature of 300°C. What is the minimum cross-section of the bus bar if no more than 0.2 W of power is to be dissipated?

89. (II) A generator delivers 75 A at a voltage of 12 V. What power does the generator deliver? How long would it take to raise the temperature of $10^{-3}\ \text{m}^3$ of water by 7.5°C? How long would it take to boil away 0.5 L of water, starting at 25°C?



90. (II) Figure 26–10 shows the I–V curve of a typical semiconductor diode. Use the data from the figure to sketch the power dissipated in the diode as a function of the current. What is the power dissipated in the ideal diode, as shown in the figure?

91. (II) A potential is set up from one end of a copper wire to the other; as a result, current flows. The copper is thermally isolated to some extent. As the charge flows, the wire heats up, causing the resistivity to increase. Suppose that, during a short time

period, the temperature of the wire as a function of time t is given by $T = T_0 + kt^2$. (a) Describe the current in the wire during this period. (b) What is the power dissipated by the wire as a function of time? (c) From the change with time of the dissipated power, will the wire continue to heat up and, perhaps, melt?

92. (II) The density of charge-carrying electrons in copper is 8.5×10^{28} electrons/m^3, its resistivity is $1.7 \times 10^{-8}\ \Omega \cdot$m, and the drift speed in a copper wire is 1.2×10^{-5} m/s. The wire has a diameter of 1 mm and a length of 3 m. At what rate must thermal energy be carried off by a cooling medium if the wire is to maintain its temperature?

93. (II) A single layer of 200 turns of closely spaced wire of radius $r_1 = 0.6$ mm is wound in a coil of diameter $D_1 = 5$ cm (Fig. 26–41). A second coil of the same length but of diameter $D_2 = 8$ cm is composed of a single layer of closely spaced wire of radius $r_2 = 0.4$ mm. The wires are made of the same material. Find the ratio of the resistances of the two coils.

▲ **FIGURE 26–41** Problem 93.

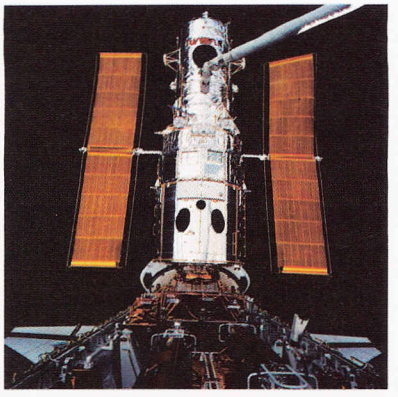
94. (III) A thin wire of length L and cross-sectional area A oriented in the x-direction is made of an ohmic material whose resistivity varies along the wire according to the empirical law $\rho = \rho_0 e^{-x/L}$. (a) Describe how the field within the wire varies with position if the end at $x = 0$ is at a potential V_0 greater than the end at $x = L$. (b) How does the potential vary as you move along the wire? (c) What is the total resistance of the wire?

95. (III) If all the energy lost from Joule heating stays in a wire, and the temperature increases as a result, the resistivity will increase according to Eq. (26–18). The current will therefore change as a function of time, the Joule heating will change, and so forth. If the wire material has a constant heat capacity, the rate of energy loss in the wire will be proportional to the rate of change of temperature. Assuming that the potential stays constant, set up a differential equation that describes the rate of temperature change. If this equation is solved, how can the current be found as a function of time?

Chapter 27

▶ This experimental aircraft runs on sunlight. The solar cells act as batteries, with energy from the Sun, and drive the electric circuits that make the propellors turn.

Direct-Current Circuits



We have seen how charges move through potential differences under the influence of electric fields, and how resistors control current and capacitors store charge. When resistors, capacitors, and batteries are connected together by conducting wires, they form electric circuits. We can understand the flow of currents in circuits by applying just two simple physical principles: the conservation of current and the conservation of energy. In this chapter, we learn to apply these principles systematically to the analysis of circuits. Our earlier work on capacitors or resistors connected in parallel and in series will be useful in this analysis. We also discuss some of the instruments available to measure and monitor the current and voltage of electric circuits. The flow of energy to and from circuit elements is an important theme that leads us to the concept of time-varying currents and voltages.

27–1 EMF

The sources of energy that cause charges to move in electric circuits have historically been called sources of **electromotive force**. They are actually sources of energy, not of force, and because the word force is misleading here, we use the abbreviation **emf** instead. Briefly, a source of emf is a device that *maintains* a potential difference across a conductor, thereby allowing a current to run continuously through the conductor. (Contrast this to the potential difference supplied by, say, a capacitor. The charged capacitor does indeed have a potential difference between its plates, but the current running under its influence is composed essentially of the charge on the plates running off, and as it runs off, the

potential difference quickly drops to zero.) When we think of sources of emf, we often think of batteries. A battery can be thought of as a device that expends chemical energy to pump charges, just as a water pump expends mechanical energy to pump water uphill to a tank with a higher gravitational potential energy. There is a wide variety of sources of electric energy beyond batteries. A battery converts chemical energy into an emf; a solar cell converts the energy of sunlight into an emf; a thermocouple produces an emf as a result of a difference in temperature; a large commercial electric power plant may burn coal, gas, or nuclear fuel, or use falling water, to drive a generator that produces an emf (Fig. 27–1).

In this chapter, we use the term "battery" to refer to any source of emf. We shall restrict ourselves to batteries for which the emf is *constant* with time. Up to Section 27–5, we focus on phenomena such as current flows or potential differences that are similarly constant in time. We refer to this as *equilibrium*, or *steady-state*, behavior, and use the terms **direct-current**, or **DC**, behavior as a label for it.

(a)

(b)

(c)

▲ **FIGURE 27–1** Various sources of emf that produce electrical energy include (a) solar panels (photovoltaic), (b) burning fuel, here nuclear, can heat water, produce steam, and turn turbines, (c) batteries, which produce their emf through chemical means.

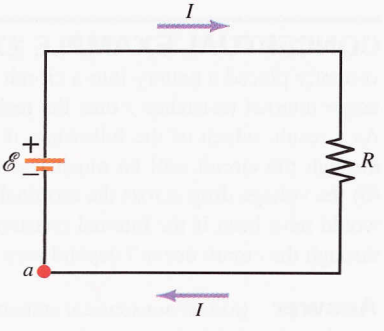
Circuits

Sources of emf supply energy to circuits. But just what is a circuit? When batteries, resistors, capacitors, or other circuit elements (some of which will be introduced later) are connected by wires (ideally of negligible resistance), they form a **circuit**. For example, when a switch is closed—meaning that a gap in a wire is closed—and a battery establishes current through the filament of the lightbulb of a flashlight, a circuit has been formed. Figure 27–2 illustrates this simple circuit with the conventional symbols for resistors, ideal wires (wires with no resistance), and batteries; the lightbulb is a simple resistor.

Circuit analysis typically requires us to relate the currents and potential differences within the circuit. For example, we may want to know the potential drop across a capacitor or the current that passes through a resistor when there is a particular emf in the circuit.

The Meaning of Emf

The fact that the force involved in moving charges under the influence of an emf is a conservative one provides us with a powerful method for the analysis of circuits. Consider the circuit of Fig. 27–2, consisting of a battery and a single resistor known as the **load** resistance. The battery has a potential difference across its terminals called the **terminal voltage**. Current flows away from the battery terminal at the higher potential—the one marked positive. How much current flows depends on the load resistance (or, in more complicated circuits, on the characteristics of the components of the rest of the circuit). Because current is defined as moving in a direction opposite to that of electrons, it is helpful to imagine positive charges flowing to the negative terminal (the terminal at the lower potential), equivalent to electrons flowing to the positive terminal, which is in fact what occurs.



Inside a chemical battery, a chemical process carries the positive charges back to the positive terminal. It is this process—the internal pumping action of the battery—that gives a precise definition of the emf. Suppose that it takes work dW to move a charge dq from the negative to the positive terminal. Then the emf of the battery is defined to be

$$\mathcal{E} \equiv \frac{dW}{dq}. \qquad (27\text{–}1)$$

EMF DEFINED

The SI unit of emf is the volt, one joule per coulomb. The word *voltage* is sometimes used loosely to describe the emf $\mathcal{E}$, but voltage more properly refers to the potential difference or terminal voltage across the emf terminals, which as we shall see below may be different from $\mathcal{E}$.

When a battery is connected to a circuit such as that in Fig. 27–2, it sets charges into motion, driving a current from the positive (higher-potential) terminal around the circuit to the negative (lower-potential) terminal, and we say that the battery *discharges*. In discharging, the battery is expending its chemical energy. If a current is driven from the negative to the positive terminal, a process that can be accomplished in conjunction with a battery of larger emf, the battery of smaller emf is said to be *charging*; this process replaces its spent chemical energy.

▲ **FIGURE 27–2** A simple circuit with a source of emf, $\mathcal{E}$, and a resistor, R.

Let us now turn to the analysis of our circuit. Start by assuming that the potential difference across the battery terminals in Fig. 27–2 is in fact the emf $\mathscr{E}$. (We'll refine this in the next subsection.) A current will flow around the circuit, and to find this current we can use the fact that the electric potential is associated with a conservative force. If the force is conservative, then the net work done by the force in sending a charge around a closed loop is zero. In turn, the total potential drop involved in any round trip that starts from any point on a closed loop must be zero. Make such a round trip that starts at point *a* of Fig. 27–2 and follow the current around the circuit. There is no change in potential as we pass through the ideal (resistanceless) wire. In crossing the battery from the negative to the positive terminal, the potential *increases* by $\mathscr{E}$. When we cross the ohmic resistance, the potential *decreases* by an amount IR [see Eq. (26–12)]. The potential drop implies a decrease in the potential energy of the charges. This potential energy is converted into thermal energy in the resistor. The net potential change as we travel once around the circuit is zero, so

$$\mathscr{E} - IR = 0. \tag{27–2}$$

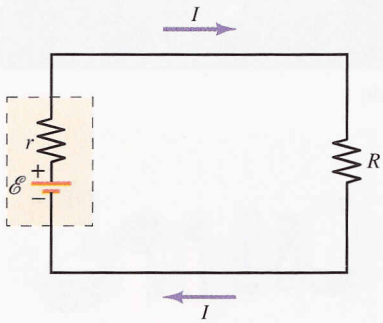
This equation determines the current, I:

$$I = \frac{\mathscr{E}}{R}. \tag{27–3}$$

Internal Resistance

Above we assumed that the voltage across a battery's lead is identical to the emf. We can imagine the existence of an ideal emf of, say, 9 V that will always have a potential difference of 9 V between its terminals. But any real source of emf will entail some energy loss as charge moves through it. You may know, for example, that a car battery heats up noticeably when it discharges, a result of resistive heating. This is true for all batteries. The reasons for this are in general rather complex, but at the very least the charge passing through a battery driving a circuit has to pass through the material of the battery itself, and this material will have some ordinary resistivity. Thus a real battery contains an *internal resistance* r in addition to maintaining an emf. This resistance is sometimes shown separately from the emf (Fig. 27–3). If we calculate the net potential change around the circuit as before, we find that Eq. (27–2) becomes

$$\mathscr{E} - Ir - IR = 0. \tag{27–4}$$



Because of internal resistance, the potential difference across the battery terminals is no longer just $\mathscr{E}$; it is given instead by

$$\text{with internal resistance: } V = \mathscr{E} - Ir. \tag{27–5}$$

This potential difference is a function of the current. Depending on the direction of current flow, the voltage across the terminals of a battery can be greater or less than the battery's emf. A second modification that results from internal resistance is that the current depends on it. From Eq. (27–4), the current in our circuit is

$$I = \frac{\mathscr{E}}{r + R}. \tag{27–6}$$

Compare this to Eq. (27–3).

▲ **FIGURE 27–3** A source of emf also contains an internal resistance r, depicted in circuit diagrams as the emf symbol with a resistor in series close by.

CONCEPTUAL EXAMPLE 27–1 An engineer has inadvertently placed a battery into a circuit (Fig. 27–3) that has a much larger internal resistance r than the resistance R outside the battery. As a result, which of the following, if any, is true: (a) The current through the circuit will be much less than the emf of the battery; (b) the voltage drop across the terminal will be much greater than it would have been if the internal resistance were less; (c) the current through the circuit doesn't depend very much on what R is.

Answer (a) is a nonsensical statement. The current and the emf may be related, but they are not comparable quantities. (b) is false—the voltage drop is in fact much less than it would have been if the internal resistance were small. In effect, the internal resistance "uses up" some of the voltage drop that the battery could otherwise supply for use within the circuit. (c) is true—the current is determined by the sum of the internal and external resistance, as in Eq. (27–6), and this is insensitive to R if $r \gg R$.

It is worth looking at (b) a little more closely, and in a quantitative way. The voltage drop across the terminals is given by Eq. (27–5), and if we insert the current from Eq. (27–6), we see the voltage drop is

$$\begin{aligned} V &= \mathscr{E} - Ir = \mathscr{E} - [\mathscr{E}/(r + R)]r \\ &= \mathscr{E}[r + R - r]/(r + R) = \mathscr{E}R/(r + R) \cong \mathscr{E}R/r, \end{aligned}$$

and this is a small fraction of the emf.

We can see from Eq. (27–5) that for small internal resistance the potential across the terminals is approximately the same as the emf. This is generally true if there is no current at all, so a reading of the potential across the terminals is also a reading of the emf when the external, or load, resistance in the circuit is very large. It is desirable that the internal resistance be "small," but we need to remember that we mean small in comparison with external resistances, which vary depending on the application. The typical internal resistance of a car battery is less than 0.01 Ω, but it may be as large as 0.1 Ω for a flashlight battery. In many situations, the internal resistance is so small relative to the resistances within the circuit that it can be ignored in electric-circuit analyses. Ordinary batteries run down with age not because their emf decreases, but because their internal resistance increases, which means that the current they can supply decreases.

EXAMPLE 27–2 One of two different resistors with respective resistances $R_1 = 5.00\ \Omega$ and $R_2 = 10.0\ \Omega$ can be placed into the circuit shown in Fig. 27–3. The emf $\mathscr{E}$ and internal resistance r of the battery are unknown. When only R_1 is inserted, the current is $I_1 = 0.291$ A; when only R_2 is inserted, the current is $I_2 = 0.147$ A. Find $\mathscr{E}$ and r.

Strategy The total resistance for the two cases under consideration are $R_1 + r$ and $R_2 + r$, and in both cases, when these resistances are multiplied by the appropriate currents I_1 and I_2, respectively, they yield the emf $\mathscr{E}$. We will then have two linear equations that we can solve for the two unknowns r and $\mathscr{E}$.

Working It Out The fact that the net potential drop around the circuit is zero for the two cases yields the two equations

$$\mathscr{E} - I_1 r - I_1 R_1 = 0,$$
$$\mathscr{E} - I_2 r - I_2 R_2 = 0.$$

Multiplying the first equation by I_2 and the second by I_1 and then subtracting to solve for $\mathscr{E}$ we find that

$$\mathscr{E} = \frac{I_1 I_2}{I_1 - I_2}(R_2 - R_1).$$

If we insert this into either of the first two equations, we can solve for r:

$$r = \frac{I_2 R_2 - I_1 R_1}{I_1 - I_2}.$$

Numerical evaluation gives

$$\mathscr{E} = \frac{(0.291\ \text{A})(0.147\ \text{A})}{0.291\ \text{A} - 0.147\ \text{A}}(10.0\ \Omega - 5.00\ \Omega) = 1.49\ \text{V}$$

and

$$r = \frac{(0.147\ \text{A})(10.0\ \Omega) - (0.291\ \text{A})(5.00\ \Omega)}{0.291\ \text{A} - 0.147\ \text{A}} = 0.104\ \Omega.$$

What Do You Think? Suppose R_2 had been $1.0 \times 10^5\ \Omega$, known to 2 significant figures. Could you have found r? *Answers to **What Do You Think?** questions are given in the back of the book.*

Electric Power and Batteries

A source of emf (or electric energy) is also a source of *electric power*. The power is the rate at which the source delivers energy. From Eq. (26–30), the power of the source is the potential drop across the source times the current that passes through it. For a source of emf $\mathscr{E}$ we have

$$P = I\mathscr{E}. \tag{27–7}$$

Let's see how this works for the circuit of Fig. 27–3. Equation (27–6) tells us that $\mathscr{E}$ is given by $I(r + R)$, where I is the current in the circuit and r and R are the internal and load resistances, respectively. If we use this relation for $\mathscr{E}$ in Eq. (27–7), we find that

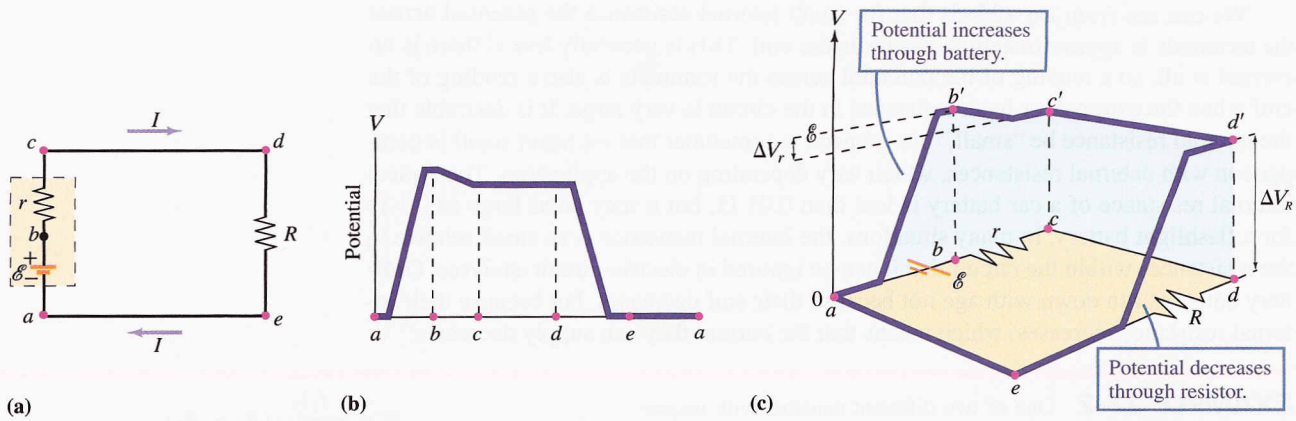
$$P = I^2 R + I^2 r. \tag{27–8}$$

Energy conservation implies that we had to find this result. The electric power of the source of emf is balanced by the sum of the power dissipated in both the internal and load resistances.

EXAMPLE 27–3 (a) A battery of emf $\mathscr{E}$ and negligible internal resistance r acts in the circuit of Fig. 27–3 with a resistor R. What is the power delivered in terms of $\mathscr{E}$ and R? (b) Suppose r is not negligible. What is the power delivered in terms of $\mathscr{E}$, R and r?

Setting It Up We want the result for power not in terms of I and $\mathscr{E}$, or in terms of I and resistance, as in the text discussion above, but in terms of $\mathscr{E}$ and resistance.

Strategy By using the expression $P = \mathscr{E}I$ and expressing the current in terms of the emf and the resistances, we will find the power in terms of the emf and the resistances.



Working It Out For case (a) $I = \mathscr{E}/R$, while for case (b) $I = \mathscr{E}/(R + r)$. We substitute these into the expression for power $P = I\mathscr{E}$: For case (a)

$$P = I\mathscr{E} = \frac{\mathscr{E}}{R}\mathscr{E} = \frac{\mathscr{E}^2}{R},$$

while for case (b)

$$P = I\mathscr{E} = \frac{\mathscr{E}}{R + r}\mathscr{E} = \frac{\mathscr{E}^2}{R + r}.$$

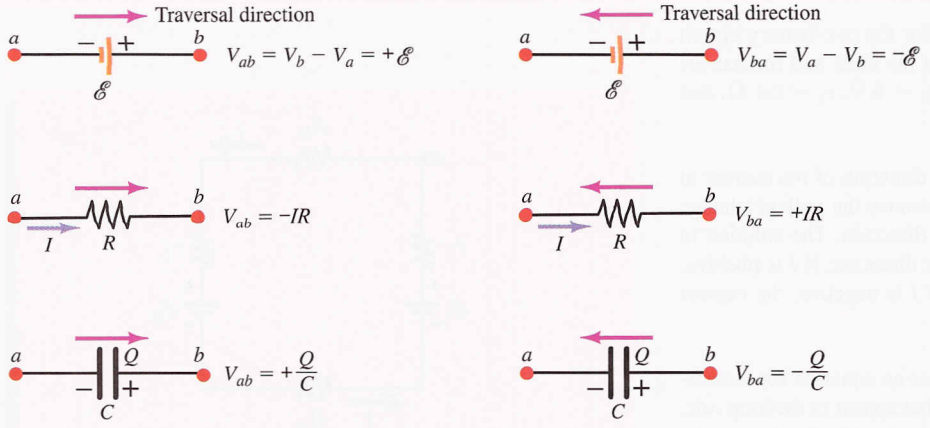
What Do You Think? The value of r determines the maximum power P_{max} a battery of a given emf can deliver in this circuit. What is P_{max}?

▲ **FIGURE 27–4** (a) A single-loop circuit showing the emf ($\mathscr{E}$), internal resistance (r), and load resistance (R). (b) The potential differences for the points labeled in part (a). (c) A three-dimensional view of part (b).

27–2 Kirchhoff's Loop Rule

A **single-loop circuit** is a circuit with a single path for the current. The simple circuit discussed in Section 27–1 (Fig. 27–3) is an example of such a circuit. Let's go around the loop and examine the potential change at every step. First we'll redraw the circuit in Fig. 27–4a and mark the points a through e. The potential is graphed in Fig. 27–4b, c, where we follow the circuit along the current direction, with zero potential chosen arbitrarily at point a. We draw the internal resistance, r, in Fig. 27–4a as though it were separate from the emf; in Fig. 27–4b, c, we draw the rise of the emf as gradual. There is no potential change in an ideal conducting wire. There is some very small resistance in a real wire, but it can usually be ignored, and we do so here.

As we observed earlier, the net potential change in traversing the complete circuit is zero. This is an expression of the conservation of energy: For this particular circuit the charge that moves round the loop gains energy from the emf and loses the same amount of energy in the resistors. If we had followed the circuit in the opposite direction—against the current—the changes would all be of the opposite sign, but the end result would remain: The potential change in a complete circuit is zero. In the context of circuits, this simple law is given a special name, after the nineteenth-century physicist Gustav Kirchhoff, **Kirchhoff's loop rule**:



The sum of the potential changes around a closed path is zero,

$$\sum_{\text{closed path}} \Delta V = 0. \tag{27–9}$$

KIRCHHOFF'S LOOP RULE

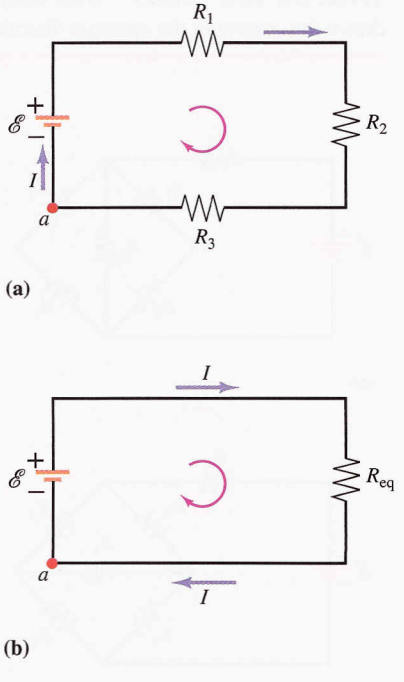
The loop rule is applicable to any closed path in any electric circuit. When a circuit is laid out in a diagram, many closed paths may be possible, and as we shall see in several of the examples that follow, the loop rule applied to these loops is an important tool for finding the desired circuit parameters, which is the aim of any circuit analysis. In Fig. 27–4a, there is only one closed loop.

In applying the loop rule, we must have knowledge of the potential differences across various parts of a circuit. It is therefore useful to summarize what we have learned here and in previous chapters about the potential changes ΔV across individual circuit elements—batteries, resistors, and capacitors—as a set of rules. Figure 27–5 is a summary figure for these rules. The quantity ΔV is the change in potential when moving from an initial point to a final point; for example, the potential change in going from point a to point b is $\Delta V = V_{ab} = V_b - V_a$.

▲ **FIGURE 27–5** Rules for potential differences across various circuit elements.

1. In going from the negative to the positive terminal of a battery with emf $\mathscr{E}$, the potential change is positive, $\Delta V = +\mathscr{E}$. In going from the positive to the negative terminal, the potential change is negative, $\Delta V = -\mathscr{E}$. This rule ignores the presence of an internal resistance, which we treat as a separate resistance in series with the battery. The actual potential difference across the terminals is the voltage change $\mathscr{E}$ plus a term associated with the internal resistance that depends on the current (see point 2, below).
2. In moving across a resistance R *along* the direction of the current, I, the potential change is negative, $\Delta V = -IR$. The sign is opposite, $\Delta V = +IR$, in moving *against* the direction of the current.
3. In moving from the negatively to the positively charged plate of a capacitor of capacitance C and charge Q, the potential change is positive, $\Delta V = +Q/C$. The potential change is negative, $\Delta V = -Q/C$, when we move from the positively charged plate to the negatively charged plate. It is worth recalling here that no actual current flows across a capacitor.

The simplest application of the loop rule involves several resistors in series in a single loop. As an example, consider the loop shown in Fig. 27–6a. Here we have an emf and three resistors. (The internal resistance of the source of emf will be ignored.) We start at point a and move toward the battery in the (clockwise) direction of the assumed current. (We could just as well follow the circuit in the opposite direction; each term would change sign, but this is irrelevant if the sum of voltage changes is zero.) Kirchhoff's loop rule, Eq. (27–9), gives



$$\sum \Delta V = \mathscr{E} - IR_1 - IR_2 - IR_3 = 0.$$

The solution for the current is

$$I = \frac{\mathscr{E}}{R_1 + R_2 + R_3}. \tag{27–10}$$

Of course, we know from Section 26–4 that we can replace resistors in series with an equivalent resistor R_{eq} given by the sum of the individual resistances, Eq. (26–21). This is illustrated in the circuit of Fig. 27–6b. There the current is $I = \mathscr{E}/R_{eq}$, and comparison of this result with Eq. (27–10) confirms Eq. (26–21).

In a single-loop circuit the internal resistance is simply included by adding it to the load resistance, since it always occurs *in series* with it. It is important in multi-loop circuits to place the battery's internal resistance adjacent to the battery.

▲ **FIGURE 27–6** (a) The circuit with three resistors connected in series is equivalent to (b) the circuit with one resistor of value R_{eq}.

EXAMPLE 27–4 Find the current for the two-battery circuit shown in Figs. 27–7a and b. The values of the emfs and resistances are $\mathscr{E}_1 = 12\ \text{V}$, $r_1 = 0.4\ \Omega$, $R_3 = 3\ \Omega$, $\mathscr{E}_2 = 6\ \text{V}$, $r_2 = 0.1\ \Omega$, and $R_4 = 10\ \Omega$.

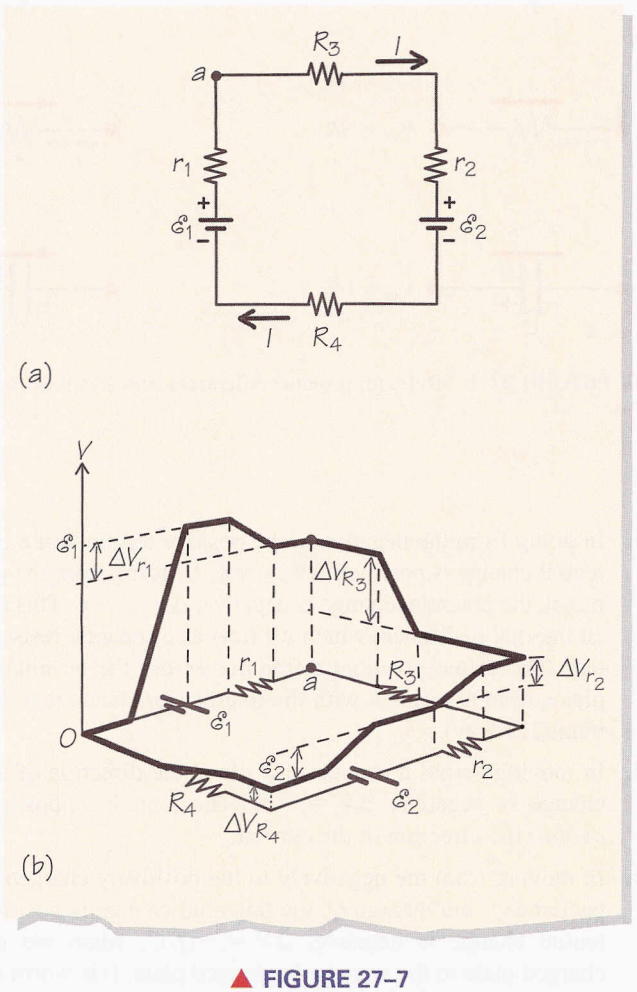
Setting It Up We have indicated the direction of the current in the figure; this assumption is necessary because the voltage change across resistors depends on the choice of direction. The solution to the problem will give us the actual current direction; if I is positive, our assumed direction was correct, and if I is negative, the current flows the other way.

Strategy We can regard the loop rule as an equation for the current, and we know all the other quantities that appear in the loop rule, including the internal resistances associated with the two emfs. These emfs are oriented in opposite directions and so will appear in the loop rule with opposite signs.

Working It Out Proceeding counterclockwise from point a, the loop rule reads

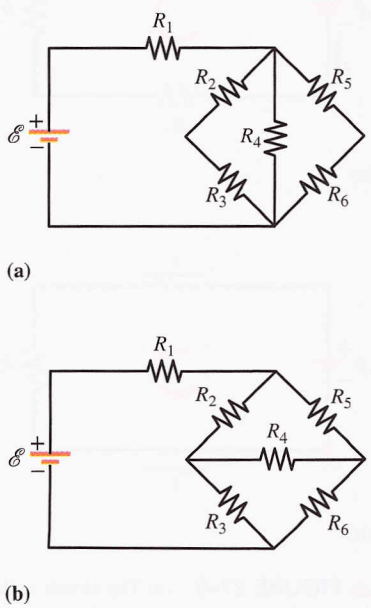
$$\sum \Delta V = +Ir_1 - \mathscr{E}_1 + IR_4 + \mathscr{E}_2 + Ir_2 + IR_3 = 0,$$

and we can solve this equation for the current. The result is



$$I = \frac{\mathscr{E}_1 - \mathscr{E}_2}{r_1 + R_4 + r_2 + R_3}.$$

Numerically,



$$I = \frac{12\ \text{V} - 6\ \text{V}}{0.4\ \Omega + 10\ \Omega + 0.1\ \Omega + 3\ \Omega} = \frac{6\ \text{V}}{13.5\ \Omega} \cong 0.4\ \text{A}.$$

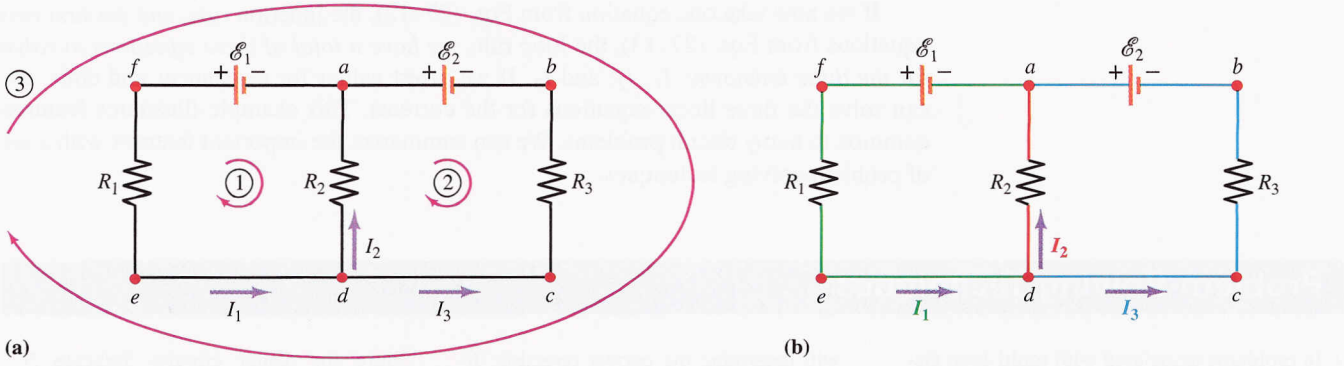
Note that the only time you might see two opposing emfs in a single-loop circuit is when one battery is charging another.

What Do You Think? What would the consequence of having drawn the current in the opposite direction have been?

▲ FIGURE 27–7

▲ FIGURE 27–8 Two multi-loop circuits.

27–3 Kirchhoff's Junction Rule



Few circuits are as simple as the one-loop circuits discussed so far. Examples of more complex circuits—multi-loop circuits—are shown in Figs. 27–8a and 27–8b. These examples have four- and three-line junctions. *Current conservation*, an experimental fact whose meaning and consequences were discussed in some detail in Chapter 26, is an additional tool that will allow a complete analysis of multi-loop circuits. We can summarize current conservation with **Kirchhoff's junction rule**. The rule states that the sum of the currents that enter a junction equals the sum of the currents that leave the junction. If we view currents that leave a junction as *negative*, and currents that enter the junction as *positive*, then we may rephrase this as

The algebraic sum of the currents that enter a junction equals zero,

$$\sum I_{\text{in}} = 0. \qquad (27\text{–}11)$$

KIRCHHOFF'S JUNCTION RULE

This equation applies for every junction. Application of Kirchhoff's two rules gives us further information for currents, voltage differences, etc., in multi-loop circuits.

▲ **FIGURE 27–9** (a) A multi-loop circuit with two independent loops and two junctions. (b) The three legs of the circuit are shown in different colors.

Solving for the Behavior of Multi-Loop Circuits

Let's take a look at how the junction rule and loop rule help us solve for the unknown values in multi-loop circuits. Consider the circuit in Fig. 27–9a. Current flows between every junction. Thus we have currents I_1, I_2, and I_3 in the three separate *legs*, or *branches afed* (green), *da* (red), and *dcba* (blue), respectively (Fig. 27–9b). (A leg is any line of the circuit that starts and finishes on a junction but does not itself include a junction. For example, the three possible lines that connect a and d in Fig. 27–9b are all legs.) We can arbitrarily choose the direction of the three currents, and as we shall see, the algebraic equations for the currents will determine the actual direction for us: If these equations give a negative value for any of the currents, then that current actually travels in the opposite direction than the one we postulated. The junction rule can be applied at junctions a and d to obtain

$$\text{for junction } a\text{: } -I_1 + I_2 + I_3 = 0; \tag{27–12a}$$

$$\text{for junction } d\text{: } I_1 - I_2 - I_3 = 0. \tag{27–12b}$$

Notice that currents drawn as leaving the junction have minus signs, while currents that are drawn as arrows entering the junction have plus signs. Notice also that these two equations are not independent of each other; in fact, they are identical! There is a general rule—we won't prove it—that if there are N' junctions in a circuit, then there are $N' - 1$ *independent* junction rules—the meaning of an independent set of equations is that one equation cannot be derived as a combination of any others. But it is perhaps not so important to remember this rule; it is always possible to write an equation for each junction, then check whether or not they are independent.

How do we use the loop rule for this circuit? We must start by counting the number of *independent* loops. (While the counting is a bit more complicated than for the junctions, it is worthwhile looking at it in more detail here.) The rule for counting the number of such loops is as follows: For planar circuits (circuits that can be drawn in a plane with no two wires crossing over each other), the number of independent loops is just the number of enclosed areas through which you could poke a pencil. According to this idea, the circuit in Fig. 27–9a has two *independent* loops. But we can draw three possible loops, those indicated by the circled integers 1, 2, and 3 of Fig. 27–9a, where 3 is around the perimeter of the circuit. Only two of these three loops can be independent, and we can choose *any* two of the three possible loops as our independent loops. Before we choose, though, let's apply the loop rule for all three loops and verify that only two are independent. Point a is part of each of the three loops, so for convenience we'll begin at point a and apply the loop rule of Section 27–2. The internal resistances for the two emfs are neglected. We traverse each loop in the direction of the loop arrow:

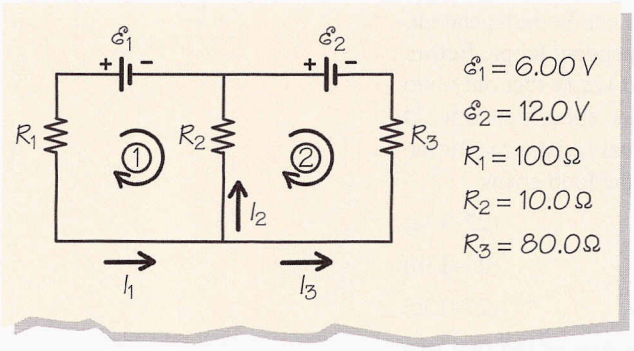
$$\text{for loop 1: } +I_2R_2 + I_1R_1 - \mathscr{E}_1 = 0; \tag{27–13a}$$

$$\text{for loop 2: } -\mathscr{E}_2 + I_3R_3 - I_2R_2 = 0; \tag{27–13b}$$

$$\text{for loop 3: } -\mathscr{E}_2 + I_3R_3 + I_1R_1 - \mathscr{E}_1 = 0. \tag{27–13c}$$

Only two of these three loop-rule equations are independent; the sum of the first two produces the third.

If we now take one equation from Eqs. (27–12), the junction rule, and the first two equations from Eqs. (27–13), the loop rule, *we have a total of three equations to solve for the three unknowns* I_1, I_2, and I_3. If we insert values for resistances and emfs, we can solve the three linear equations for the currents. This example illustrates features common to many circuit problems. We can summarize the important features with a set of problem-solving techniques.



Problem-Solving Techniques

In problems associated with multi-loop circuits, we must find unknown circuit parameters (such as resistance or current) when other parameters are given. To solve these problems, the following procedure may be helpful.

1. Draw a diagram with sources of emf, resistors, capacitors, and so forth clearly labeled. List the known and unknown parameters.
2. Assign a separate current for each leg of the circuit, and indicate that current on the diagram. The direction of current flow may not be immediately obvious; any direction can be assumed for the current, and the final algebraic solution will determine the correct direction. If the solution for a current turns out to be negative, the actual direction of current is opposite to your initial guess.
3. Apply the junction rule for the currents at each junction. Currents that you have chosen to draw as incoming have plus signs; those you have chosen to draw as outgoing have minus signs. If the circuit has N' junctions, then $N' - 1$ of the equations relating currents at the junctions will be independent.
4. Identify the number of independent loops N by counting the number of different ways that a pencil can poke through the circuit—a simple procedure for planar circuits. Indicate N loops on the diagram (for example, the loops labeled 1 and 2 on Fig. 27–9a).
5. Apply the loop rule to each of these loops.
6. Check to see that the number of linear equations from steps 3 and 5 matches the number of unknowns.
7. Solve these equations for the unknowns—whether they are currents or other parameters of the circuit. It is usually best to solve these equations *algebraically* and substitute numerical values later. Any checks, in the form of special cases or simple limits, can easily be made this way.

EXAMPLE 27–5 Find the currents for the circuit of Fig. 27–10, given that $\mathscr{E}_1 = 6.00\ \text{V}$, $\mathscr{E}_2 = 12.0\ \text{V}$, $R_1 = 100\ \Omega$, $R_2 = 10.0\ \Omega$, and $R_3 = 80.0\ \Omega$.

Strategy We follow the Problem-Solving Techniques (p. 774). The circuit diagram is given, and all parameters are labeled on Fig. 27–10. In this case, the unknowns are I_1, I_2, and I_3. For the application of the junction rules, we note that there are only two junctions, and hence only one of them is independent. For the loop rules, we choose loop 1 and loop 2 as the two independent ones. In fact, we have already written the junction and loop equations for this circuit: Eqs. (27–12) and (27–13), respectively. Accordingly, our single independent junction equation will be Eq. (27–12b), and our two independent loop equations will be Eqs. (27–13a) and (27–13b). We have three equations to solve for the three unknowns.

▲ FIGURE 27–10

Working It Out Equation (27–12b) gives $I_1 = I_2 + I_3$. We substitute this into the loop equations:

$$I_2R_2 + (I_2 + I_3)R_1 - \mathscr{E}_1 = 0; \qquad (27\text{–}14a)$$

$$-\mathscr{E}_2 + I_3R_3 - I_2R_2 = 0. \qquad (27\text{–}14b)$$

Solve Eq. (27–14b) for I_3:

$$I_3 = \frac{I_2R_2 + \mathscr{E}_2}{R_3}. \qquad (27\text{–}15)$$

When this result is inserted into Eq. (27–14a), we find an equation for I_2, namely $I_2(R_1 + R_2) + (I_2R_2 + \mathscr{E}_2)\dfrac{R_1}{R_3} - \mathscr{E}_1 = 0$, and this has solution

$$I_2 = \frac{R_3\mathscr{E}_1 - R_1\mathscr{E}_2}{R_1R_2 + R_1R_3 + R_2R_3}. \qquad (27\text{–}16)$$

If we substitute this result into Eq. (27–15), we get an expression for I_3:

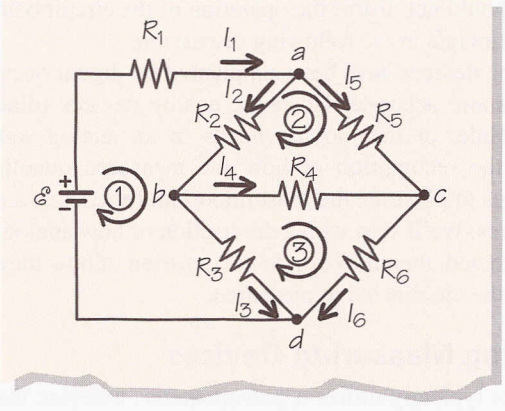
$$I_3 = \frac{R_2(\mathscr{E}_1 + \mathscr{E}_2) + R_1\mathscr{E}_2}{R_1R_2 + R_1R_3 + R_2R_3}. \qquad (27\text{–}17)$$

Finally, I_1 is the sum of I_2 and I_3:

$$I_1 = \frac{R_2(\mathscr{E}_1 + \mathscr{E}_2) + R_3\mathscr{E}_1}{R_1R_2 + R_1R_3 + R_2R_3}. \qquad (27\text{–}18)$$

Equations (27–16), (27–17), and (27–18) constitute the desired algebraic solution. Numerically, we can most simply start with the

denominator combination, $(100\ \Omega)(10.0\ \Omega) + (100\ \Omega)(80.0\ \Omega) + (10.0\ \Omega)(80.0\ \Omega) = 9.80 \times 10^3\ \Omega^2$. In turn,



$$I_1 = \frac{(10.0\ \Omega)(6.00\ \text{V} + 12.0\ \text{V}) + (80.0\ \Omega)(6.00\ \text{V})}{9.80 \times 10^3\ \Omega^2}$$
$$= 67.3\ \text{mA}$$
$$I_2 = \frac{(80.0\ \Omega)(6.00\ \text{V}) - (100\ \Omega)(12.0\ \text{V})}{9.80 \times 10^3\ \Omega^2} = -73.5\ \text{mA}$$
$$I_3 = I_1 - I_2 = 140.8\ \text{mA}.$$

Note that I_2 is negative, meaning that it flows in a direction opposite to the one we assumed in Fig. 27–10.

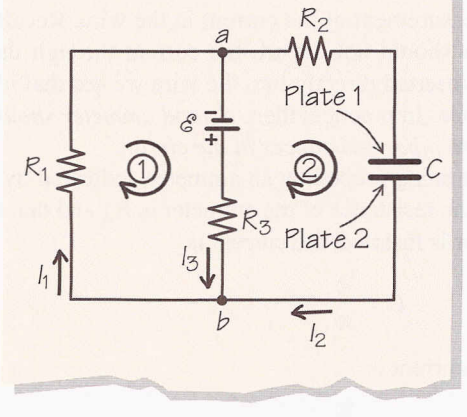
What Do You Think? What do you expect to happen if the resistance R_2 is much larger than any other resistance in the problem? Verify your expectation by using the expressions above for the currents.

EXAMPLE 27–6 Assume that the emf and resistors are known for the circuit in Fig. 27–8b. Express the linear equations that can be solved to find all currents.

Setting It Up Figure 27–11 identifies our choice of junctions and loops to which the Kirchhoff rules are to be applied.

▲ **FIGURE 27–11** The circuit of Fig. 27–8b is labeled with loops and junctions to be solved by circuit analysis.

Strategy As we see from the figure, there are six currents, so we need six linear equations. Three independent loops in the circuit are drawn in Fig. 27–11. There are four junctions, hence three independent junction rule equations—one of the four junction rule equations will not be independent of the others. Thus we choose any three junctions to apply the junction rules, giving three equations. The three loop equations provide the necessary remaining three equations.



Working It Out The six equations are

for junction *a*:	$I_1 - I_2 - I_5 = 0;$
for junction *b*:	$I_2 - I_3 - I_4 = 0;$
for junction *c*:	$I_4 + I_5 - I_6 = 0;$
for loop 1:	$\mathscr{E} - I_1R_1 - I_2R_2 - I_3R_3 = 0;$
for loop 2:	$-I_5R_5 + I_4R_4 + I_2R_2 = 0;$
for loop 3:	$-I_6R_6 + I_3R_3 - I_4R_4 = 0.$

With sufficient patience, we can solve these six equations for the six unknown currents. This, however, is not required in this example.

What Do You Think? Suppose loop 1 were chosen so that it goes all the way around (battery–*a*–*c*–*d*) rather than (battery–*a*–*b*–*d*), as chosen in the example. Could you still solve for the unknowns?

EXAMPLE 27–7 Find the steady-state currents I_1 and I_2 in the circuit drawn in Fig. 27–12. Also find the resistance of resistor R_3 that will give a steady-state current $I_3 = 50$ mA. Finally, determine the potential drop across the capacitor. The values of the known elements are $\mathscr{E} = 6$ V, $R_1 = 100\ \Omega$, $R_2 = 80\ \Omega$, and $C = 2\ \mu$F.

▲ **FIGURE 27–12** Notice that, in steady-state operation, the capacitor acts as an open switch despite the fact that it has voltage across its plates.

Strategy A capacitor acts as an open switch for steady-state current flow. Nevertheless, there is a voltage drop across the capacitor, because charge can build up on the capacitor plates under the impetus of the battery as the steady state is achieved. (Once steady state is reached, there is no further buildup of charge.) We must accordingly include the capacitor in application of the loop rule, and we cannot simply ignore, for example, the loop (*a*–capacitor–*b*–*a*). There will therefore be two loop equations and one junction equation—with two junctions, there is always only one independent equation. With three equations, we will be able to solve for the three unknowns I_1, R_3, and the potential drop across the capacitor.

Working It Out We first write down the loop equations, remembering that the currents are constant in time, so that no current passes through the leg containing the capacitor, and $I_2 = 0$. This simplifies the independent junction (*b*) equation which reads

$$I_1 = I_2 + I_3 = I_3.$$

For the loop equations: loop 1 gives

$$\mathscr{E} - I_3R_3 - I_1R_1 = 0,$$

from which we obtain the resistance

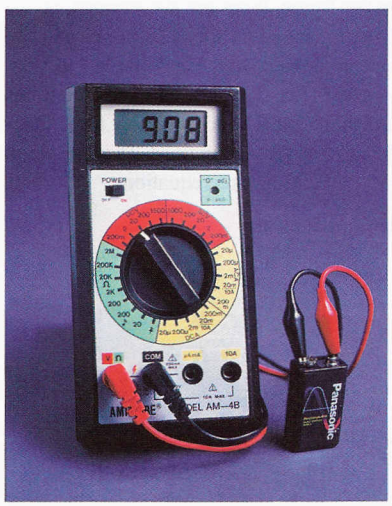
$$R_3 = \frac{\mathscr{E} - I_1R_1}{I_3} = \frac{\mathscr{E} - I_3R_1}{I_3} = \frac{\mathscr{E}}{I_3} - R_1.$$

(continues on next page)

Finally, the equation for loop 2 reads $-I_2R_2 + V_C + I_3R_3 - \mathscr{E} = 0$, where V_C is the potential difference across the capacitor, and with $I_2 = 0$ we get

$$V_C = \mathscr{E} - I_3R_3.$$

The numerical results are



$$R_3 = \frac{6\text{ V}}{50\text{ mA}} - 100\ \Omega = \frac{6\text{ V}}{50 \times 10^{-3}\text{ A}} - 100\ \Omega = 20\ \Omega$$

and

$$V_C = (6\text{ V}) - (50 \times 10^{-3}\text{ A})(20\ \Omega) = 5\text{ V}.$$

What Do You Think? (a) Could the equation for R_3 lead to a negative value for this resistance under certain circumstances? (b) Which of the two capacitor plates is at the higher potential?

27–4 Measuring Instruments

▲ **FIGURE 27–13** A multimeter can be used as a voltmeter, ohmmeter, or ammeter.

We have referred to the currents and voltages in various circuit elements, but we have not yet explained how these quantities are measured. A variety of instruments exists for this purpose: **Ammeters** measure current, **voltmeters** measure voltage, and **ohmmeters** measure resistance. These devices are often combined into one instrument called a **multimeter** (Fig. 27–13). We shall focus our attention on ammeters and voltmeters. Whatever the detailed operation of such instruments, a general principle must be respected: The measuring device should not distort the operation of the circuit being measured. We shall emphasize this principle in the following discussion.

For most applications, analog devices have been supplanted by digital ones, which are usually less expensive and more accurate. However, analog devices (dials)—the gasoline gauge of your automobile, or the moving hands of an analog watch, for example—remain superior for the recognition of how the measured quantities are changing. It will be simplest for us to illustrate the most important features of ammeters and voltmeters with analog devices. We'll start with a description of how analog ammeters and voltmeters can be constructed, then move on to the question of how they can be used in ways that do not disturb the circuits being measured.

How to Construct Analog Measuring Devices

Analog ammeters and voltmeters typically utilize a *galvanometer*, a device that relies on magnetic effects. The galvanometer, indicated by a circled *"G"* in circuit diagrams, consists of a coil of wire that rotates in the magnetic field produced whenever a current passes through the wire. (We'll explore this when we study the effects of magnetic fields, in Chapter 28.) A needle connected to the coil is deflected by an amount proportional to the current that passes through the coil. The position of the needle, properly calibrated, is the analog measurement.

Ammeters: An ammeter measures the current in a circuit wire by direct insertion into the wire—in other words, it is placed in series in the circuit segment through which the current to be measured passes. That means that the current flowing through the ammeter is the current flowing through the wire, and a measurement of the current passing through the ammeter itself is a measurement of the current in the wire. Recall now the general principle that an ammeter should not disturb the current through the circuit. From the fact that the ammeter is inserted directly into the wire we see that ideally the ammeter should have zero resistance. In practice, then, *a good ammeter should have a resistance that is small compared to other resistances in the circuit.*

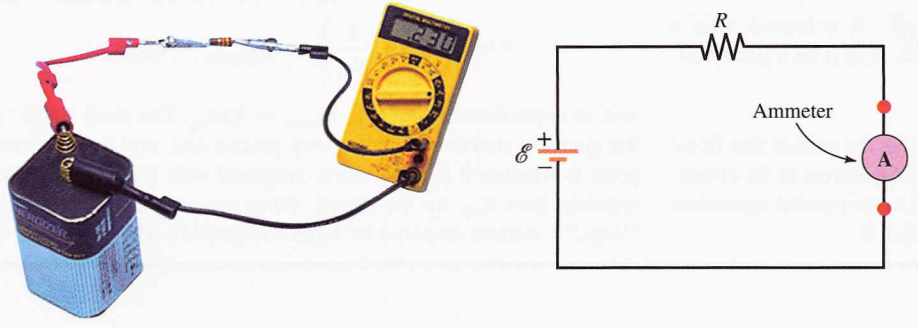


Figure 27–14a shows a circuit being probed by an ammeter, indicated by a circled "A" in Fig. 27–14b. Suppose that the resistance of the ammeter is R_A and that the series resistance is R. Before the ammeter is inserted, the current is

$$I = \frac{\mathscr{E}}{R}.$$

After the ammeter is inserted, the current is

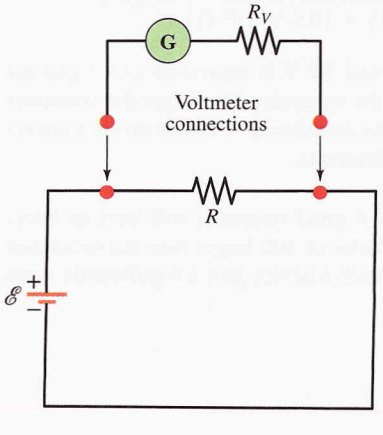
$$I = \frac{\mathscr{E}}{R + R_A}. \tag{27–19}$$

The current will be the same with or without the ammeter attached only if $R_A \ll R$.

(a) (b)

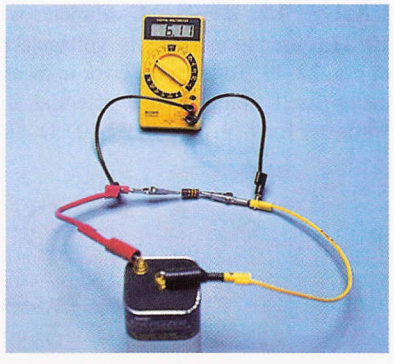
◀ **FIGURE 27–14** (a) An ammeter is placed in series where the current is to be measured. The resistance of an ammeter should be small so as not to change the current. (b) Schematic diagram of the circuit.

Voltmeters: Voltmeters measure potential differences across circuit elements. They do so by being placed in parallel with those elements, so that the potential drop across the voltmeter is the same as across the circuit element. Figure 27–15a shows a voltmeter—indicated by the circled "*V*" in Fig. 27–15b—used to measure the potential across a resistor. A voltmeter should not disturb the potential difference being measured, and so *a good voltmeter should have a large resistance*. Why is this? If the internal resistance of the voltmeter is R_V, the combination of voltmeter and resistance in Fig. 27–15b forms a parallel resistance circuit with equivalent resistance



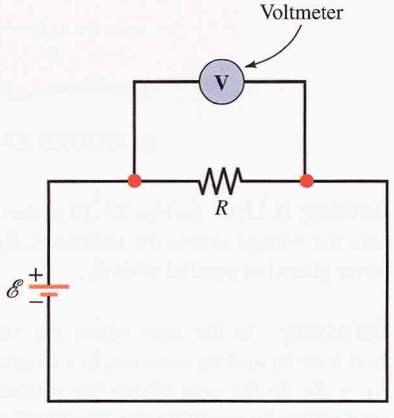
$$\frac{1}{R_{\text{eq}}} = \frac{1}{R_V} + \frac{1}{R}.$$

When $R_V \gg R$, then $R_{\text{eq}} \cong R$, and none of the parameters of the original circuit are affected.



A galvanometer connected in series with a resistor of large resistance can serve as a voltmeter. If the current I passing through the galvanometer is measured (and that is just what the needle deflection measures), then the potential drop across the voltmeter is approximately IR_V. For example, take a galvanometer that can measure a maximum current of 100 μA. This is equivalent to a measurement of 10 V if the internal resistance is set at

$$R_V = \frac{10\ \text{V}}{100 \times 10^{-6}\ \text{A}} = 10^5\ \Omega.$$



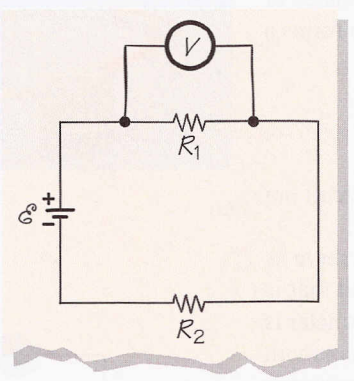
An analog voltmeter is then a galvanometer with a series resistor of resistance R_V (Fig. 27–16). If there are potential differences within a circuit of 1000 V, then the 100 μA current would be exceeded and the resistor in our example would not be adequate. With a 10^5-Ω resistor the full-scale reading is 10 V. To measure a full-scale voltage of 1000 V with 100 μA, we must take $R_V = 10^7\ \Omega$.

◀ **FIGURE 27–16** A galvanometer with a large series resistance can serve as a voltmeter.

(a)

(b)

▲ **FIGURE 27–15** (a) A voltmeter is placed in parallel across the circuit element whose potential drop is to be measured. The resistance of a voltmeter should be large so as not to change the circuit. (b) Schematic diagram of the circuit.



CONCEPTUAL EXAMPLE 27–8 A voltmeter with a large resistance R_V is used as in Fig. 27–15. Will it be a good voltmeter for all circuits?

Answer The point of the apparatus is that the current that flows through the voltmeter be small compared to the current in the circuit. This means that R_V must be large compared to the parallel equivalent resistance. In this way, the total current, which is

$$I = \mathscr{E}\left(\frac{1}{R_V} + \frac{1}{R_{\text{eq}}}\right) = I_{\text{voltmeter}} + I_{\text{circuit}},$$

will be approximately equal to $I_{\text{circuit}} = \mathscr{E}/R_{\text{eq}}$. The word "large" in the question statement is not a very precise one, and the important point is whether it is large when compared with the corresponding quantity, here R_{eq}, for the circuit. When someone uses a word like "large," a suitable response is "large compared to what?"

EXAMPLE 27–9 A voltmeter with an internal resistance of $10^5\ \Omega$ is used to measure the voltage across resistor R_1 in the circuit of Fig. 27–17. To learn the error in measurement caused by the voltmeter itself compare the potential drop with and without the voltmeter for $\mathscr{E} = 6$ V, $R_1 = 10\ \text{k}\Omega$, and $R_2 = 5\ \text{k}\Omega$.

▲ FIGURE 27–17

Setting It Up As Fig. 27–17 makes clear, we are asked to compare the voltage across the resistance R_1 without and with the voltmeter placed in parallel with R_1.

Strategy In the case where the voltmeter is not present, we deal with R_1 and R_2 in series, in a single loop with a load resistance $R_1 + R_2$. In the case where the voltmeter is present, we can proceed either by applying the Kirchhoff rules to two loops or, more directly, by treating the voltmeter as a resistor parallel to R_1 and replacing the combination of these parallel resistors with a single equivalent resistance in a single-loop problem. The second alternative is simpler.

Working It Out With the voltmeter absent and a load resistance of $R_1 + R_2$, the current flowing is

$$I = \frac{\mathscr{E}}{R_1 + R_2}.$$

From this we calculate the voltage across the resistor R_1 to be

$$V_1 = IR_1 = \frac{\mathscr{E}R_1}{R_1 + R_2}.$$

When the voltmeter is connected, the resistance R_1 is replaced by the equivalent resistance R_1^* given by

$$\frac{1}{R_1^*} = \frac{1}{R_1} + \frac{1}{R_V} \quad \text{or} \quad R_1^* = \frac{R_1 R_V}{R_1 + R_V}.$$

The current is now

$$I^* = \frac{\mathscr{E}}{R_1^* + R_2}$$

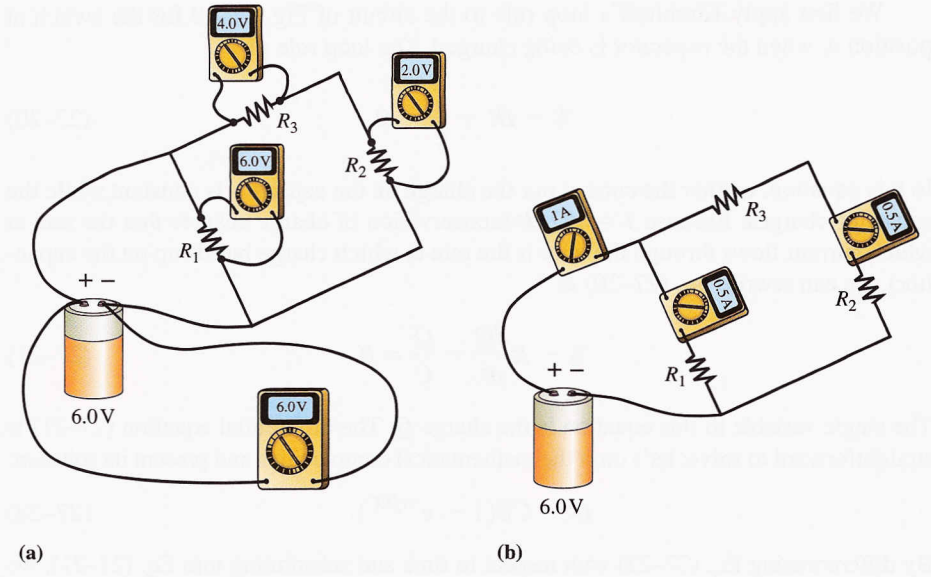
and the voltage drop is just the voltage drop across the effective resistance R_1^*,

$$V_1^* = R_1^* I^* = \frac{\mathscr{E}R_1^*}{R_1^* + R_2}.$$

Numerically,

$$V_1 = IR_1 = \frac{6\ \text{V}}{10\ \text{k}\Omega + 5\ \text{k}\Omega}(10^4\ \Omega) = 4\ \text{V}.$$

With the voltmeter we have



$$R_1^* = \frac{R_1 R_V}{R_1 + R_V} = \frac{(10^4\ \Omega)(10^5\ \Omega)}{(10^5\ \Omega)(1 + 0.1)} = 0.9 \times 10^4\ \Omega$$

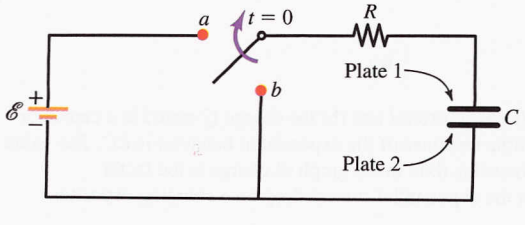
and therefore

$$V_1^* = R_1^* I^* = \frac{ER_1^*}{R_1^* + R_2} = \frac{(6\ \text{V})(0.9 \times 10^4\ \Omega)}{(0.9 \times 10^4\ \Omega) + (0.5 \times 10^4\ \Omega)} = 3.9\ \text{V}.$$

The difference between 4 V and 3.9 V is equivalent to a 3 percent error due to the presence of the voltmeter. The larger the voltmeter resistance, the smaller the error introduced. Whether this is a tolerable error depends on the requirements.

What Do You Think? A good voltmeter will have an internal resistance of 10 MΩ, a factor of 100 larger than the resistance used in this example. Would such a device give a significantly more accurate reading?

◀ **FIGURE 27–18** (a) Measuring voltage across circuit elements. (b) Measuring current through circuit elements.



In Fig. 27–18, we summarize the use of voltmeters and ammeters in a typical circuit.

27–5 *RC* Circuits

RC circuits are circuits that contain both resistors and capacitors. Unlike the circuits we have considered so far that have a steady current flowing through them, the currents and potentials of *RC* circuits can exhibit time-varying behavior when we introduce another element, a switch (Fig. 27–19). Even for circuits containing steady sources of emf, we introduce time dependence in a circuit every time we open or close the switch. *RC* circuits with switches have time-dependent effects that are useful for the control of motors, machinery, or computers.

We first observed the effect of a fully charged capacitor in an electric circuit in steady-state operation in Example 27–7. Now we want to examine the more complex, transient behavior that occurs when a capacitor is being charged and discharged. Consider the circuit shown in Fig. 27–19, with an initially uncharged capacitor. When the switch is closed (to position a) at $t = 0$, current begins to flow from the positive terminal of the battery, and positive charge begins to collect on plate 1 of the capacitor, while an equal amount of negative charge collects on plate 2. Current flows everywhere in the circuit *except* through the plates of the capacitor. Immediately after the switch is closed, the current has its maximum value, but the charge that builds up on the capacitor plates opposes further charge flow, and the current decreases. When the potential across the capacitor plates equals the emf and equilibrium is reached, the current is zero. This occurs when the charge on the capacitor plates, Q_0, is such that $\mathcal{E} = Q_0/C$.

After equilibrium has been reached and the current has become zero, we change the switch to position b, effectively taking the battery out of the circuit. The circuit now consists only of the charged capacitor and the resistor, and it is not in equilibrium. Current flows through the circuit from plate 1 of the capacitor to plate 2. The rate of flow is limited by the resistor. At first the current is high, but it decreases as the capacitor discharges through the resistor. Eventually the capacitor discharges completely, and the current again falls to zero when equilibrium is reached.

◀ **FIGURE 27–19** A circuit used to charge and discharge a capacitor through a resistor. When the switch is closed at a, the capacitor is charged by the source of emf, whereas the capacitor discharges through R when the switch is thrown to b.

We first apply Kirchhoff's loop rule to the circuit of Fig. 27–19 for the switch at position *a*, when the capacitor is being charged. The loop rule gives

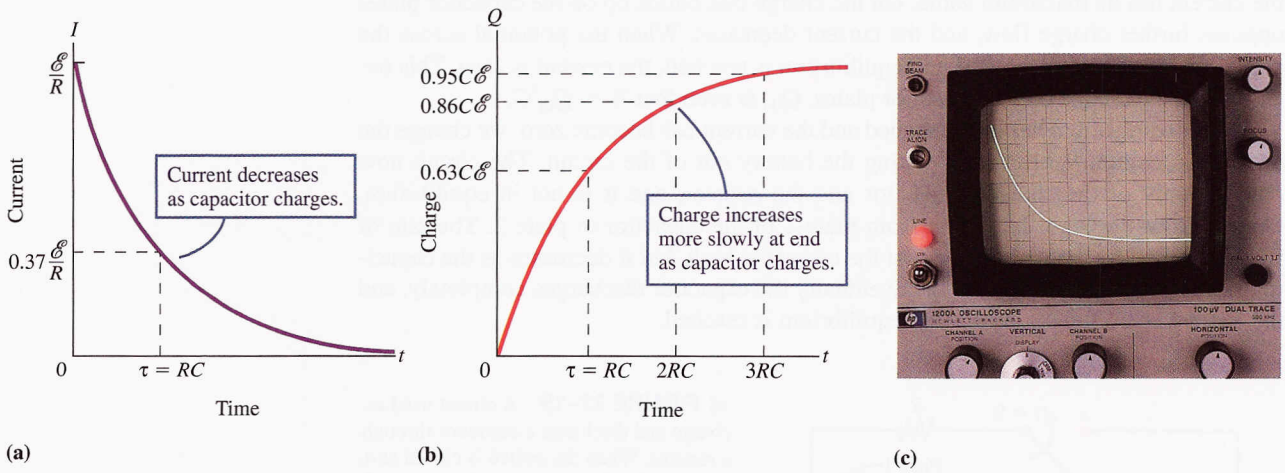
$$\mathcal{E} - IR - \frac{Q}{C} = 0. \tag{27–20}$$

In this equation, neither the current nor the charge on the capacitor is constant while the capacitor charges. Because $I = dQ/dt$ (conservation of charge ensures that the rate at which current flows through the wire is the rate at which charge builds up on the capacitor), we can rewrite Eq. (27–20) as

$$\mathcal{E} - R\frac{dQ}{dt} - \frac{Q}{C} = 0. \tag{27–21}$$

The single variable in this equation is the charge Q. The differential equation (27–21) is straightforward to solve; let's omit the mathematical complexities and present its solution:

$$Q = C\mathcal{E}(1 - e^{-t/RC}). \tag{27–22}$$



By differentiating Eq. (27–22) with respect to time and substituting into Eq. (27–21), we can see that it satisfies Eq. (27–21) (see Problem 54). More important, does it agree physically with what we expect? According to Eq. (27–22), the charge on the capacitor is zero at $t = 0$ and builds smoothly to $C\mathcal{E}$ at large times, in agreement with our earlier discussion.

We can find the current in the circuit by differentiating Eq. (27–22) with respect to time:

$$I = \frac{dQ}{dt} = C\mathcal{E}\left(\frac{1}{RC}e^{-t/RC}\right) = \frac{\mathcal{E}}{R}e^{-t/RC}. \tag{27–23}$$

The sign of the current is positive, so we chose the correct current direction (clockwise). The maximum value of the current is $\mathcal{E}/R$, at $t = 0$, and the current is zero at $t = \infty$, which also agrees with our earlier discussion. Just after the switch is closed, the potential drop across the resistor is $\mathcal{E} = IR$, with no potential drop across the uncharged capacitor. As the capacitor charges, the current drops *exponentially* to zero.

Equations (27–22) and (27–23) show that the time dependence of both charge and current is determined by the product $\tau \equiv RC$; τ is called the **time constant**. It has units of time; with R and C in SI units, RC will be in seconds. The time constant determines how fast a capacitor charges and discharges. The smaller the value of RC, the more quickly the exponentials in the equations for Q and I fall; similarly, the larger the value of RC, the more slowly the exponentials change. Figure 27–20a and c show the current

▲ **FIGURE 27–20** The time response of (a) the current I and (b) the charge Q stored in a capacitor as the capacitor is charged. The characteristic time response of the exponential behavior is RC. The value 0.37 in the graph of current is the factor e^{-1}; the value 0.63 in the graph of charge is the factor $(1 - e^{-1})$. (c) This oscilloscope screen shows the exponential current drop on a charging capacitor.

in the circuit, and Fig. 27–20b shows the charge on the capacitor as a function of time while the capacitor is being charged. After a time RC, the current has dropped to $e^{-1} \cong 0.37$ times its original value. After this same amount of time, the capacitor is $(1 - e^{-1}) \cong 63$ percent fully charged. It is 86 percent charged at time $2RC$ and 95 percent charged at time $3RC$.

Let's return to the circuit of Fig. 27–19. Suppose that the switch has been in position a for a long time, the capacitor is fully charged, and there is no current. At time $t = 0$, we throw the switch to position b. Only the discharging capacitor and the resistor are now in the circuit (Fig. 27–21). The positive charge is on plate 1, and we assume as before that the current is clockwise. The loop rule now gives

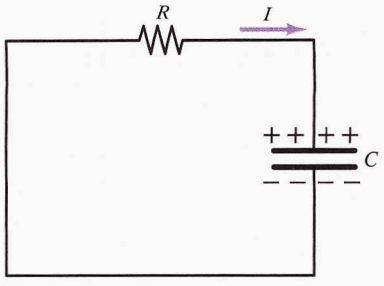
$$-IR - \frac{Q}{C} = 0. \tag{27–24}$$

Using $I = dQ/dt$, we have

$$R\frac{dQ}{dt} + \frac{Q}{C} = 0. \tag{27–25}$$

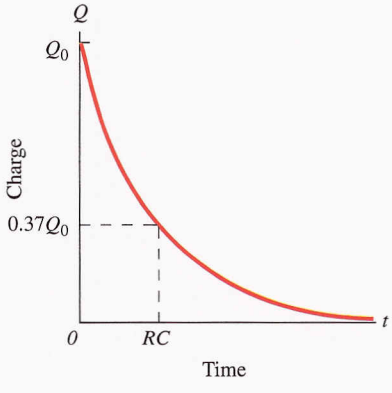
This differential equation is solved by the function

$$Q = Q_0 e^{-t/RC}, \tag{27–26}$$



where Q_0 is the initial charge on the capacitor when the switch is changed, $Q_0 = C\mathscr{E}$. Equation (27–26) may be substituted into Eq. (27–25) to verify that it is a solution (see Problem 55). The charge on the capacitor decreases exponentially with the time constant RC, and after a long time, there will be no charge on the capacitor.

We find the current by differentiating Eq. (27–26):



$$I = \frac{dQ}{dt} = -\frac{Q_0}{RC}e^{-t/RC}. \tag{27–27}$$

The current in this case is negative, indicating that the actual current is counterclockwise, opposite in direction to the current we assumed when we drew the diagram. It is again a maximum at $t = 0$, when the magnitude of the current is $Q_0/RC = \mathscr{E}/R$. After a long time, the current is again zero.

The behavior of the charge and current for the capacitor that discharges through a resistor is qualitatively what we expected from our earlier discussion. The magnitude of the current for this case is just as shown in Fig. 27–20a for the charging capacitor. The charge on the capacitor is plotted as a function of time in Fig. 27–22. Again, the factor 0.37 is e^{-1}.

▲ **FIGURE 27–21** The circuit of Fig. 27–19 after the switch has been thrown to position b.

▲ **FIGURE 27–22** The capacitor charge as the capacitor of Fig. 27–21 discharges through the resistor as a function of time. The characteristic time response of the exponential behavior is again RC.

THINK ABOUT THIS. . .

CAN CAPACITORS REPLACE BATTERIES IN LAPTOP COMPUTERS?

Rechargeable batteries in laptop computers work only for a few hours, and recharging takes a long time. Could a capacitor replace the battery? The computer requires a steady current of around 2 μA but can work with a range of voltage from 6 V to a minimum voltage of 2.5 V (the lower limit is determined by the necessity to maintain memory function). If the charged capacitor is placed in series with a resistance, the current produced by the capacitor as it discharges will drop as the voltage drop V_C across the capacitor decreases. A constant current I calls for a nonohmic device for which I is *independent* of the voltage drop V across it over some range of V. (The device that achieves this is a *zener diode*.) When such a device is placed in series with a capacitor, then the relation $Q = CV$ implies that the current obeys the equation $I = dQ/dt = C\,dV/dt$. Since the device produces constant I, V must drop linearly with time. If $I = 2\ \mu$A how long will it take before the potential difference across the capacitor changes from 6 V to 2.5 V? From the relation $I = C\,dV/dt$ with constant I we calculate $\Delta t = C \times (\text{change in } V)/I = C(3.5\text{ V})/(2 \times 10^{-6}\text{ A})$. With a capacitor of $C = 1$ F this time scale is 1.8×10^6 s $\cong$ 20 days. Whether this is a practical option depends on the existence of capacitors with capacitance of farads—a very large capacitance—yet compact enough to be used in portable devices, and as we already discussed in Chapter 26 this technology is being actively pursued.

Energy in *RC* Circuits

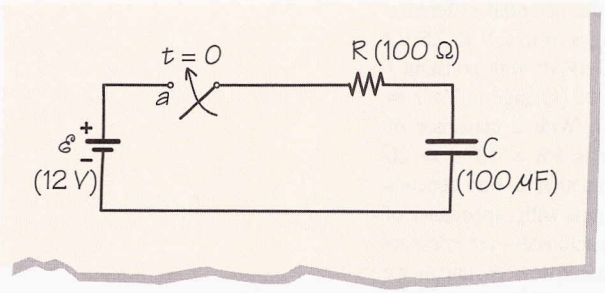
Let's now examine the role of energy and its conservation during the charging of a capacitor. From the definition of potential, the amount of work done by the battery emf during the charging process is $\mathscr{E}$ times the total charge processed by the battery. This charge is the final charge $C\mathscr{E}$ on the capacitor plates after a long period of time. Thus, the work done by the battery, W_{bat}, is

$$W_{\text{bat}} = \mathscr{E}(C\mathscr{E}) = C\mathscr{E}^2. \tag{27–28}$$

How do we account for the energy that matches this work? In part, the energy is stored in the capacitor. We know from Eq. (25–9) that the total energy stored by a capacitor is $CV^2/2$. The voltage V in this case is $\mathscr{E}$, so the energy stored by the capacitor, E_{cap}, is

$$E_{\text{cap}} = \tfrac{1}{2}C\mathscr{E}^2. \tag{27–29}$$

Where has the other half of the work done by the battery gone? The only other circuit element is the resistor, and the other half of the work has gone into Joule heating of that resistor. From Eq. (26–27), we know that the power loss in the resistor is $P = I^2R$. We can integrate the power over time to find the energy loss in the resistor, E_{res}, using the current from Eq. (27–23)



$$\begin{aligned} E_{\text{res}} &= \int_0^\infty I^2R\,dt = \frac{\mathscr{E}^2}{R}\int_0^\infty e^{-2t/RC}\,dt \\ &= \frac{\mathscr{E}^2}{R}\left(-\frac{RC}{2}e^{-2t/RC}\right)\Bigg|_0^\infty = \frac{C\mathscr{E}^2}{2}. \end{aligned} \tag{27–30}$$

The thermal energy loss in the resistor accounts for the other half of the work done by the battery. This 50-percent split of energy between the resistor and the capacitor is *independent* of $\mathscr{E}$. For the case of the discharging capacitor, all the energy stored in the capacitor dissipates as heat in the resistor. A spectacular demonstration of the rapid release of the energy contained within a capacitor was shown in Fig. 25–8.

EXAMPLE 27–10 The charging circuit shown in Fig. 27–23 (with a switch thrown to position a at $t = 0$) has a 12 V emf, a 100 Ω resistance, and a 100 μF capacitance. (a) Find the time constant, the final charge on the capacitor, and the work done by the battery. (b) How long does it take for the capacitor to be charged to 99.9 percent of its final charge?

Setting It Up We label the given emf, resistance, and capacitance $\mathscr{E}$, R, and C, respectively.

Strategy (a) Knowing both R and C, the time constant is $\tau = RC$. The final charge on the capacitor is $Q_f = C\mathscr{E}$ (as we already know from Chapter 25), and the work done by the battery is $W_f = C\mathscr{E}^2$. As for part (b), this is a matter of solving the expression $Q = Q_f(1 - e^{-t/\tau})$ for t knowing that $Q = 0.999Q_f$.

▲ FIGURE 27–23

Working It Out (a) We need only plug numerical values into the appropriate expressions:

$$\begin{aligned} \tau = RC &= (100\ \Omega)(10.0 \times 10^{-6}\ \text{F}) \\ &= 1.00 \times 10^{-3}\ \text{s} = 1.00\ \text{ms}, \\ Q_f &= C\mathscr{E} = (10.0 \times 10^{-6}\ \text{F})(12\ \text{V}) = 1.2 \times 10^{-4}\ \text{C}, \\ W_{\text{bat}} &= C\mathscr{E}^2 = (10.0 \times 10^{-6}\ \text{F})(12\ \text{V})^2 = 1.4 \times 10^{-3}\ \text{J}. \end{aligned}$$

(b) With $Q = 0.999Q_f$, we want to solve Eq. (27–22) for t. The factor Q_f cancels, leaving $0.999 = (1 - e^{-t/\tau})$, or

$$e^{-t/\tau} = 1 - 0.999 = 0.001.$$

Taking the natural logarithm of both sides gives

$$-\frac{t}{\tau} = -6.91.$$

The time to reach 99.9 percent of its final charge is thus

$$t = 6.91\tau = (6.91)(1.00\ \text{ms}) = 6.91\ \text{ms}.$$

What Do You Think? If it takes 6.91 ms to charge the capacitor to 99.9% of its final voltage, how long do you estimate it will take to reach 99.99%?

Summary

Sources of emf (electromotive force) $\mathscr{E}$, such as chemical batteries, are sources of electric energy. The emf is defined by the amount of work it can do to move charge:

$$\mathscr{E} \equiv \frac{dW}{dq}. \tag{27–1}$$

Batteries cause charges to move in circuits. The simplest circuits to analyze are direct-current circuits, in which no circuit parameters change with time.

Analysis of single- or multi-loop circuits is accomplished by the use of Kirchhoff's two rules. Kirchhoff's loop rule states that the sum of the potential changes around a closed path of a circuit is zero:

$$\sum_{\text{closed path}} \Delta V = 0. \tag{27–9}$$

We can specify the potential change across batteries, resistors, and capacitors. Any source of emf has an internal resistance r that may be large enough to require consideration.

Kirchhoff's junction rule is "circuit language" for the conservation of electric current. It states that the sum of the currents that enter a junction equals the sum of the currents that leave the junction. If we interpret an outgoing current as an ingoing current with a minus sign in front of it, then the junction rule takes the simple form:

$$\sum I_{\text{in}} = 0. \tag{27–11}$$

Ammeters, voltmeters, and ohmmeters measure current, voltage, and resistance, respectively. Ammeters must have a small internal resistance so that they do not affect the circuit leg in which the current is measured. Conversely, voltmeters need a large internal resistance because they are used in parallel with the circuit element being measured, and they too should not affect the circuit being measured.

A circuit exhibits time-varying behavior when a capacitor is being charged with a source of emf or when the capacitor is being discharged. For a simple circuit with an emf $\mathscr{E}$, a resistor R, and a capacitor C, an initially uncharged capacitor has charge

$$Q = C\mathscr{E}(1 - e^{-t/RC}) \tag{27–22}$$

and current

$$I = \frac{\mathscr{E}}{R} e^{-t/RC}. \tag{27–23}$$

When the source of emf is disconnected from the circuit and the capacitor is allowed to discharge through the resistor, the charge decreases exponentially:

$$Q = Q_0 e^{-t/RC}. \tag{27–26}$$

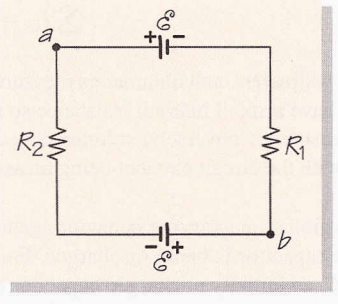
The time constant RC determines the time dependence of exponential increase or decrease of the charge and the current during the charging and discharging of a capacitor.

Understanding the Concepts

1. Why is it dangerous to be in a bathtub when an electrical appliance is standing on the edge of the tub?
2. One voltmeter measures the voltage of a flashlight battery as 0.9 V, whereas another measures 1.5 V. What might cause this difference?
3. Show that it is irrelevant whether, in drawing a circuit diagram, the internal resistance of a source of emf is placed before or after the emf itself.
4. What sense does it make to draw a circuit diagram with resistanceless wires when real wires always have some resistance?
5. By taking a special combination of batteries of constant emf, resistors, and capacitors, is it possible to construct a circuit in which the emf around a closed loop is not zero?
6. You measure a potential difference of 3 V across the terminals of a 3-V battery with some age to it and proclaim it to be just fine. Are you right?
7. A flash unit on a camera discharges by means of an RC circuit. Find out (say, from a local camera store) what the R and C values are, and obtain the RC time.
8. You have an RC circuit and three identical capacitors available to you. How should you arrange them to make the discharge time as short as possible?
9. It would appear superficially that, in Section 27–5, if we had chosen the current in the wrong direction, we would have ended up with the equation $IR - (Q/C) = 0$ rather than Eq. (27–7) to describe the current in an RC circuit. This would be disastrous

because the solution of our new equation would be a rising exponential, $e^{+t/RC}$, rather than a falling exponential, and this expression would grow without limit. What is wrong with this reasoning?

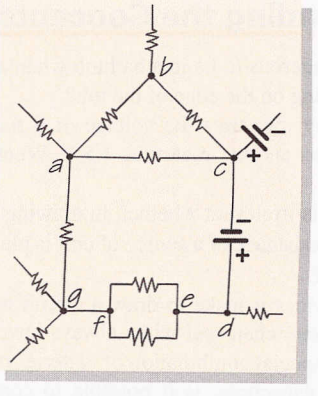
10. When you reverse the polarities of all batteries in a circuit, the magnitudes of all currents stay the same. Why?
11. Given two identical sources of emf and two identical light bulbs, how would you arrange these elements so that both bulbs glow with maximum brightness?
12. Suppose that you connect the terminals of two batteries of different emfs + to + and − to −. What do you expect to happen?
13. What happens if the emf of battery 2 in Example 27–4 is reversed?
14. It might appear that the only effect of the internal resistance of a battery in a circuit is to change the battery's emf from $\mathcal{E}$ to $\mathcal{E}' = \mathcal{E} - Ir$, where $\mathcal{E}'$ acts as though there were no internal resistance. Could this be true? If not, why not?
15. Show that the circuit in Fig. 27–8(a) can be reduced to a one-loop circuit. Is this also true of the circuit in Fig. 27–8(b)?
16. Two reckless teenagers hang by both hands on a wire that can be connected to a constant voltage source. One teenager hangs from a position in which there is a resistor between his hands; the other one does not. The resistance of the resistor is much larger than that of the wire, which is very small. When the wire is connected to the battery, how do the teenagers experience that fact?
17. What happens to the current I_1 of Example 27–7 if the resistance R_3 is increased?
18. To start a car in cold weather, one sometimes first turns the lights on for a while. How could this help?



Problems

27–1 EMF

1. (I) A 12-V car battery is rated at 80 A, meaning that it will send 80 A through a wire connected to its terminals. What is its internal resistance?
2. (I) The *Magellan* spacecraft that studied Venus in 1990 used two solar panels capable of producing 1200 W. If the solar array was capable of producing a total of 40 A, what was the terminal voltage of the device?
3. (I) A battery with an emf of 3.00 V sends a current of 1.99 A when it is connected in series with a 1.50-Ω resistor. What is the internal resistance of the battery?
4. (I) Nickel–cadmium batteries used in space flight are rated at 30 A · h (they can put out 30 A for 1 hr) and 30 V. How much energy do the batteries contain?
5. (I) A defibrillator used by emergency medical staff to restart an accident victim's heart has an internal resistance of 20 Ω, and a power supply that produces an average 5000 V over a short period of time. If the body resistance between the two electrodes is 230 Ω, how much current passes through the body to restart the heart?
6. (II) A flashlight battery with an internal resistance of 0.06 Ω produces a 170-mA current through a 15-Ω resistor. What is the emf of the battery? What is the terminal voltage of the battery in this usage?
7. (II) A certain automobile battery has an emf of 12 V. When it produces a current of 100 A, the terminal voltage reads 9.0 V. Calculate the internal resistance of the battery. What is the power dissipated in the battery when it produces this current?
8. (II) The resistance of the starter of a car, including the cables, is 0.11 Ω. On a frigid winter morning, cranking the engine for 10 s reduces the terminal voltage of the car's 12-V battery to 8 V. The car does not start. How much heat (in kilocalories) is produced in the battery during this time? Does it improve your chances of starting the car on a second try?
9. (II) The internal resistance of a battery whose emf is 12 V varies with the current according to the equation $r = (\alpha + \beta I)$, where $\alpha = 0.15\ \Omega$ and $\beta = 0.018\ \Omega/\text{A}$. Find the terminal voltages and the power dissipated in the battery when $I = 1.0$ A and $I = 10$ A.

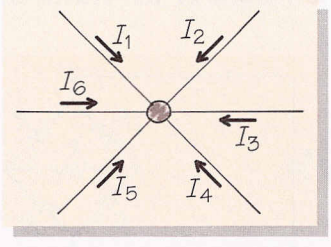


27–2 Kirchhoff's Loop Rule

10. (I) Two bulbs in series are connected across an emf of 110 V. The normal operating ratings of the bulbs are given as (2.5 V, 0.5 A) for one bulb and as (110 V, 10 W) for the other. Calculate how much power will actually be developed in each lamp.
11. (I) For what value of R_2 in the circuit of Fig. 27–24 is the voltage across the points a and b zero? For what value is the current in the circuit zero?

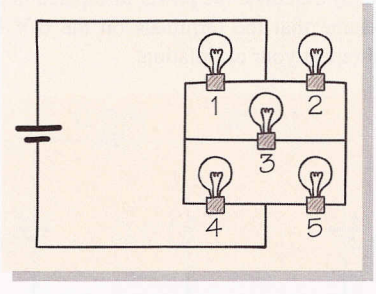
▲ **FIGURE 27–24** Problem 11.

12. (II) A generator (a "battery" that uses mechanical rather than chemical energy) of emf 110 V and internal resistance 0.50 Ω is used to charge a series of 20 batteries, each with emf 2.2 V and internal resistance 0.06 Ω. A series resistor is used to limit the charging current. (a) What is the terminal voltage of the generator? (b) the terminal voltage of the bank of batteries? (c) What series resistance must be included to allow a charging current of 15 A? (d) What is the power dissipated in all the resistors?
13. (II) A portion of a larger circuit is shown in Fig. 27–25. The potential drop between the pairs of points labeled in the figure is $V_{ba} = 2$ V, $V_{cb} = 3.5$ V, $V_{cd} = 2$ V, and $V_{df} = -0.5$ V. Find the potential differences V_{gf}, V_{ag}, and V_{ca}.



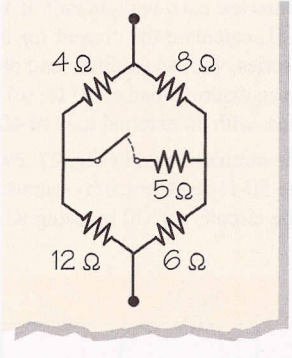
▲ **FIGURE 27–25** Problem 13.

14. (II) A flashlight consists of two 1.5-V batteries connected in series to a bulb with resistance 10 Ω. (a) What is the power delivered to the bulb? (b) Batteries run down when they acquire an (internal) resistance. How large is the additional resistance if the power delivered to the bulb has decreased by one-third of its initial value?



27–3 Kirchhoff's Junction Rule

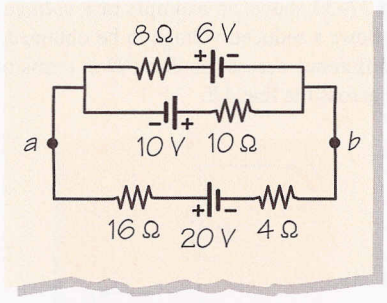
15. (I) In Fig. 27–26, the currents $I_1 = 2$ A, $I_2 = 0.5$ A, $I_3 = -3$ A, $I_4 = -0.5I_6$, and $I_5 = -I_6$. Find the unknown currents I_4, I_5, and I_6.



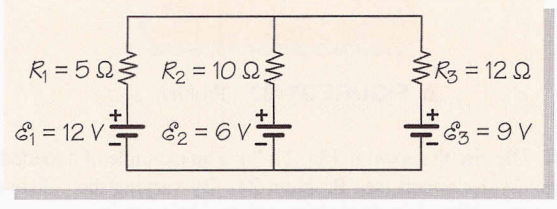
▲ FIGURE 27–26 Problem 15.

16. (I) Five identical lightbulbs are placed in a circuit as shown in Fig. 27–27. What is the brightness of bulb #3 relative to bulb #1? Even though this problem can be worked without them, use the Kirchhoff rules.

▲ FIGURE 27–27 Problem 16.



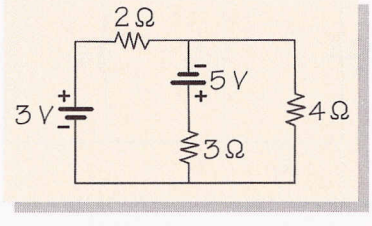
17. (II) Consider the part of a circuit shown in Fig. 27–28. What is the total resistance if (a) the switch is open, and (b) the switch is closed?



▲ FIGURE 27–28 Problem 17.

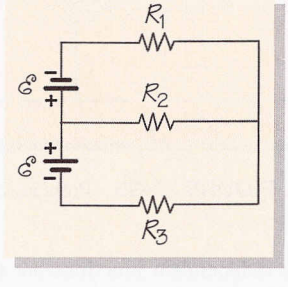
18. (II) Consider the circuit in Fig. 27–29. Calculate the current through the 16 Ω resistor, and the voltage across *ab*.

19. (II) Find the current that passes through each of the resistors in the circuit shown in Fig. 27–30.



▲ FIGURE 27–29 Problem 18.

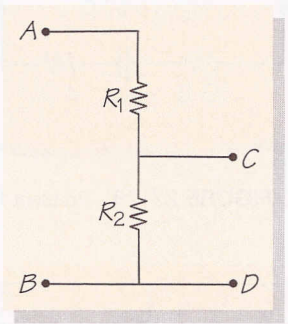
▲ FIGURE 27–30 Problem 19.



20. (II) Find the current that passes through the 4-Ω resistor in the circuit shown in Fig. 27–31.

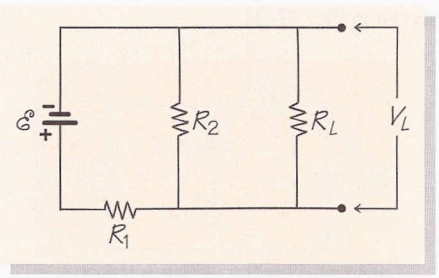
▲ FIGURE 27–31 Problem 20.

21. (II) Three resistors connected in parallel have resistances of 250 Ω, 420 Ω, and 510 Ω, respectively. The total current passing through the set is 0.020 A. What is the potential difference across the set, and what are the currents in each of the resistors?



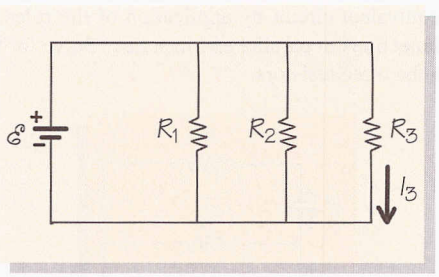
22. (II) Can the resistors of the circuit in Fig. 27–32 be reduced to a single equivalent circuit by application of the rules for circuits with connections in parallel and in series? Solve for the currents through the three resistors.

▲ FIGURE 27–32 Problem 22.



23. (II) N identical batteries, with emf $\mathcal{E}$ and internal resistance r, are connected in parallel across a resistance R. Obtain the value for the current, and compare its value with that obtained if the batteries are connected in series.

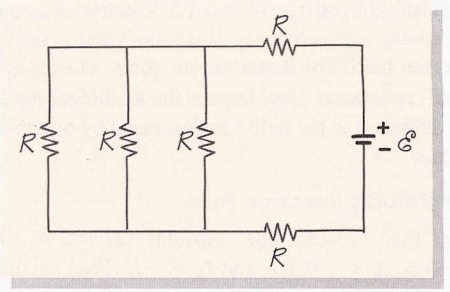
24. (II) Figure 27–33 shows an example of a *voltage divider*, a device that allows a reduced voltage to be obtained. Calculate the potential difference across the line CD in terms of the potential difference across the line AB.



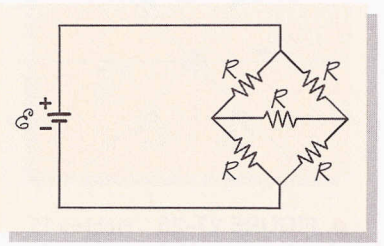
▲ **FIGURE 27–33** Problem 24.

25. (II) The circuit shown in Fig. 27–34 is an example of a loaded voltage-divider circuit (see Problem 24). By varying the values of R_1 and R_2, different values of V_L can be obtained; R_L represents the load. Let $R_1 = R_2 = 3.3\ \text{k}\Omega$ and $\mathscr{E} = 10$ V. For load resistances of 20 kΩ, 200 kΩ, and 2 MΩ, how much different is V_L than 5 V?

▲ **FIGURE 27–34** Problem 25.



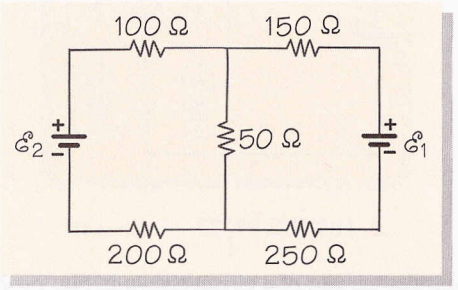
26. (II) Consider the circuit shown in Fig. 27–35. If $\mathscr{E} = 2.8$ V, and if all three resistors have identical resistances, find the resistance that ensures that the current I_3 will be 55 mA. Even though this problem can be worked without them, use the Kirchhoff rules.



▲ **FIGURE 27–35** Problem 26.

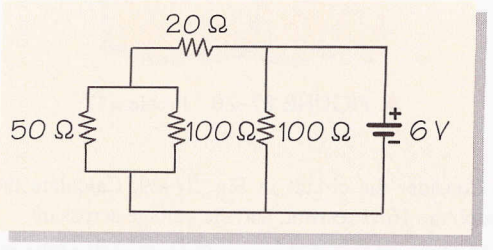
27. (II) How many independent junctions are there in the circuit shown in Fig. 27–36? To verify your answer, solve for all currents.

28. (II) Replace the network of resistors in Fig. 27–37 by a single equivalent resistor. Can the combination of resistors be reduced to a single resistor by successive application of the rules for parallel and series resistors?



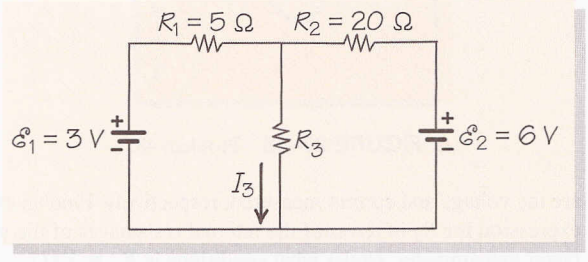
▲ **FIGURE 27–36** Problem 27.

▲ **FIGURE 27–37** Problem 28.



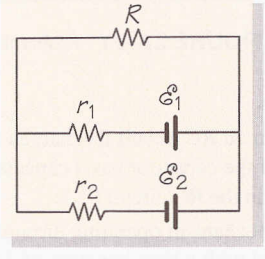
29. (II) Two batteries with emf $\mathscr{E}_1 = 6$ V and $\mathscr{E}_2 = 9$ V, respectively, are connected to resistors with the resistances as marked in Fig. 27–38. (a) Calculate the power dissipated in the 50-Ω resistor. (b) Assume that the terminals on the 6-V battery are reversed, and repeat your calculation.

▲ **FIGURE 27–38** Problem 29.



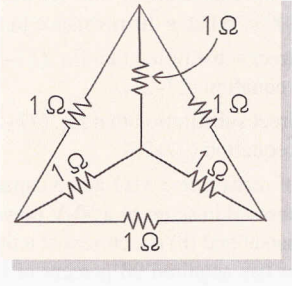
30. (II) Given 20 batteries, each with an emf of 12 V and an internal resistance of 2 Ω, calculate the current for the following cases: (a) batteries in series, with an external load of 80 Ω; (b) batteries in parallel, with an external load of 20 Ω; (c) 4 parallel rows of 5 batteries in series, with an external load of 40 Ω.

31. (II) Consider the circuit shown in Fig. 27–39. Calculate the current through the 50-Ω resistor (a) by calculating the equivalent resistance for the circuit, and (b) by using Kirchhoff's rules.



▲ **FIGURE 27–39** Problem 31.

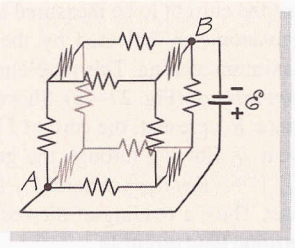
32. (II) The known elements of the circuit in Fig. 27–40 are indicated. Find the value of R_3 that will give a current I_3 of 0.1 A with the indicated sign. Is there a value of R_3 that will give a current I_3 of the same magnitude but of opposite sign? If so, what is it?



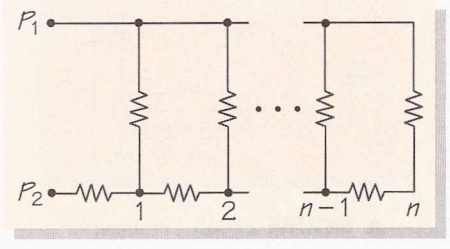
▲ FIGURE 27–40 Problem 32.

33. (II) Two batteries are connected in parallel as in Fig. 27–41 and supply current to a load resistor of 5 Ω. One of the batteries is freshly charged, with an emf of $\mathcal{E}_1 = 12$ V and an internal resistance of $r_1 = 0.1\ \Omega$. The other one is almost dead, with an emf of $\mathcal{E}_2 = 10$ V and an internal resistance of $r_2 = 10\ \Omega$. What is the current through the load resistor? How much of this current is supplied by each of the batteries?

▲ FIGURE 27–41 Problem 33.



34. (III) Consider a tetrahedron whose sides consist of identical wires, each with resistance 1 Ω (Fig. 27–42). Suppose that this arrangement is attached at two of its corners to a generator with potential 4 V. What is the power dissipated in each of the wires?



▲ FIGURE 27–42 Problem 34.

35. (III) A cube consisting of identical wires, each of resistance R, is put across a line with voltage V (Fig. 27–43). What is the equivalent resistance of the cube? What is the current in each of the wires?

36. (III) Figure 27–44 shows a ladder of resistors with n rungs. (a) Find the equivalent resistance between points P_1 and P_2 for $n = 1$; (b) for $n = 2$; (c) for $n = 3$; (d) for the limit $n \to \infty$. [*Hint*: Write an expression for R_n (the equivalent resistance of a ladder of n rungs) in terms of R_{n-1} (the equivalent resistance of a ladder of $n - 1$ rungs) and R, and use that equation in the limit $n \to \infty$.]

▲ FIGURE 27–43 Problem 35.

▲ FIGURE 27–44 Problem 36.

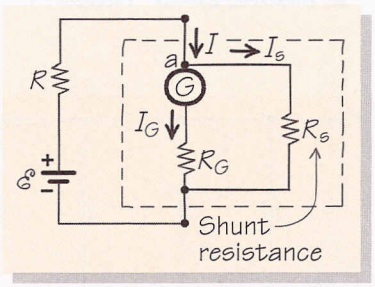
27–4 Measuring Instruments

37. (I) Look at Example 27–9 again, with emf = 6 V, $R_1 = 1400\ \Omega$, and $R_2 = 10\ k\Omega$. Calculate the voltage across R_1 for the two cases of when the voltmeter's internal resistance is 200 kΩ and 10 MΩ.

38. (I) A voltmeter with an internal resistance of 60 kΩ measures the voltage of a D-cell flashlight battery (of nominal voltage 1.5 V) as 1.45 V. What is the internal resistance of the battery?

39. (I) Currents produced with a 12-V source of emf and a range of resistances from 10 Ω to 1000 Ω are to be measured to an accuracy of at worst 0.1 percent with an ammeter. How small must the resistance of the ammeter be?

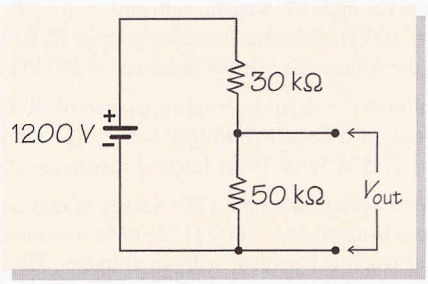
40. (I) A voltmeter is to be used to measure the voltage across a range of resistances from 5 Ω to 5000 Ω. What is the minimum value of the internal resistance of the voltmeter such that a measurement can be carried out to 0.1 percent accuracy?



41. (I) A certain voltmeter has an internal resistance of $10^5\ \Omega$. The voltmeter is used to measure the potential drop across resistors of (a) 10 Ω, (b) $10^5\ \Omega$, and (c) 100 MΩ. In each case, what is the equivalent resistance of the voltmeter and the resistor across which it is placed? (The voltmeter is a suitable one if this equivalent resistance is as close as possible to the resistance of the resistor across which the potential drop is measured.)

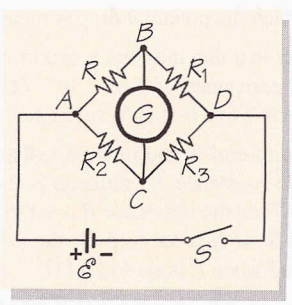
42. (II) An ammeter that can measure a maximum current of 5 mA has an internal resistance of $1.8 \times 10^{-4}\ \Omega$. What series resistance will convert it to a 0-to-3-V voltmeter?

43. (II) A battery with emf $\mathcal{E}$ and internal resistance r is connected across a variable resistance. A voltmeter is also connected across the resistance. When the resistance R is set to 20 Ω then the voltmeter reads 23 V; if R is set to 5 Ω, the voltmeter reads 16 V. What will it read when R is set to 50 Ω?



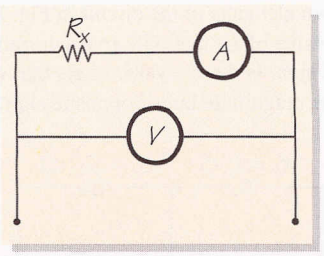
44. (II) A galvanometer whose resistance is 20 Ω will go through its full deflection when a current of 2×10^{-4} A flows through it. What would you do to have its full deflection occur for a current of 2×10^{-3} A? What would you have to do to make it into a voltmeter so that the full deflection corresponds to 0.2 V?

45. (II) Suppose that the current to be measured by an ammeter is so large that a galvanometer deflected by the current would be pinned at its maximum reading. This problem can be resolved by the use of a *shunt resistor* (Fig. 27–45). Show that with the shunt resistor (resistance R_s) present, the current I is given in terms of a reduced current I_G flowing through the galvanometer by the formula $I = I_G[1 + (R_G/R_s)]$, where R_G is the resistance of the galvanometer. Thus, a reading of the reduced current I_G allows us to determine the current I.



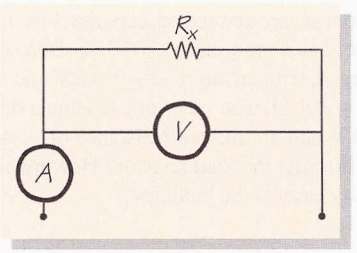
▲ FIGURE 27–45 Problem 45.

46. (II) The output of the voltage-divider network shown in Fig. 27–46 is to be measured with two voltmeters of internal resistances 500 kΩ and 100 MΩ, respectively. What voltage will each indicate?



▲ FIGURE 27–46 Problem 46.

47. (II) A *Wheatstone bridge* is a device that measures resistances. In the circuit shown in Fig. 27–47, R is an unknown resistance. The resistances R_1, R_2, and R_3 are variable. A galvanometer, G, can be used to determine when the potential difference between B and C is zero, given that the battery is connected between A and D. The variable resistances are varied until there is no current in the galvanometer when the circuit is closed at the switch S. Obtain an expression for R in terms of R_1, R_2, and R_3.



▲ FIGURE 27–47 Problem 47.

48. (II) The circuit shown in Fig. 27–48 is used to measure the resistance R_x. Draw the circuit including internal resistances. V and I are the voltage and current measured, respectively. Find an exact expression for R_x in terms of the internal resistances of the voltmeter and ammeter. Under what conditions is $R_x = V/I$?

▲ FIGURE 27–48 Problem 48.

49. (II) Repeat Problem 48 for the circuit shown in Fig. 27–49.

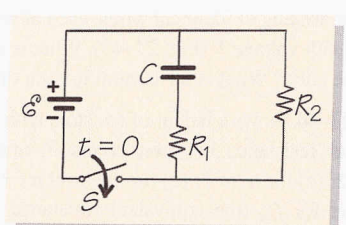
▲ FIGURE 27–49 Problem 49.

27–5 *RC* Circuits

50. (I) A flashbulb in an *RC* circuit discharges with a time constant of 5×10^{-4} s. If the capacitor has a capacitance of 16 μF, what is the resistance in the *RC* circuit?

51. (I) A flashbulb mechanism operating through an *RC* circuit has a capacitor charged with a time constant of 2.0 s. If the resistance in the *RC* circuit is 10^5 Ω, what is the capacitance of the charging mechanism?

52. (I) Show that the product *RC* has units of seconds. Find the time constants for the following values of R and C: 5 MΩ, 30 μF; 8 kΩ, 3 μF; 20 Ω, 50 pF.



53. (I) The flash attachment of a camera has a capacitance of 600 μF. The flash time—the characteristic time for the discharge of the capacitor—is 1/500 s. What is the resistance in the *RC* circuit?

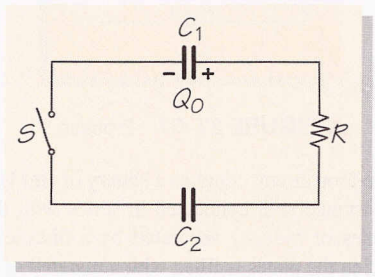
54. (II) Show by direct substitution that Eq. (27–22) is a solution for the differential equation (27–21).

55. (II) Show by direct substitution that Eq. (27–26) is a solution for the differential equation (27–25).

56. (II) A resistor of resistance 3 MΩ and a capacitor of capacitance 350 μF are connected in series to a 50-V power supply. Calculate (a) the time constant and (b) the current at a time when the charge on the capacitor has acquired 90 percent of its maximum value.

57. (II) Calculate the current in the battery as a function of time for the circuit shown in Fig. 27–50 if the switch S is closed at time $t = 0$.

▲ FIGURE 27–50 Problem 57.



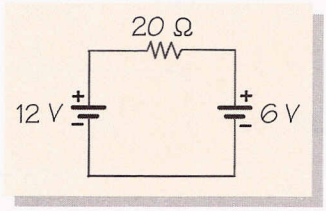
58. (II) The circuit of Fig. 27–19 has $\mathcal{E} = 200$ V, $R = 350\ \text{k}\Omega$, and $C = 20\ \mu\text{F}$. What are the voltage across the resistor and the charge on the capacitor 4 s after the switch is closed to position *a*?

59. (II) You have two capacitors of capacitance 5 μF and three resistors, one of resistance 250 Ω and the remaining two of resistance 300 Ω. Find the connection between these elements that will make a circuit whose time constant is 1 ms.

60. (II) Show that the time constant of a parallel-plate capacitor filled with a dielectric with a finite resistivity is independent of the area and separation of the plates.

61. (II) Polycarbonate, a so-called polar polymer, is a material with a dielectric constant $k = 3.2$. It has a resistivity $\rho = 2 \times 10^{14}\ \Omega \cdot \text{m}$. Suppose that it is used to fill the space in a parallel-plate capacitor of area $0.03\ \text{m}^2$ and plate separation 0.50 mm. A charge of $Q = 2\ \mu\text{C}$ is placed on the plates of the isolated capacitor. How long does it take for 70 percent of the charge to leak away?

62. (III) A capacitor C_1 is charged to Q_0 and connected to an uncharged capacitor C_2 via the resistor R (Fig. 27–51). Find the charge on each capacitor as a function of time, assuming that the switch is closed at $t = 0$.



▲ **FIGURE 27–51** Problem 62.

General Problems

63. (I) Imagine that a household circuit uses direct current. Compare the current drawn from the main supply at 120 V if three household appliances of resistances 50 Ω, 60 Ω, and 20 Ω, respectively, are connected in parallel. (The appliances would not work in series, because each appliance requires a voltage drop of 120 V. Actual household circuits use alternating currents; see Chapter 33.)

64. (II) Consider the circuit shown in Fig. 27–52, in which a 12-V battery is used to charge a 6-V battery. The resistance in the circuit is 20 Ω. Calculate (a) the current in the circuit; (b) the rate at which the energy of the smaller battery increases; (c) the total rate of energy dissipation in the resistor.

▲ **FIGURE 27–52** Problem 64.

65. (II) A student has a wide range of resistors, all rated for 5 W. How can a student combine identical resistors to obtain an effective resistance of 100 Ω rated for 30 W?

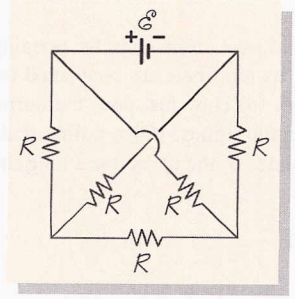
66. (II) If a battery of fixed emf and internal resistance r is connected to an external resistor of resistance R, show that the maximum power delivered to the external resistor occurs when $R = r$.

67. (II) Automobile batteries typically have 12.6 V output and an internal resistance of 0.05 Ω. They have a rating of ampere-hours, which demonstrates how long they can produce suitable currents for 20 hours. A good battery has a rating of 75 A · hr. The battery is charged at the rate of 2.5 A for 10 hours. (a) How much current is the battery capable of providing? (b) What is the voltage across the battery terminal during recharging? (c) What total electrical energy is stored in the battery after recharging?

68. (II) Suppose you have n identical batteries, each with emf $\mathcal{E}$ and internal resistance r. The cells may be placed in series, or in parallel across a load resistance R. Which arrangement should you use to maximize the current through the external resistor? Does your answer depend on how large r is?

69. (II) The battery considered in Problem 9 is connected to a load resistor R. Calculate and plot the current in the circuit as a function of R in the range $R = 0$ (short circuit) to $R = 5\ \Omega$. Plot the ratio of the power delivered to the load to that dissipated in the internal resistance of the battery.

70. (II) When separately connected across a line with voltage V, two resistors generate power P_1 and P_2, respectively. What is the power generated when the two resistors are connected in series? In parallel?

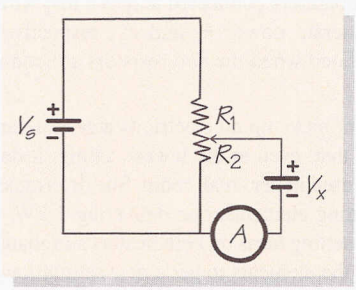


71. (II) A student picks up an electric heater at a yard sale. She discovers later that, even at the lowest setting, it delivers too much power to be used in her small room. She determines that the heater has two heating elements, one delivering 1 kW, the other 2 kW. The highest setting turns on both heaters simultaneously. How can she connect the elements to get a new setting lower than the lowest setting, and what is the power output for the new setting?

72. (II) A resistor R forms a single loop with an arrangement of two batteries of emf $\mathcal{E}$ and internal resistance r. The batteries are arranged (a) in series and (b) in parallel. Find the current through the resistance in both cases. Which arrangement gives the larger current for large R? for small R?

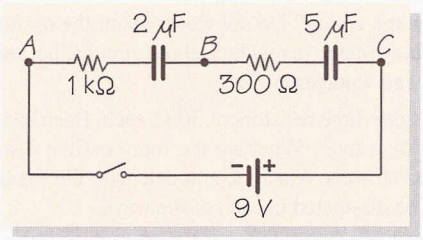
73. (II) An 800-W kitchen mixer, a 600-W vacuum cleaner, and a chandelier with 10 60-W bulbs are all plugged into the same outlet in a 120-V circuit. A *fuse* acts as a switch that opens if the current exceeds 15 A. How much current does each device draw? What is the minimum number of screwed-in bulbs that will blow the circuit? Do not worry about the oscillations of the current and voltage in real household circuits, but assume that all currents and voltages are DC.

74. (II) Consider three resistors of 30 Ω each. Each resistor can dissipate 2 W at most. What are the four possible distinct ways of arranging all three resistors, and calculate the maximum power that can be dissipated in each of the ways.



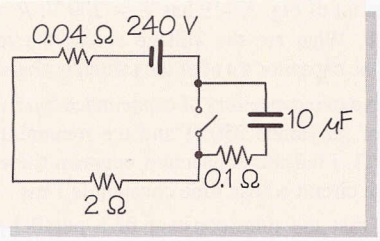
75. (II) Find the currents in each leg of the circuit shown in Fig. 27–53.

▲ **FIGURE 27–53** Problem 75.



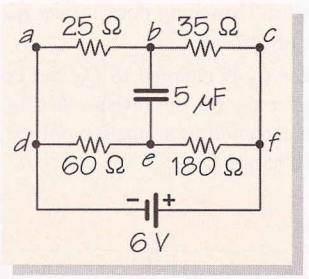
76. (II) By using Table 26–2, compare the current density, electric field strength, and power loss in two cylindrical wires of the same length and same radius, one made of aluminum and the other made of copper. The wires are connected (a) in series and (b) in parallel. (c) If wires of a given length and radius were constructed from all the materials listed in Table 26–2, and if the same current were passed through each, which wire would have the largest current density, the weakest electric field, and the least power loss? Assume throughout that the temperature dependence is unimportant.

77. (II) A simple *potentiometer* circuit used to measure unknown voltages accurately is shown in Fig. 27–54. Here V_s is the known source voltage, V_x is the unknown voltage, and the resistor is a variable one from which the values R_1 and R_2 can be read from the position of the pointer. These resistances are varied until the current in the ammeter is zero. Show that the unknown voltage then has the value $V_x = V_s R_2/(R_1 + R_2)$.



▲ FIGURE 27–54 Problem 77.

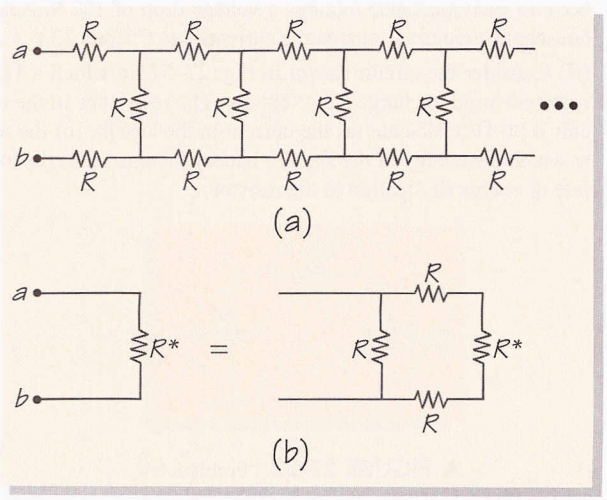
78. (II) Two resistors and two capacitors are connected in series to a battery as shown in Fig. 27–55. Calculate the potential at B relative to that at A: (a) shortly after the closing of the switch and (b) a long time after the closing of the switch. (c) How fast does the circuit reach a steady state? (Give a time scale.)



▲ FIGURE 27–55 Problem 78.

79. (II) To avoid sparks accompanying the opening of a high-current circuit breaker, its terminals are connected to a large capacitor, as in Fig. 27–56. (a) How fast does the current decrease in the circuit shown in the figure? (Give a time scale.) (b) What is the charge on the plates of the capacitor a long time after the switch is opened?

▲ FIGURE 27–56 Problem 79.



80. (II) The circuit shown in Fig. 27–57 has been established for a long time. (a) What is the charge on the capacitor? Indicate which plate carries the positive charge and which one carries the negative charge. (b) Calculate the current flowing through the 35-Ω resistor.

▲ FIGURE 27–57 Problem 80.

81. (II) A single-loop circuit contains a battery of emf V_0 and negligible internal resistance and, connected in series with the battery, two circular plates of radius r separated by a distance $d \ll r$. The space between the plates is filled with a material of conductivity σ and dielectric constant 1. (a) What is the electric field between the two plates? (b) What is the current flowing in the circuit?

82. (III) Consider the infinite network of resistors shown in Fig. 27–58a. Calculate the resistance R^* of the network by noting that with an infinite set of resistors, adding one more rung to the ladder does not change the resistance. Thus the network may be broken up as shown in Fig. 27–58b.

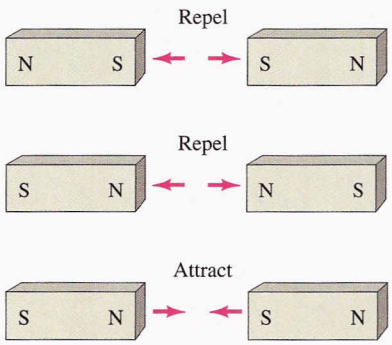
Chapter 28



◀ The aurora is a phenomenon that depends on the existence of Earth's magnetic field. When the stream of charged particles known as the solar wind enters Earth's atmosphere under the influence of Earth's magnetic field, its interaction with the atoms of the upper atmosphere produce excitations that lead to the emission of light: the aurora.

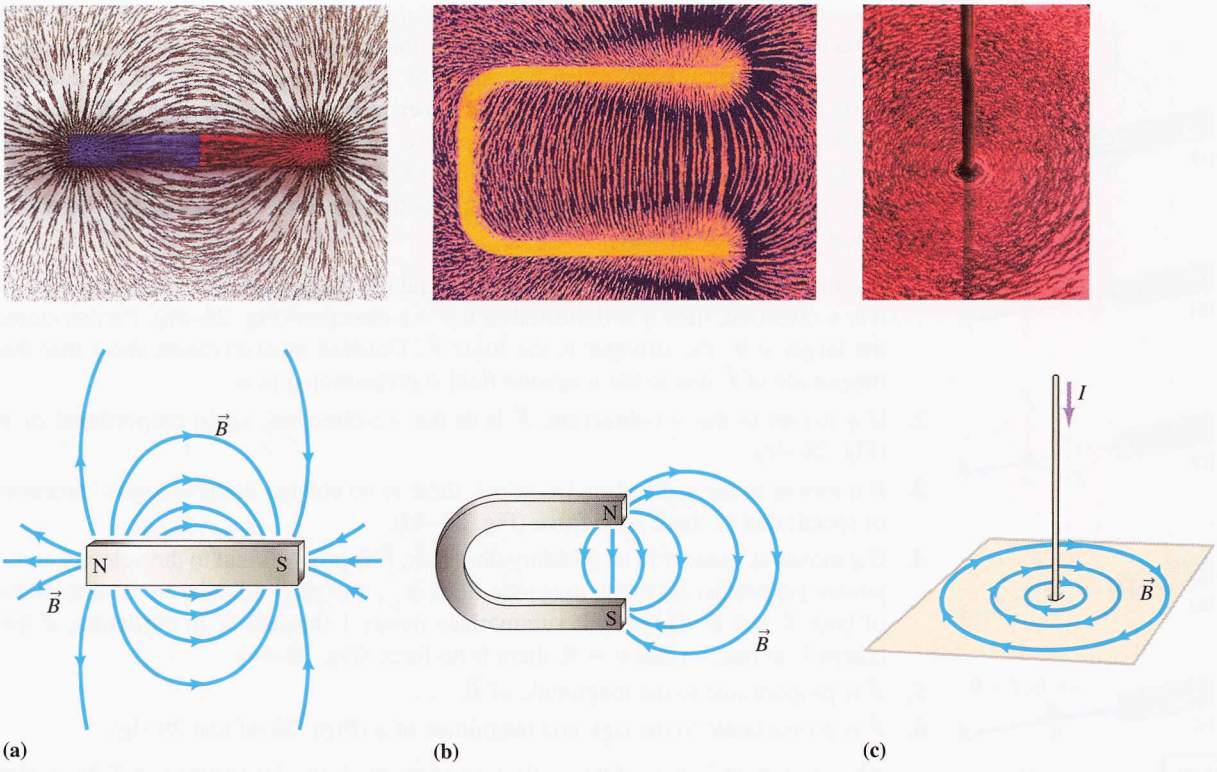
The Effects of Magnetic Fields

We are all familiar with magnets. Sailors have used navigational compasses made from treated iron or lodestone—the natural mineral magnetite—for at least 800 years, and possibly far longer. The behavior of compass needles was systematically studied around the year 1600 by William Gilbert, an English physician. He correctly suggested that the action of a compass is a manifestation of magnetic forces. These forces arise because Earth is itself a giant lodestone, or magnet. Magnetism was not associated with electricity until 1820, when André Ampère used his own experiments and those of Hans Christian Oersted to show that magnetic effects arise when electric charges move. In the 1820s, Michael Faraday uncovered another connection between electricity and magnetism, but it was James Clerk Maxwell who, in the late 1860s, made the ultimate synthesis of electricity and magnetism. We now know that electrical and magnetic phenomena are both aspects of the interactions of electrically charged objects. The synthesis of electricity and magnetism is described entirely by Maxwell's equations, and our understanding of light and other electromagnetic waves rests on Maxwell's great achievement. Maxwell's equations, together with Newton's work, the ideas of thermodynamics, and Einstein's special theory of relativity, summarize virtually all of classical physics. In Chapters 28 to 34 we shall study magnetic phenomena, their connection to electrical phenomena, their practical applications, and other remarkable consequences of Maxwell's equations.

In this chapter we describe the laws of magnetic forces through experiments involving magnets and electric currents. We'll also learn how magnetic forces are associated with magnetic fields, just as electric forces are associated with electric fields. We will here concentrate on the effects of magnetic fields on test objects, leaving the description of how magnetic fields are generated for the next chapter.

28–1 Magnets and Magnetic Fields

▲ **FIGURE 28–1** Bar magnets exert magnetic forces on each other.



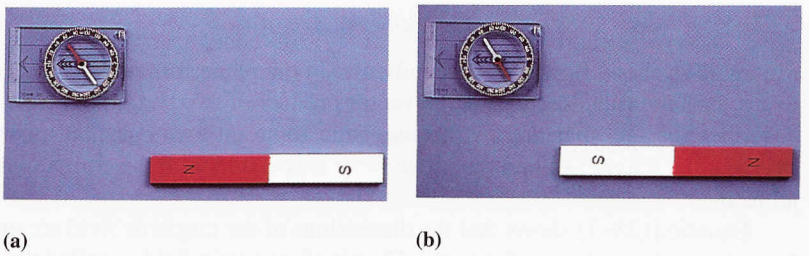
When two bar **magnets** are brought close to each other, the forces between them—**magnetic forces**—become evident. These forces are of a type we have not yet encountered. In some positions they attract each other, while in other positions they repel (Fig. 28–1); in still other positions, they exert torques on each other. These forces suggest that bar magnets have an orientation, or an axis. We arbitrarily label the end of a magnet that is attracted to a point very near Earth's geographic South Pole as the *south pole*, S, while the other end of the magnet is called the *north pole*, N. If we experiment with two bar magnets labeled in this way, we find that the N end of one attracts the S end of the other, whereas the two N ends repel each other, as do the two S ends, as Fig. 28–1 shows. (The fact that the south pole of a bar magnet is attracted toward Earth's South Pole means that Earth's South Pole actually behaves like the north pole of a magnet! Similarly, Earth's North Pole behaves like the south pole of a magnet. These labelings are of course historical artifacts.) Based on our experience with charges, we might be tempted to conclude that a bar magnet contains "magnetic charges" (or *magnetic monopoles*) at each end and, further, that we could somehow extract them. A little bit of experimentation suggests that this is not possible; when you break a bar magnet in two, you end up with two bar magnets, not two separated magnetic charges. (Magnetic monopoles remain, nevertheless, the subject of modern searches.)

Iron and a few other materials (all known as *ferromagnetic* materials) have a particular property: If we place a piece of iron, for example, near a lodestone (a "natural" magnet), the piece of iron also becomes a magnet. Later we'll discuss the reasons why this occurs. For now we note that we can use this property to turn tiny shavings of iron (iron filings) into tiny magnets that can be used as test probes of magnetic forces.

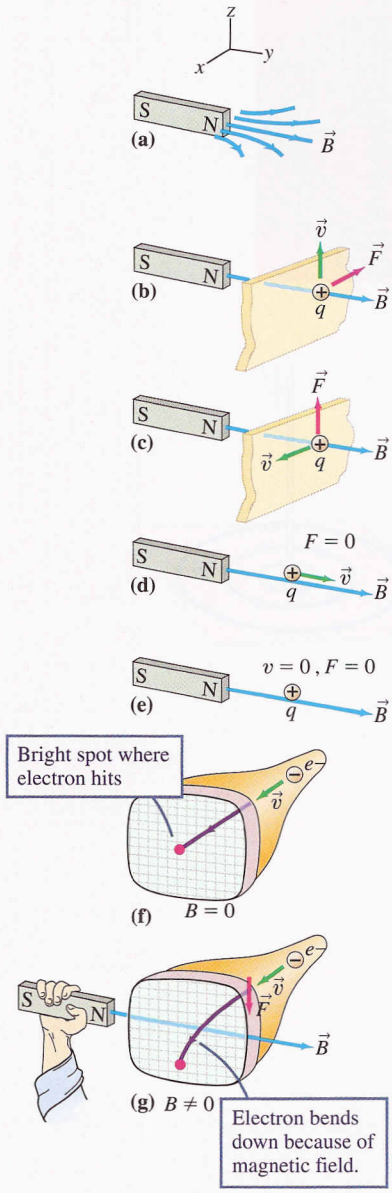
Magnetic Fields

If we scatter iron filings on a sheet of plastic above a bar magnet, as in Fig. 28–2, the magnetic forces acting on them line up the iron filings in certain directions, which are dependent on their position in relation to the magnet. Moreover, the filings clump more densely in certain regions, such as near the poles. For different magnets, the scattered filings have different densities and alignments. Figure 28–2 shows the distribution of iron filings around a straight bar magnet, a horseshoe magnet, and—surprise!—a wire that carries current. This last example is a clue that magnetic forces are associated with moving charges as well as with magnets. The magnetic force acts at a distance, just like gravitational and electric forces. Just as an object with mass sets up a gravitational field and a charged object sets up an electric field, a magnet, a moving charge, or an electric current sets up a **magnetic field** throughout space. We denote this field with the symbol $\vec{B}$. The bar magnet, horseshoe magnet, and current-carrying wire each set up a characteristic magnetic field. Magnetic forces have a marked directional character, and the magnetic field, like the electric field, is a vector.

How do we find the magnetic field due to a magnet or a current? Just as an electric field can be mapped with a small test charge, the response of iron filings to the presence of a magnet or a current can be used to map out the magnetic field. The magnetic field $\vec{B}$ is oriented along the alignment direction of the filings, and the magnitude of $\vec{B}$ is proportional to the density of the filings. (Actually, the density-magnitude connection is only an approximation, which we will refine later.) We can picture the magnetic field by using magnetic field lines—continuous lines that run parallel to the direction of the field at every point and whose density (the number of lines per unit area) is proportional to the strength of the field, in analogy to electric field lines representing electric fields. As an example of this mapping process, take a look at Fig. 28–2a



▲ **FIGURE 28–2** Iron filings map the magnetic field for (a) a straight bar magnet, (b) a horseshoe magnet, and (c) a current-carrying wire.



and b: The iron filings align themselves between the poles of magnets, and, therefore, the magnetic field lines associated with the magnet run from pole to pole. We take the direction of the magnetic field of a magnet to run *from the N pole to the S pole*, just as we assign the electric field to run from positive electric charges to negative charges. Notice, however, that the magnetic field around a current-carrying wire has no magnetic pole—it has no starting or ending point. Once we have mapped out a magnetic field in this way, or by the technique of Fig. 28–3, we can further investigate its effects and find the force laws associated with magnetism.

28–2 Magnetic Force on an Electric Charge

Experiments show that compass needles or iron filings are not the only objects to experience forces in the presence of magnetic fields. Moving charged particles also experience forces due to magnetic fields. The effect of a magnetic field on electric charge is most easily studied by using a bar magnet to deflect the electron beam of an oscilloscope. When a bar magnet is placed in different orientations near the beam, the beam deflects in various ways. The deflection allows us to measure the magnetic forces on the beam.

◀ **FIGURE 28–3** A compass needle is sensitive to a magnetic field and can be used to map the field due to a magnet.

▲ **FIGURE 28–4** (a) The magnetic field of a bar magnet will be used to influence a moving charge. (b)–(e) Experiments on a positive charge moving in a magnetic field. (f) An oscilloscope can be used to measure the effects of a magnetic field on moving negative charges, here an electron in a cathode-ray tube. (g) In the orientation shown the electron is deflected down, whereas for the positive charge in part (c) the force was upward.

Consider a bar magnet with its N pole oriented so that the magnetic field is in the $+y$-direction (Fig. 28–4a). The magnitude of the magnetic field at the position of a moving electric test charge q can be varied by altering the distance of the magnet from the charge. The results of a series of experiments are shown in Fig. 28–4, with the deflected particle chosen to have a *positive* charge. (If the actual experiment is done with an oscilloscope, keep in mind that the test charge, a moving electron, has a negative charge.) We observe the following (below the list, we summarize these observations in a different way):

1. If q moves at speed v in the $+z$-direction and the magnetic field points in the positive y-direction, then q is deflected in the $-x$-direction (Fig. 28–4b). Furthermore, the larger v is, the stronger is the force $\vec{F}$. Detailed measurements show that the magnitude of $\vec{F}$ due to the magnetic field is proportional to v.
2. If q moves in the $+x$-direction, $\vec{F}$ is in the $+z$-direction, again proportional to v (Fig. 28–4c).
3. If q moves in the y-direction ($+$ or $-$), there is no change in the charge's direction or speed; that is, there is no force (Fig. 28–4d).
4. If q moves at speed v in an arbitrary direction, $\vec{F}$ is proportional to the velocity component perpendicular to the magnetic field, $v_\perp$, and perpendicular to the directions of both $\vec{v}$ and $\vec{B}$. This result summarizes points 1 through 3. In particular, if the charge is at rest, so that $v = 0$, there is no force (Fig. 28–4e).
5. $\vec{F}$ is proportional to the magnitude of $\vec{B}$.
6. $\vec{F}$ is proportional to the sign and magnitude of q (Figs. 28–4f and 28–4g).

One important feature of this collection of results is the dependence on $\vec{v}$. In results 1 and 2, the initial velocity is purely in the z- or x-directions and is therefore perpendicular to $\vec{B}$. In result 4, there is no $\vec{v}$ and also no force. A stationary charge in a magnetic field experiences no force. Moreover, Figure 28–4 indicates that the force is always perpendicular to both $\vec{v}$ and $\vec{B}$.

To summarize:

The magnetic force $\vec{F}$ on a moving charge is proportional in magnitude to q, $v_\perp$, and B, where $\vec{v}_\perp$ is the velocity component perpendicular to the field, while the direction of $\vec{F}$ is perpendicular to both $\vec{B}$ and $\vec{v}$ and depends on the sign of q.

A direction perpendicular to both $\vec{v}$ and $\vec{B}$ can be represented by the *vector product*, or *cross product*, which was discussed extensively in Chapter 10 in connection with torques and rotational motion (see the problem-solving techniques box, p. 284). Recall that a vector $\vec{c} = \vec{a} \times \vec{b}$ (the vector product of $\vec{a}$ and $\vec{b}$) has magnitude $ab \sin\theta$, where θ is the angle between vectors $\vec{a}$ and $\vec{b}$ and is always taken to be less than 180° (Fig. 28–5). Vector $\vec{c}$ is perpendicular to both $\vec{a}$ and $\vec{b}$, in a direction determined by the right-hand rule. Thus our experiments have determined that the magnetic force on a test charge q moving with velocity $\vec{v}$ in a magnetic field $\vec{B}$ is given by

$$\vec{F} = q\vec{v} \times \vec{B}. \qquad (28\text{–}1)$$

MAGNETIC FORCE LAW

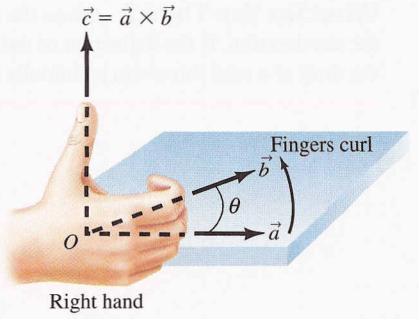
This important result is the **magnetic force law**. If θ is the angle between vectors $\vec{v}$ and $\vec{B}$, the magnitude of $\vec{F}$ is given by

$$F = qvB \sin\theta = qv_\perp B. \qquad (28\text{–}2)$$

Figure 28–6 shows how $\vec{F}$ is perpendicular to the plane formed by $\vec{v}$ and $\vec{B}$ according to a right-hand rule. Recall that the vector product of two *parallel* vectors is zero; this describes the fact that there is no magnetic force on a charge that moves along the axis of a bar magnet and no magnetic force associated with the component of $\vec{v}$ parallel to $\vec{B}$.

Equation (28–1) shows that the dimensions of the magnetic field are quite different from those of the electric field. The SI unit of magnetic field is called the *tesla* (T), in

honor of Nikola Tesla, who made important contributions to the technology of electrical energy generation. In terms of previously defined SI units,



$$1\ \text{T} = 1\frac{\text{kg}}{\text{C}\cdot\text{s}}. \tag{28–3}$$

Another (non-SI) unit for the magnetic field that is in common use is the *Gauss* (G); $10^4\ \text{G} = 1\ \text{T}$.

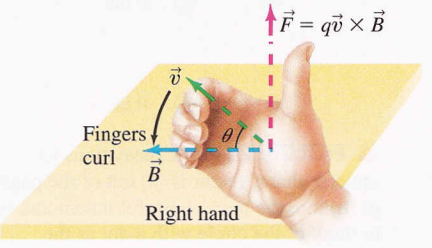


Table 28–1 contains some representative values of magnetic fields.

TABLE 28–1 • Some Magnetic Fields

Location or Source	Magnitude (T)
Interstellar space	10^{-10}
Near Earth's surface	5×10^{-5}
Refrigerator magnet for notes	10^{-2}
Bar magnet near poles	10^{-2}–10^{-1}
Near surface of Sun	10^{-2}
Large scientific magnets	2–4
Largest steady-state magnet	30
Largest pulsed field in laboratory	500–1000
Near surface of pulsar	10^{8}
Near surface of atomic nucleus	10^{12}

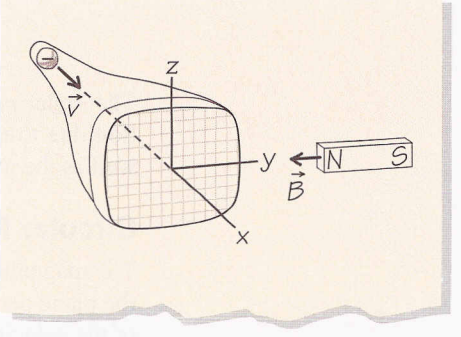
▲ **FIGURE 28–5** The vector product $\vec{c} = \vec{a} \times \vec{b}$ and the right-hand rule that determines the direction of the vector product. See Chapter 10, Fig. 10–5.

▲ **FIGURE 28–6** The right-hand rule for the magnetic force law $\vec{F} = q\vec{v} \times \vec{B}$.

CONCEPTUAL EXAMPLE 28–1 Consider the situation depicted in Fig. 28–4f, with the electron beam showing a spot on the oscilloscope screen. Suppose we now bring a bar magnet down from above to the top of the oscilloscope, with the S pole of the magnet closest to the beam. As we bring the magnet down slowly, how will the spot move on the screen?

Answer We see from Fig. 28–2a that our action effectively brings in an increasing B field that points up in the vertical direction. An application of the right-hand rule shows that the direction of the cross-product of the velocity and the field points in the left-side direction as seen when facing the screen. Note, however, that the electrons in the beam are *negatively* charged, so that the force points toward the right side of the screen, as seen from the front. The electrons are therefore accelerated to the right and will therefore strike the screen to the right of the original spot (always as seen from the front). As the magnet is slowly brought down from above, the field strength at the electron location increases, and the deflection will also increase, so the spot will be seen to move to the right.

EXAMPLE 28–2 The undisturbed electron beam of an oscilloscope moves along the x-direction. The north pole of a bar magnet approaches the cathode-ray tube from the right, as seen facing the screen, and deflects the beam. The magnitude of the magnetic field from the magnet is 0.050 T in the vicinity of the beam, and the speed of the electrons in the beam is 2.0×10^5 m/s. What is the magnitude of the magnetic force on the electrons? What is the direction of this force; that is, which way is the beam deflected?



Setting It Up We draw the situation in Fig. 28–7 and note that we are given both the magnitude of the velocity v and the magnitude of the magnetic field B, as well as their directions. The electron charge $-e$ is known.

Strategy We can obtain the direction of the force by using the right-hand rule, but to get some experience with the notion of vector products, we here set up a coordinate system and use unit vectors along the x-, y- and z-axes to work out the direction of the force. It is convenient to choose the direction of the beam as the positive x-axis. We also choose the horizontal line pointing to the right on the screen to be the y-axis, so that the conventional (right-hand) choice of z-axis is upward. We then simply apply the force law.

Working It Out We have $\vec{v} = v\hat{i}$ and $\vec{B} = -B\hat{j}$, and with the help of the right-hand rule for unit vectors, $\hat{i} \times \hat{j} = \hat{k}$, we find

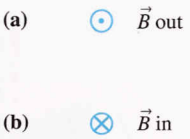
$$\vec{F} = (-e)(v)(-B)\hat{k} = (-1.6 \times 10^{-19}\ \text{C})(2.0 \times 10^5\ \text{m/s})(-0.050\ \text{T})\hat{k}$$
$$= (1.6 \times 10^{-15}\ \text{N})\hat{k}.$$

The force is upward, and this is the direction in which the spot moves.

▲ **FIGURE 28–7** The magnetic field points away from the north pole of the bar magnet and is therefore oriented in the $-y$-direction. The spot at which the beam reaches the screen is deflected in the $+z$-direction.

(continues on next page)

What Do You Think? Given the force, we can easily calculate the acceleration. Is the deflection of the spot as simple to calculate as the drop of a rock thrown in an initially horizontal direction and subject to gravity? *Answers to **What Do You Think?** questions are given in the back of the book.*



The Lorentz Force

Further experimentation shows that charges react independently to electric and magnetic fields. Thus if an electric field is present in addition to a magnetic field, it produces an additional force $\vec{F} = q\vec{E}$ on a charge. The net force on a charged particle in an electric and a magnetic field is then

$$\vec{F} = q(\vec{E} + \vec{v} \times \vec{B}). \qquad (28\text{–}4)$$

LORENTZ FORCE LAW

This equation is known as the **Lorentz force law**, named after the late-nineteenth-century physicist Hendrik A. Lorentz, who influenced the development of many areas of classical physics.

▲ **FIGURE 28–8** Conventions to indicate that a vector is (a) out of the page or (b) into the page. A useful mnemonic is to think of the circle with a dot as the point of the arrow coming toward you, and the circle with an x as the feathered tail of the arrow moving away from you.

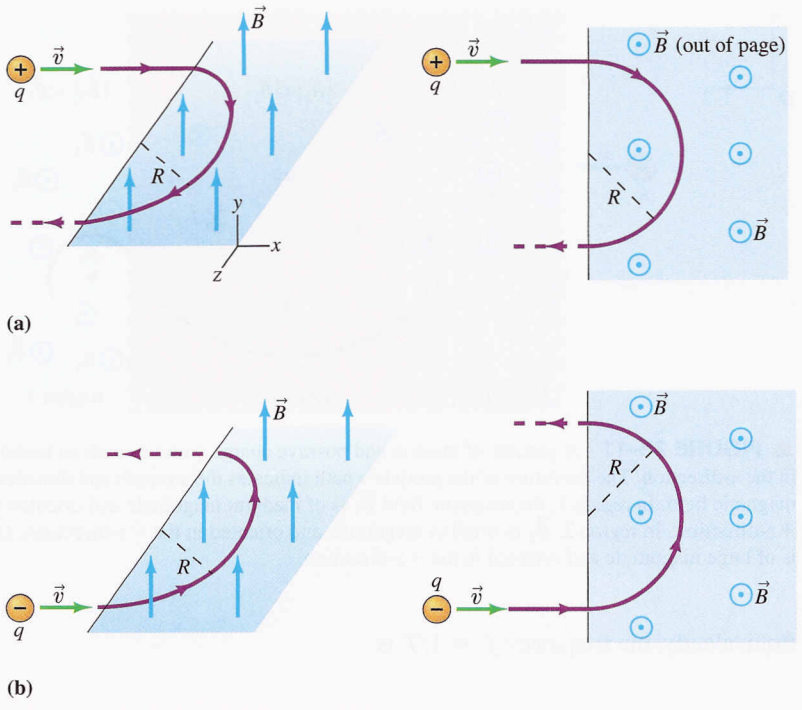
A Notation for Vectors Perpendicular to the Page

Because the three-dimensional aspect of magnetic forces is so important, it is useful to have a notation for vectors oriented perpendicular to the page. Figures 28–8a and 28–8b show a vector coming out of and going into the page, respectively. We shall often use this convention when we illustrate magnetic fields.

28–3 Consequences of the Magnetic Force on a Charge

Magnetic forces on charged particles have important implications that range from medical imaging devices to complicated phenomena in astrophysics and plasma physics. In this chapter, we'll keep things simple and assume that the magnetic fields are constant and do not change over time. When magnetic fields are independent of time, we are dealing with **magnetostatics**.

Energy of a Charged Particle in a Static Magnetic Field



Magnetic forces have a special property: *A charged particle moving in a static magnetic field has a constant kinetic energy*. One way to see this is to note that the force on a charge is perpendicular to its velocity, and hence to its infinitesimal displacement. The work done by the force is then zero, and by the work-energy theorem, the kinetic energy is unchanging. *A static magnetic field does no work on a charge*. Another way to see it is to calculate the rate of change of the kinetic energy. We have

$$\frac{d}{dt}\left(\frac{1}{2}m\vec{v}^2\right) = \frac{1}{2}m\frac{d}{dt}(v_x^2 + v_y^2 + v_z^2) = m\left(v_x\frac{dv_x}{dt} + v_y\frac{dv_y}{dt} + v_z\frac{dv_z}{dt}\right)$$
$$= m\vec{v}\cdot\frac{d\vec{v}}{dt} = m\vec{v}\cdot\vec{a}.$$

The scalar product on the right is zero, since magnetic forces, and hence the acceleration due to those forces, always point in a direction perpendicular to the velocity (as well as the magnetic field).

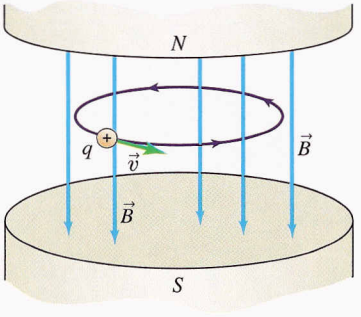
Circular Motion in a Constant Magnetic Field

The magnetic force law—Eq. (28–1)—states that only the component of the velocity in the plane perpendicular to $\vec{B}$ contributes to the expression for the force. *The component of the velocity of a charged particle parallel to the magnetic field is not affected by the field*, and it is therefore unchanging in the absence of any other forces. In addition, Eq. (28–1) states that *the force on the charge, and hence the charge's acceleration, is perpendicular to $\vec{B}$ and thus acts only in the plane perpendicular to $\vec{B}$.*

◀ **FIGURE 28–9** (a) A positively charged particle moves perpendicularly to a constant magnetic field, $\vec{B}$, shown in both an oblique perspective and a view from above. The charged particle traces a circular path in the plane perpendicular to $\vec{B}$, which is directed out of the plane of the page. (b) The direction of the curvature is opposite for a negatively charged particle.

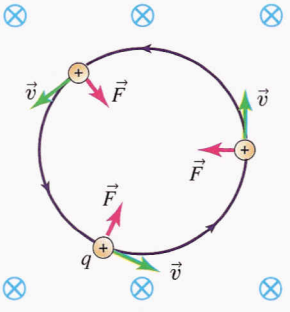
To explore the consequences of these observations more closely, consider a magnetic field $\vec{B}$ that is uniform in some region of space and a test charge q that enters this region with a velocity $\vec{v}$ perpendicular to the field (Fig. 28–9). What is the consequent motion of the charge? According to Eq. (28–1), the force will be perpendicular to $\vec{v}$ and have magnitude $F = qvB$. We saw in Chapter 3 that when the acceleration (and hence the force) is constant in magnitude and perpendicular to the velocity, there is *circular motion at constant speed*. A charged particle moving perpendicularly to a constant, spatially uniform magnetic field will move in a circle (Fig. 28–9a). The magnitude of the acceleration for circular motion is $a = v^2/R$, where R is the radius of the particle's circular path; the direction of the acceleration is toward the center of the circular path. By Newton's second law, the force must have magnitude $ma = mv^2/R$. In our case, the force responsible for the acceleration has magnitude F, and Newton's second law ($F = ma$) becomes (Fig. 28–10)

$$F = qvB = \frac{mv^2}{R}.$$



We solve for R:

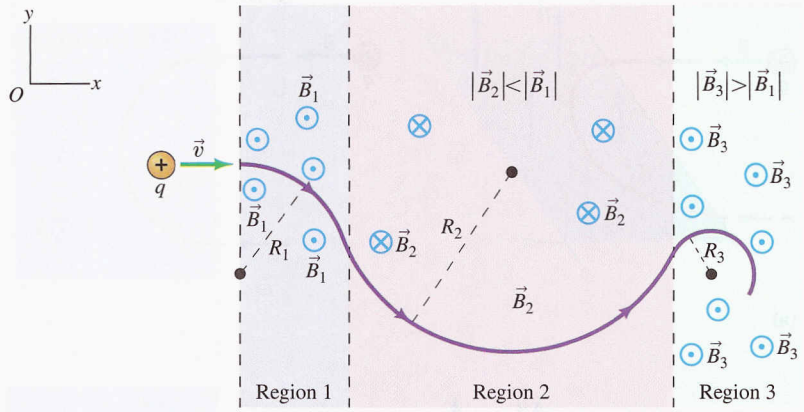
$$R = \frac{mv}{qB}. \tag{28–5}$$



R is proportional to the product of m and v—that is, to the momentum of the moving particle, $p = mv$—and is inversely proportional to the magnitudes of the charge q and of the field, $\vec{B}$. Equation (28–5) holds *only* when the velocity is perpendicular to $\vec{B}$. Whether the motion is clockwise or counterclockwise depends on the sign of the charge, according to the right-hand rule. Figure 28–9b depicts the motion for a test charge of opposite sign to the test charge in Fig. 28–9a. The larger B is, the larger is the magnetic force, and the "tighter" is the curved path, which corresponds to a smaller radius of curvature (the radius of the segment of a circle along which the charge moves at a given moment). The smaller the magnetic field, the smaller the force, and the larger is R. If the magnetic field varies in strength from place to place, then so will the radius of curvature of the path (Fig. 28–11).

The circular motion has a period $T = 2\pi R/v$, or, from Eq. (28–5),

$$T = \frac{2\pi}{v}\frac{mv}{qB} = \frac{2\pi m}{qB}. \tag{28–6}$$

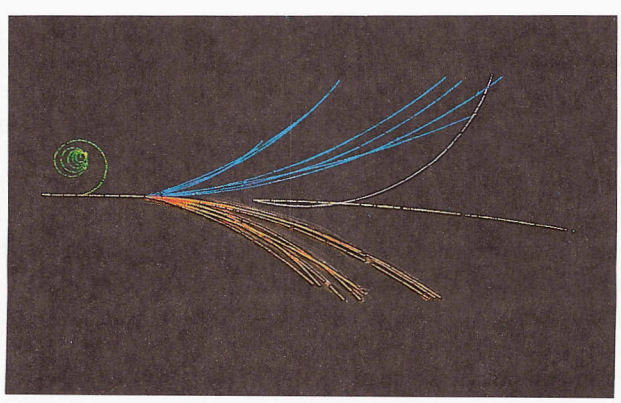


(a)

(b)

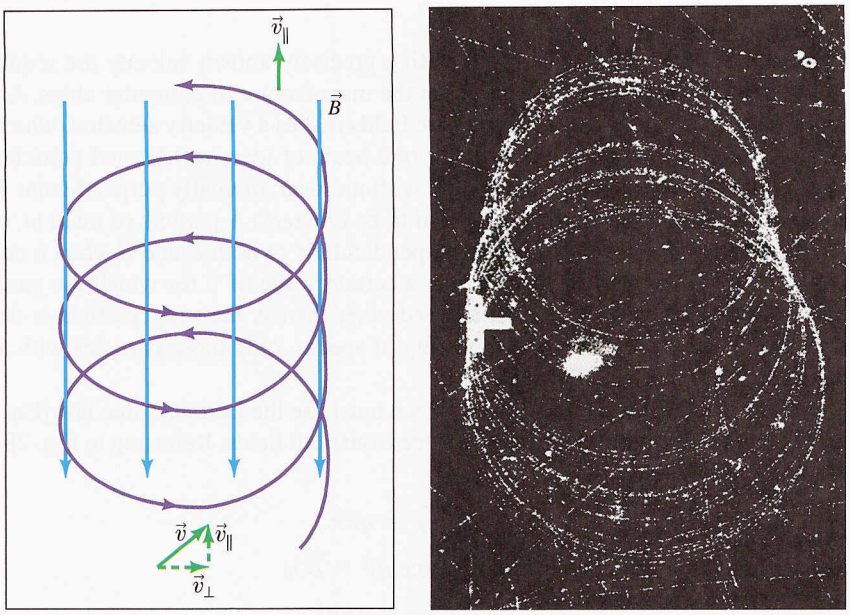
▲ **FIGURE 28–10** Forces on a charged particle that is moving perpendicularly to a uniform magnetic field.

▲ **FIGURE 28–11** A particle of mass m and positive charge q moves with an initial velocity $\vec{v}$ in the x-direction. The curvature of the particle's path indicates the strength and direction of the magnetic field. In region 1, the magnetic field $\vec{B}_1$ is of medium magnitude and oriented in the $+z$-direction. In region 2, $\vec{B}_2$ is small in magnitude and oriented in the $-z$-direction. In region 3, $\vec{B}_3$ is of large magnitude and oriented in the $+z$-direction.



Equivalently, the frequency $f = 1/T$ is

$$f = \frac{qB}{2\pi m}. \tag{28–7}$$

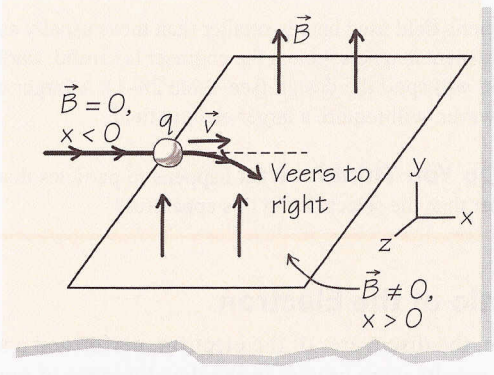


CYCLOTRON FREQUENCY

This frequency is called the **cyclotron frequency**. Notice that the period and frequency are *independent* of the speed. A slow particle traces out a tight circle in the same time that a fast particle traces out a large circle. The constancy of the cyclotron frequency is a guiding principle of a device called the *cyclotron* (see Problem 31).

Equation (28–5), which specifies the radius of the circular path of a charged particle, has found application in many particle-detection devices—the *bubble chamber* illustrates the principle well. When charged particles produced in high-energy collisions speed through liquid hydrogen, they leave tracks that consist of very tiny bubbles, like a jet leaving a vapor trail in the atmosphere (Fig. 28–12). The momentum of these particles can be obtained by measuring the radius of curvature of their tracks when an external magnetic field is imposed. As we know from Chapter 8, information about momentum is helpful in deciphering collisions—in this case, the collisions of subatomic particles. (Although today bubble chambers are rarely used in such experiments, the more modern detectors that have replaced them rely on the same principles for the measurement of momentum.)

▲ **FIGURE 28–12** The tracks left by charged particles moving through a bubble chamber in a magnetic field. The colors are computer generated.



◀ **FIGURE 28–13** (a) A charged particle follows a helical path in a region where the magnetic field is constant. (b) An electron in a cloud chamber produced this 10-m-long spiral track. The electron's path begins at the bottom. The helix becomes more tightly wound about halfway up because the electron loses energy by radiation while moving in the helical path.

Finally, when there is a component $v_\parallel$ of velocity $\vec{v}$ that lies along $\vec{B}$, that component of the velocity does not change. The particle advances along $v_\parallel$ while it moves in a circle in the plane perpendicular to $v_\parallel$ (Fig. 28–13a). The resulting trajectory forms a *spiral* (or *helix*), with its axis along $\vec{B}$ (Fig. 28–13b). The circular motion in the plane perpendicular to $\vec{B}$ has a radius (the "radius of curvature") given by

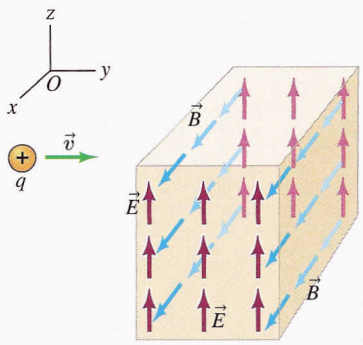
$$R = \frac{mv_\perp}{qB}. \tag{28–8}$$

EXAMPLE 28–3 A particle of unknown charge q and unknown mass m moves at speed $v = 4.8 \times 10^6$ m/s in the $+x$-direction into a region of constant magnetic field. The field has magnitude $B = 0.50$ T and is oriented in the $+y$-direction. The particle is deflected in the $+z$-direction and traces out a segment of a circle of radius $R = 0.10$ m. What is the sign of the particle's charge, and what is the ratio q/m?

Setting It Up The situation described is drawn in Fig. 28–14.

▲ **FIGURE 28–14** If the speed of a particle of unknown charge and mass that moves in a region of constant magnetic field is known, then a measurement of the radius of curvature of the particle's path gives the charge-to-mass ratio of the particle.

Strategy Given the velocity and the magnetic field, we can find the force. The acceleration will be in the same direction as the vector product $\vec{v} \times \vec{B}$ when the charge is positive, and opposite to the vector product if the charge is negative. The information on the deflection of the particle thereby tells us about the charge's sign. For the ratio q/m, we use the equation of motion, which links this ratio to the radius and the field magnitude if the field is constant, as in Eqs. (28–8) or (28–5).



Working It Out The standard rules for vector products give $\vec{v} \times \vec{B} = vB\hat{i} \times \hat{j} = vB\hat{k}$. For a positive charge this would lead to a deflection in the $+z$-direction, and since the observed deflection is in that direction, the *charge is positive*.

To calculate q/m, we use Eq. (28–5), which gives

$$\left|\frac{q}{m}\right| = \frac{v}{BR} = \frac{4.8 \times 10^6 \text{ m/s}}{(0.50 \text{ T})(0.10 \text{ m})} = 9.6 \times 10^7 \text{ C/kg}.$$

It is possible that this particle is a proton. We can see why if we assume that the unknown charge is that of a proton, $q = 1.6 \times 10^{-19}$ C. Then $m = q/(9.6 \times 10^7 \text{ C/kg}) = (1.6 \times 10^{-19} \text{ C})/(9.6 \times 10^7 \text{ C/kg}) = 1.7 \times 10^{-27}$ kg, which is just the mass of a proton. Note, however, that the experiment described in this example can measure only the charge-to-mass ratio, not the charge or the mass alone.

What Do You Think? A deuteron is one type of hydrogen nucleus. It has the charge of a proton and (approximately) the mass of two protons. What fraction of the proton's speed would a deuteron have if it followed exactly the same path as the protons in the example above?

▲ **FIGURE 28–15** A charged particle enters a region of crossed electric and magnetic fields. If the speed of the particle is $v = E/B$, the particle will cross the region undeflected.

Velocity Selectors

Beams of charged particles moving with a precisely known velocity are required in a wide range of applications, including in the manufacture of computer chips. A particular arrangement of electric and magnetic fields makes a **velocity selector**, which passes only particles of a specific velocity out of a beam of identical charged particles with a variety of velocities. Consider a region with uniform, mutually perpendicular $\vec{E}$ and $\vec{B}$ fields (Fig. 28–15). (Such fields are said to be *crossed*.) A particle of mass m, charge q (positive), and velocity $\vec{v}$ is directed perpendicularly to both $\vec{E}$ and $\vec{B}$ when it enters this region. We will now show that there is a certain value of v for which the particle traverses the region undeflected. At a speed other than v, the same particle *is* deflected; thus, in a beam of particles with a variety of speeds, only those particles with a certain speed pass through undeflected.

Both $\vec{E}$ and $\vec{B}$ fields are present, so we must use the Lorentz force law [Eq. (28–4)] and compute the contributions to the force from both fields. Referring to Fig. 28–15, the electric force is

$$\vec{F}_E = qE\hat{k}.$$

By the right-hand rule, the magnetic force $q\vec{v} \times \vec{B}$ is

$$\vec{F}_B = -qvB\hat{k}.$$

The electric and magnetic forces will cancel if their magnitudes are equal, because they point in opposite directions; in this case, the particle will travel undeflected. This cancellation occurs for $qvB = qE$, so the speed of a charged particle that passes through the crossed fields undeflected is

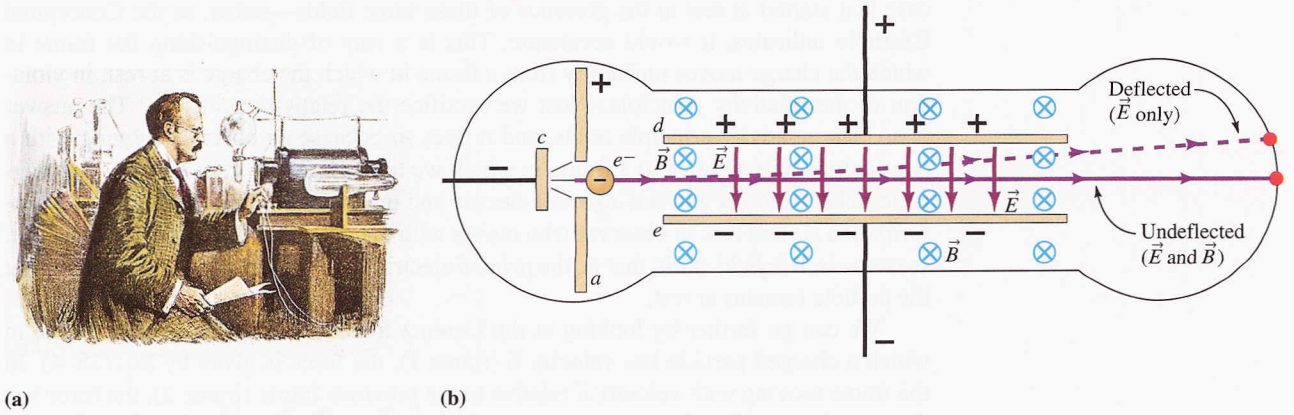
$$v = \frac{E}{B}. \tag{28–9}$$

If we reverse the sign of charge q, the electric force points in the $-z$-direction while the magnetic force points in the $+z$-direction; the forces still cancel when v is given by Eq. (28–9).

EXAMPLE 28–4 A hole is cut in the wall of a container of a plasma (matter that is composed of positively charged ions and electrons acting as a kind of gas), creating a beam of particles of various charges. It is necessary to choose particles from the beam that have a speed of 3.2×10^6 m/s in order to carry out some materials testing. The engineer designing the speed selector uses crossed $\vec{E}$ and $\vec{B}$ fields, and the $\vec{B}$ field comes from a magnet with field strength $B = 6.5 \times 10^{-4}$ T. What must the engineer choose as the magnitude of the electric field? Will all the particles so chosen have the same momentum and energy?

Strategy With B and v given, there is enough information to calculate the magnitude of the electric field required, and we can use the relation $v = E/B$. Since that relation is independent of the charge q and the mass m of the particle, the particles selected by the apparatus are only characterized by the velocity v. The momentum and the energy of a particle depends not only on its velocity but on the mass of the particle, and this is not given, so we have no information on the momentum and energy. Thus, for example, electrons will be chosen in the same way as positive ions of a variety of charges. Both momentum and energy will take on a variety of values. This fact would make the particles so chosen not so useful to test materials, because their effect on materials depends more on their momentum and energy than on their speed.

Working It Out The relation in Eq. (28–9) leads to



$$E = vB = (3.2 \times 10^6 \text{ m/s})(6.5 \times 10^{-4} \text{ T}) = 2.1 \times 10^3 \text{ V/m}.$$

The magnetic field used here is smaller than those usually associated with permanent magnets; unless the engineer is careful, Earth's magnetic field will spoil the design (see Table 28–1). A larger magnetic field, however, will require a larger electric field.

What Do You Think? What happens to particles that move a little faster than the selected v in this apparatus?

The Charge-to-Mass Ratio of the Electron

In 1897 Sir Joseph John Thomson, the discoverer of the electron, performed a series of wide-ranging experiments whose results were crucial in the development of our understanding of the electrical nature of matter. A velocity selector was an important component of his experiment to measure the charge-to-mass ratio of the electron (Fig. 28–16). He first accelerated electrons in an electric field—not the electric field of the velocity selector—by passing them through an electric potential V. The work thereby done on

▲ **FIGURE 28–16** (a) J. J. Thomson at work in his laboratory. (b) Schematic diagram of Thomson's apparatus for measuring the charge-to-mass ratio of the electron. The magnetic field is directed into the plane of the page.

the electrons is qV. Assuming they started from rest, the electrons gained a speed v determined by $mv^2/2 = qV$, so

$$v = \sqrt{\frac{2qV}{m}}. \tag{28–10}$$

The electrons accelerated in this way continued into a region of crossed electric and magnetic fields. Thomson adjusted the magnitudes of these fields until the electrons passed through the apparatus undeflected. When we combine Eqs. (28–9) and (28–10), we find that

$$v = \frac{E}{B} = \sqrt{\frac{2qV}{m}}.$$

When both sides of this equation are squared, we can solve for q/m:

$$\frac{q}{m} = \frac{E^2}{2VB^2}. \tag{28–11}$$

The electrons in Fig. 28–16b are accelerated between plates c and a. They travel on to the region between plates d and e where the magnetic field was adjusted until electrons were undeflected. The electric field and the required magnetic field may be used in Eq. (28–11) to obtain q/m. More refined experiments based on Thomson's scheme have led to a value for q/m of 1.759×10^{11} C/kg.

*The Mixing of Electric and Magnetic Fields

CONCEPTUAL EXAMPLE 28–5 Is there an arrangement of non-zero $\vec{E}$ and $\vec{B}$ fields that will leave a particle at rest if it starts at rest?

Answer This question has a simple answer: When a particle is at rest, so that $v = 0$, there is no magnetic force on the particle. In the presence of a non-zero electric field, there will be an electric force and therefore an acceleration. The particle cannot remain at rest unless the electric field is zero.

The Conceptual Example above is more interesting than it might appear. In Section 4–2 we described an overriding law of physics, what we referred to as the relativity principle: Observers in different inertial frames—frames that move at constant velocity with respect to one another—cannot decide by any experiment which of them is at rest and which is moving. In particular, observers in different inertial frames all see the same forces. But above we constructed a velocity selector, in which a combination of electric and magnetic fields produces no net force on a moving charge. The charge moves without acceleration in the fields of the velocity selector, yet this would not be the

case if it started at rest in the presence of these same fields—rather, as the Conceptual Example indicates, it would accelerate. This is a way of distinguishing the frame in which the charge moves uniformly from a frame in which the charge is at rest, in violation of the relativity principle. Must we sacrifice the relativity principle? The answer is no. The relativity principle holds, and it does so because an observer moving with a constant velocity relative to a frame in which we have given constant electric and magnetic fields $\vec{E}$ and $\vec{B}$ will see *different* electric and magnetic fields $\vec{E}'$ and $\vec{B}'$. The transformation is such that an observer who moves with the charge, and thereby sees it at rest, sees *no electric field at all*, that is, the *primed* electric field vanishes. This guarantees that the particle remains at rest.

We can go farther by looking at the Lorentz force law, Eq. (28–4). In a frame in which a charged particle has velocity $\vec{v}$ (frame 1), the force is given by Eq. (28–4). In the frame moving with velocity $\vec{u}$ relative to the previous frame (frame 2), the force has the same form as Eq. (28–4), but with the changes $\vec{E} \rightarrow \vec{E}'$; $\vec{B} \rightarrow \vec{B}'$; $\vec{v} \rightarrow \vec{v} - \vec{u}$. Since according to the relativity principle the forces are the same in the two inertial frames, we must have

$$\vec{E} + \vec{v} \times \vec{B} = \vec{E}' + (\vec{v} - \vec{u}) \times \vec{B}'.$$

Since this holds whatever $\vec{v}$ is, we conclude that

$$\vec{B}' = \vec{B}, \quad \vec{E}' = \vec{E} + \vec{u} \times \vec{B}.$$

For our velocity selector, the combination $\vec{E} + \vec{v} \times \vec{B}$ is zero. We now see that if $\vec{u}$ is chosen to equal $\vec{v}$, so frame 2 is the frame in which the particle is at rest, then the electrical force on the object, $q\vec{E}'$, is also zero. This shows that the Lorentz force is not merely the sum of two forces, electrical and magnetic, that are independent of each other, but that it involves both the electric and the magnetic field intrinsically intertwined. The relativity principle inevitably leads to a close relation between electric and magnetic forces.

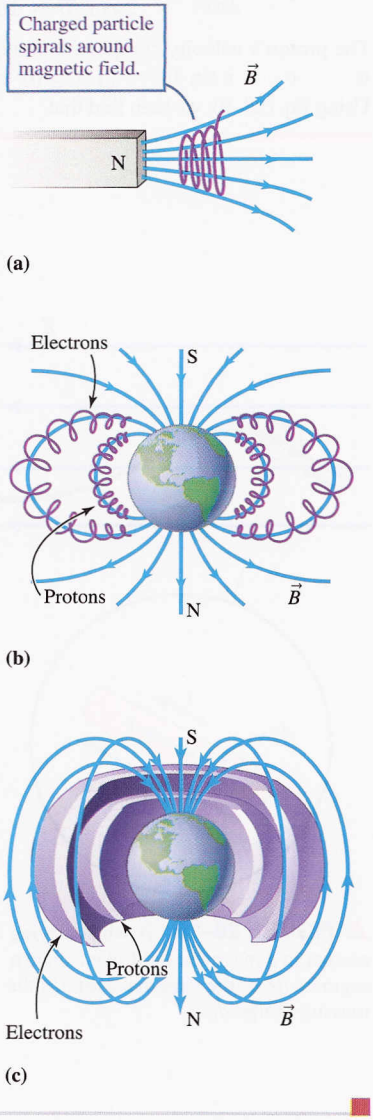
We conclude this brief discussion with a caveat that the results we have described are only approximate. When speeds are comparable to the speed of light, the discussion needs refinement. We'll discuss this further in Chapter 39.

Magnetic Fields in Outer Space

Magnetic fields exist in outer space. Throughout our galaxy, the magnetic field strength is in the range of 10^{-10} T (although the fields also have a great deal of structure). Charged particles (*cosmic rays*) are generated and accelerated by various stellar processes. If their momentum is less than a certain critical value p_c, they drift in gigantic circles within the galaxy due to the magnetic forces on them.[†] Cosmic rays with a momentum greater than p_c move on a circle with a radius of curvature greater than the galaxy's radius, and they therefore escape the galaxy. To estimate p_c for a cosmic ray whose charge has the magnitude e of the electron charge, we use the observation that the radius of the galaxy is about 5×10^{21} m. From Eq. (28–5), the critical momentum has magnitude

$$p_c = eBR = (1.6 \times 10^{-19}\ \text{C})(10^{-10}\ \text{T})(5 \times 10^{21}\ \text{m}) = 8 \times 10^{-8}\ \text{kg} \cdot \text{m/s}.$$

For a particle such as an electron or a proton, this momentum is enormously large. For comparison, an electron in the beam of a television picture tube typically has a momentum of 10^{-22} kg · m/s, while protons in the huge Fermilab proton accelerator attain momenta of 5×10^{-16} kg · m/s. Because cosmic rays with a momentum greater than p_c leave the galaxy, we should expect to detect more cosmic rays that strike Earth with momenta lower than p_c than with momenta greater than p_c. Experimental observations of particles arriving from outer space help us to estimate the value of the interstellar magnetic field.



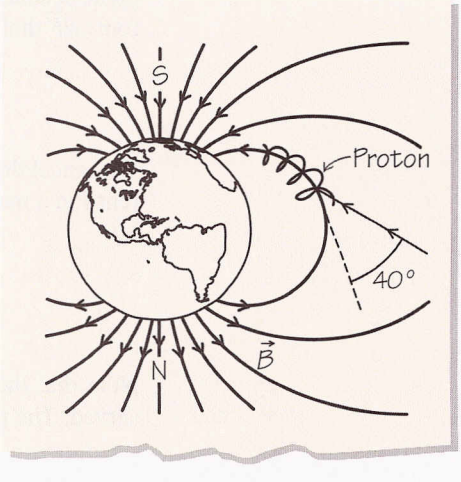
[†]We use momentum rather than speed because a calculation of the speed here gives a critical speed greater than the speed of light. This indicates that special relativity is necessary, and special relativity shows that momentum should be used here.

THINK ABOUT THIS. . .

HOW DOES EARTH'S MAGNETIC FIELD CREATE THE NORTHERN LIGHTS?

Earth has a magnetic field like that of a huge bar magnet, directed from the geographic South Pole to the geographic North Pole. As Fig. 28–17 shows, the lines get denser near the poles. (The field extends down into the atmosphere, but ions within the atmosphere tend to be affected more by the presence of the atmosphere than by Earth's magnetic field.) The field interacts with charged particles, one evidence of which is the aurora, also known in the northern hemisphere as the northern lights. Charged elementary particles reach Earth from two sources. One is the *solar wind*, which consists of electrons and positive ions ejected from the sun. Most of these particles are of relatively low energy, and in the vicinity of Earth they are trapped by the magnetic field, moving in spiral paths along Earth's magnetic field lines. The helical orbits of particles around the field lines get flattened as the lines approach each other near the pole, and ultimately the particles are turned around. The mechanism for the reversal is known as a **magnetic mirror** (the process has to do with magnetic fields of varying strength; we'll look at the dynamics of this situation in Chapter 29.). In this way, the trapped charged particles, mainly electrons, bounce back and forth between the poles creating the *outer Van Allen radiation belt*. Particles also reach Earth as **cosmic rays**, consisting of very energetic particles coming from distant space. Some of these lose energy by collisions with atmospheric particles, and if they are charged, they get trapped along magnetic field lines closer to Earth than the outer Van Allen belt. Electrons and protons originating with cosmic rays have spiral paths wide enough that they touch the atmosphere and, because of collisions with atmospheric molecules, don't stay around very long. The neutral particles, *neutrons*, which are produced in the high-energy collisions of the cosmic rays with the atmosphere, will eventually decay into protons, electrons, and neutrinos. The protons that come from some of these neutron decays are captured by the magnetic field lines lying relatively close to Earth, and they also accumulate slowly to form the stable *inner Van Allen radiation belt*. The outer belt averages about 15,000 km from the surface of Earth, the inner one about 3000 km, although both approach Earth more closely in the polar regions.

An aurora occurs (see photo on page 791) when a sufficient number of charged particles from the belts (or directly from the solar wind) enter the atmosphere and excite the molecules in the air through collisions. When the excited atoms decay back to their normal configuration, they emit radiation with wavelength (i.e. color) that is characteristic of the state of excitation (see Chapter 41). The auroras are more noticeable near the poles, where the magnetic field lines, and therefore the Van Allen belts, dip toward Earth.



▶ **FIGURE 28–17** (a) Charged particles spiraling around the varying magnetic field near the pole of a magnet. The pitch, or inclination, of the helix decreases to zero as particles near the poles, where the field lines are denser, and the particles reverse the direction of their helical path. (b) When this is applied to particles spiraling around Earth's magnetic field, we see that the particles are trapped, bouncing back and forth between the polar regions. The trapped particles form the two Van Allen belts, one for electrons and one for protons. (c) A three-dimensional view of the magnetic field lines and of the belts.

EXAMPLE 28–6 Assume that a proton of speed 1.5×10^7 m/s approaches Earth at an angle of 40° to Earth's magnetic field lines and is captured in the lower Van Allen belt (at a mean altitude of 3000 km) without a change in speed. If the mean strength of the field at this altitude is 10^{-5} T, find the cyclotron frequency and the radius of curvature for the circular part of the proton's helical motion.

Setting It Up Figure 28–18 shows the path of the proton. The curvature is the radius of the circular part of the motion. Given the angle of approach of 40° and the speed, we know the speed perpendicular to the magnetic field. We also know the field strength B and therefore have all the data necessary for the calculation.

Strategy The cyclotron frequency, Eq. (28–7), depends only on B and on the proton mass $m_p = 1.67 \times 10^{-27}$ kg and charge $e = +1.6 \times 10^{-19}$ C. For the calculation of the curvature of the proton's motion, we note that the proton does not change speed when it starts its helical motion along the magnetic field line, whose B value is given. We can use Eq. (28–8). Given a speed v, the component of velocity that is perpendicular to the direction of B is $v \sin 40°$, and it is this quantity that appears in Eq. (28–8).

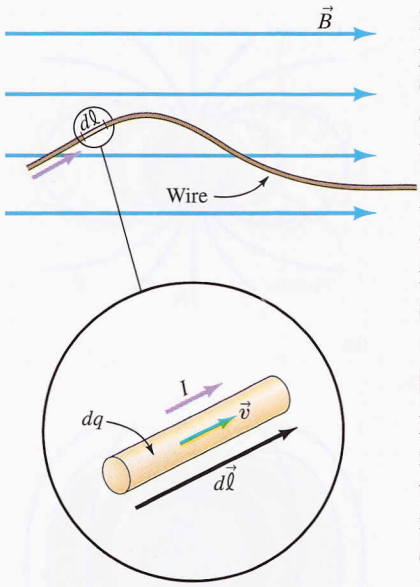
▲ **FIGURE 28–18** A proton approaches and passes into Earth's magnetic field.

(continues on next page)

Working It Out The cyclotron frequency is

$$f = \frac{qB}{2\pi m} = \frac{(1.6 \times 10^{-19}\,\text{C})(10^{-5}\,\text{T})}{2\pi(1.67 \times 10^{-27}\,\text{kg})} = 150\,\text{Hz}.$$

The proton's velocity component perpendicular to the magnetic field is $v_\perp = v \sin 40° = (1.5 \times 10^7\,\text{m/s})(0.64) = 9.6 \times 10^6\,\text{m/s}$. Using Eq. (28–8), we then find that



$$R = \frac{mv_\perp}{qB} = \frac{(1.67 \times 10^{-27}\,\text{kg})(9.6 \times 10^6\,\text{m/s})}{(1.60 \times 10^{-19}\,\text{C})(10^{-5}\,\text{T})} = 10^4\,\text{m} = 10\,\text{km}$$

The radius of curvature is much less than the altitude of the Van Allen belt. Since it is collisions with the atmosphere that tend to be most effective at removing particles from the belt, this proton is likely to stay within the belt for a while.

28–4 Magnetic Forces on Currents

In the previous sections, we have seen that moving charges in a magnetic field may experience a force due to the field. Because electric currents in wires consist of moving charges, we can expect that a magnetic field will exert a force on the charges in a current-carrying wire, and thus on the wire itself (Fig. 28–19), and experiment shows this is the case.

A wire contains moving charges throughout its length, and a magnetic field may vary significantly along its length. The total force on a current-carrying wire is the vector sum of the magnetic forces on all of the moving charges within it. To find the total force, we first determine the force on a small segment of a current-carrying wire, and subsequently sum (integrate) the infinitesimal force on each segment.

▲ **FIGURE 28–19** A wire carrying a current in a magnetic field. We isolate a segment $d\ell$ of the wire that contains the moving charge dq.

Magnetic Forces on Infinitesimal Wires with Currents

Let's denote the small segment of a thin current-carrying wire by $d\vec{\ell}$. It has both an infinitesimal magnitude $d\ell$ and a direction along the instantaneous current carried by the wire at the location of the segment. If the moving charge dq contained in the segment has velocity $\vec{v}$ along the wire (Fig. 28–19), its displacement $d\vec{\ell}$ in time dt is $d\vec{\ell} = \vec{v}\,dt$ so

$$\vec{v} = \frac{d\vec{\ell}}{dt}. \tag{28–12}$$

Because the current, I, is dq/dt by definition, the amount of moving charge within the segment is

$$dq = I\,dt. \tag{28–13}$$

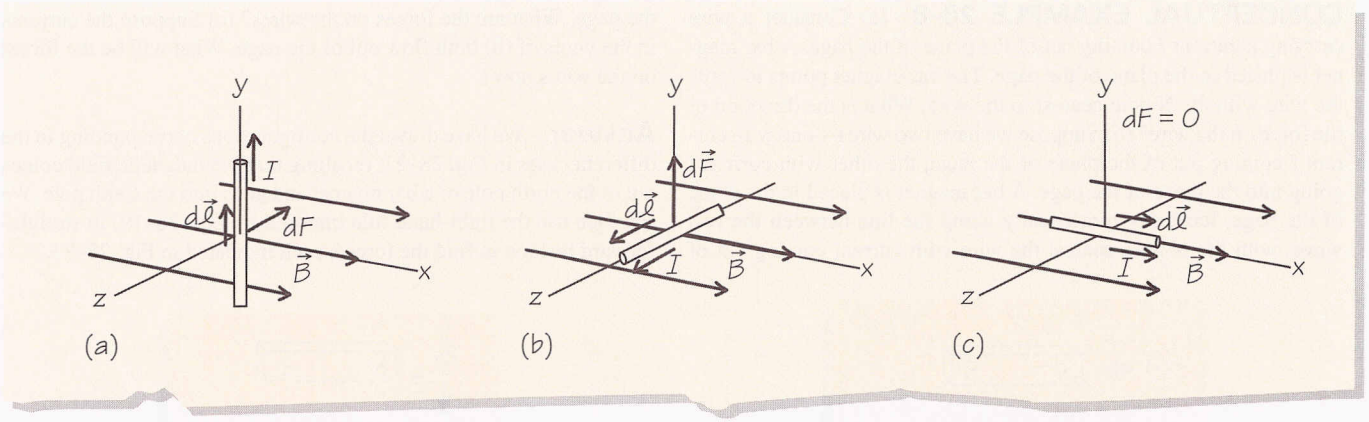
Note that the magnetic field will be uniform over the length of the segment if the segment is small enough. With Eqs. (28–12) and (28–13) we can calculate the magnetic force $d\vec{F}$ that acts on our charge element dq and hence on the wire element:

$$d\vec{F} = dq(\vec{v} \times \vec{B}) = (I\,dt)\left(\frac{d\vec{\ell}}{dt} \times \vec{B}\right).$$

We cancel the factor dt to find the infinitesimal force on a wire element $d\vec{\ell}$ carrying current I in a magnetic field $\vec{B}$:

$$d\vec{F} = I\,d\vec{\ell} \times \vec{B}. \tag{28–14}$$

MAGNETIC FORCE ON WIRE SEGMENT



Note that the current is the same everywhere along the wire because current is conserved. The magnitude of the magnetic force $d\vec{F}$ is given by

$$dF = I(d\ell)B \sin\theta, \tag{28–15}$$

where θ is the angle between the direction of the wire segment (the current's direction) and the direction of the magnetic field.

CONCEPTUAL EXAMPLE 28–7 What is the direction of the force on a current-carrying wire (a) perpendicular to and (b) parallel to the direction of a constant magnetic field?

Answer We sketch the three different placements of a segment of current-carrying wire in a uniform magnetic field that points in the $+x$-direction in Fig. 28–20. In each case, the direction of the force on the wire segment is given by the right-hand rule and Eq. (28–14). In Fig. 28–20a, $d\vec{\ell}$ points in the $+y$-direction, so that the force points in the $-z$-direction. In Fig. 28–20b, $d\vec{\ell}$ points in the $+z$-direction, so the force points in the $+y$-direction. In Fig. 28–20c, $d\vec{\ell}$ points in the $+x$-direction, parallel to $\vec{B}$, and since the vector product of two parallel vectors is zero, there is no force.

▲ **FIGURE 28–20** A wire segment, aligned with the (a) y-axis, (b) z-axis, and (c) x-axis, in a magnetic field aligned along the $+x$-direction, with the infinitesimal forces $d\vec{F}$ that act on the segment indicated.

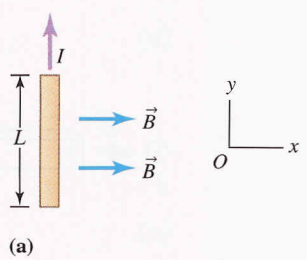
Magnetic Forces on Finite Wires with Currents

The *net* force $\vec{F}$ on a *finite* section of wire is the vectorial sum of the forces on the various infinitesimal segments that make up the wire. We find the net force by integrating $d\vec{F}$ [Eq. (28–14)] over the total length of the wire. Because I is the same everywhere along the wire, the summation of Eq. (28–14) has the form

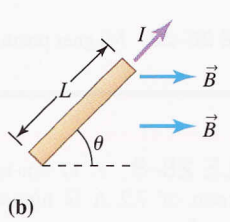
$$\vec{F}_B = I \int (d\vec{\ell} \times \vec{B}). \tag{28–16}$$

Whether the integral is easy to perform or not depends on the particular situation. A straight wire within a constant magnetic field represents an important special case. Let's suppose first that the wire, with length L and current I, is oriented perpendicular to the field (Fig. 28–21a). To perform the integration of Eq. (28–16), notice that each segment $d\vec{\ell}$ of the wire points in the y-direction, $d\vec{\ell} = d\ell\,\hat{j}$, and $\vec{B}$ is constant at each segment, $\vec{B} = B\hat{i}$. The infinitesimal force on each segment is therefore identical:

$$d\vec{F} = I[(d\ell\,\hat{j}) \times (B\hat{i})] = I(d\ell)B(\hat{j} \times \hat{i}) = I(d\ell)B(-\hat{k}),$$



which is a vector that points in the $-z$-direction. We can easily check the direction with the right-hand rule. The net force $\vec{F}$ is an integral over $d\vec{F}$:



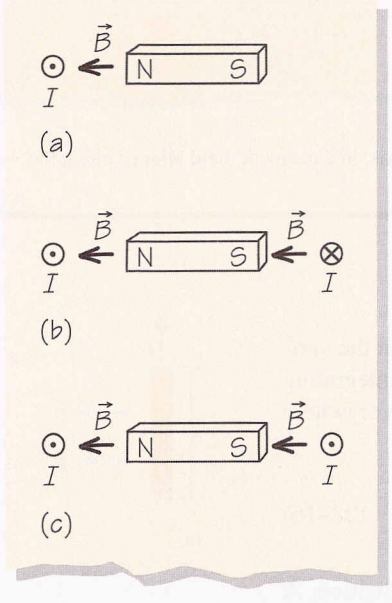
$$\vec{F} = \int d\vec{F} = I \int d\ell B(-\hat{k}) = IB(-\hat{k}) \int_0^L d\vec{\ell} = -IBL\hat{k}. \tag{28–17}$$

The net force points in the $-z$-direction (here, into the paper), and its magnitude is IBL.

Next, suppose that the wire makes an angle θ to the field (Fig. 28–21b). The only change we must make is in the expression for the magnitude of the infinitesimal force element: There is an additional factor $\sin\theta$ in dF [Eq. (28–15)]. The direction of the force remains in the $-z$-direction by the right-hand rule. Because θ is constant, it does not enter into the integration, which thus remains as in Eq. (28–17). The result is identical to Eq. (28–17) with an additional factor of $\sin\theta$:

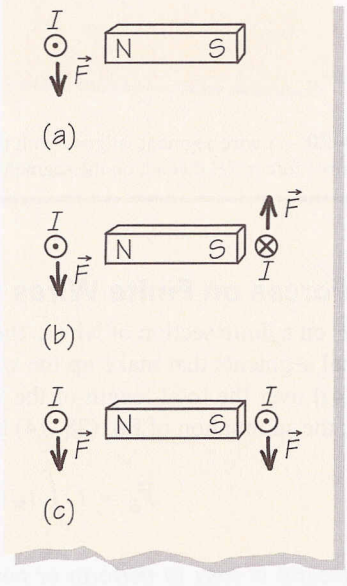
$$\vec{F} = -IBL \sin\theta\,\hat{k}. \tag{28–18}$$

▲ **FIGURE 28–21** (a) A wire segment is oriented perpendicularly to a magnetic field. (b) The same wire segment at an angle to the field.



Equations (28–17) and (28–18) are useful and important results. They can be combined into one vectorial equation that gives the force on a thin, straight wire of length L in a magnetic field, namely,

$$\vec{F} = I\vec{L} \times \vec{B}, \tag{28–19}$$



where the vector $\vec{L}$ is oriented along the wire in the direction of the current.

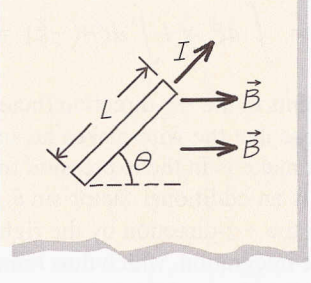
CONCEPTUAL EXAMPLE 28–8 (a) Consider a wire carrying a current I coming out of the plane of the page. A bar magnet is placed in the plane of the page. The bar magnet points towards the wire with the N pole nearest to the wire. What is the direction of the force on the wire? (b) Suppose we have two wires—one with current I coming out of the plane of the page, the other with current I going into the plane of the page. A bar magnet is placed in the plane of the page, located symmetrically along the line between the two wires, with the N pole nearest the wire with current coming out of the page. What are the forces on the wires? (c) Suppose the currents in the wires of (b) both flow out of the page. What will be the forces on the wires now?

Answer We have drawn the configurations corresponding to the different cases in Fig. 28–22, recalling that the magnetic field comes out of the north pole of a bar magnet and goes into the south pole. We can then use the right-hand rule imposed by Eq. (28–19) in straightforward fashion to find the forces, each indicated in Fig. 28–23.

▲ **FIGURE 28–22** Magnet positions for each of the configurations described.

▲ **FIGURE 28–23** Forces for each of the configurations described.

EXAMPLE 28–9 A 12-cm-long straight segment of wire carrying a current of 7.2 A is maneuvered entirely within a region known to contain a constant magnetic field until the force on the wire has a maximum magnitude of 0.37 N. Find the magnitude of the magnetic field.



Strategy Figure 28–24 shows the orientation of a wire relative to the direction of the magnetic field in the plane which contains both the field and the direction of the wire. Since there is no force on the component of the wire parallel to the field, the maximum force occurs when the wire and the magnetic field are perpendicular to each other. In the relation $F = IBL \sin\theta$ [Eq. (28–18)] that expresses the magnitude of the force on the wire, the maximum occurs for $\theta = \pi/2$ (90°). The magnetic field can be calculated from this relation.

Working It Out For $\theta = \pi/2$, we have $F = ILB$, and hence

$$B = \frac{F}{IL} = \frac{0.37\ \text{N}}{(7.2\ \text{A})(12 \times 10^{-2}\ \text{m})} = 0.43\ \text{T}.$$

The measurement of forces on wires represents an important tool for the accurate measurement of magnetic fields.

What Do You Think? What is the direction of the magnetic force on the wire?

▲ **FIGURE 28–24**

The expression for the magnetic force on an isolated moving charge has led us directly to the expression for the magnetic force on a current-carrying wire. Historically, the order of discovery was just the reverse: Oersted, François Arago, and Ampère, who early in the nineteenth century performed the first quantitative experiments on magnetic forces, observed those forces on current-carrying wires. Their results then led to an understanding of magnetic forces on moving charges.

28–5 Magnetic Force on Current Loops

Magnetic fields exert forces on all kinds of current-carrying wires, including those of closed loops. As we shall see, a uniform magnetic field actually exerts only a torque on a current loop. This phenomenon provides the torque that runs direct-current electric motors and the galvanometer (the device cited in Chapter 27 for use in ammeters and voltmeters).

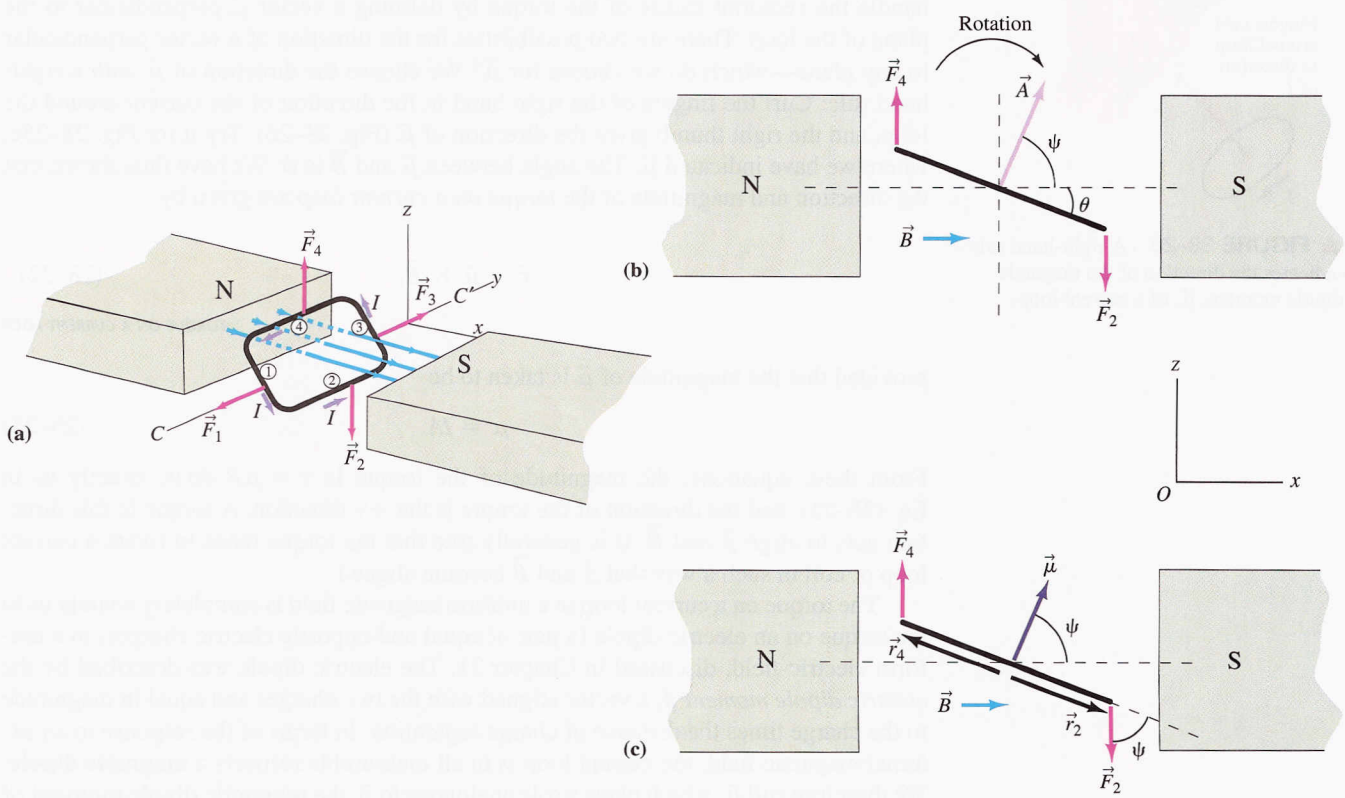


Figure 28–25a shows a stiff rectangular loop of wire carrying current I in the presence of a constant magnetic field along the $+x$-direction. The rectangular wire loop has sides of length a and b (denoted 1, 2, 3, and 4 in Fig. 28–25), and can be thought of as a series of straight wire segments. Figure 28–25b is a side view of the apparatus along the $+y$-direction. A perpendicular to the plane of the loop (the direction of the thumb when the fingers of the right hand follow the current direction) makes an angle ψ with the magnetic field. Fig. 28–25b also shows the angle θ between the direction of the magnetic field and the direction of the current for leg 1. We can calculate the force on each leg of the loop by using Eq. (28–19), and we find:

$$F_1 = IaB \sin\theta, \text{ in the } -y\text{-direction;} \quad (28\text{–}20a)$$

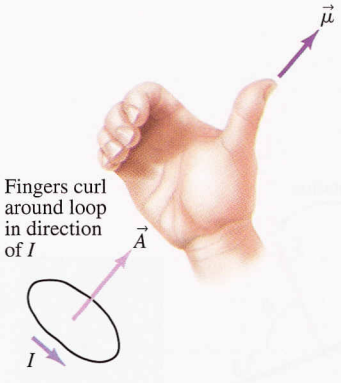
$$F_2 = IaB, \text{ in the } -z\text{-direction;} \quad (28\text{–}20b)$$

$$F_3 = IaB \sin\theta, \text{ in the } +y\text{-direction;} \quad (28\text{–}20c)$$

$$F_4 = IaB, \text{ in the } +z\text{-direction.} \quad (28\text{–}20d)$$

▲ **FIGURE 28–25** (a) A stiff, rectangular loop of wire is placed in a constant magnetic field. (b) A side view, looking along the y-axis, of the loop. (c) Geometry of the loop that allows us to calculate the torque on the loop. The torque tends to align the vector $\vec{\mu}$ with the magnetic field, $\vec{B}$.

These forces are indicated in Figs. 28–25a and 28–25b. Forces $\vec{F}_1$ and $\vec{F}_3$ are equal and opposite, as are forces $\vec{F}_2$ and $\vec{F}_4$, so *there is no net force on a current loop in a uniform magnetic field.* However, there is an important difference between these two sets of forces: $\vec{F}_1$ and $\vec{F}_3$ act along the same axis (CC' in Fig. 28–25a) and exert no torque on the loop. As Fig. 28–25b shows, $\vec{F}_2$ and $\vec{F}_4$ act along different axes and therefore produce a torque that causes the wire loop to rotate clockwise in the magnetic field. When the wire has rotated into the yz-plane (when $\theta = 90°$ in Figure 28–25b), $\vec{F}_2$ and $\vec{F}_4$ act along the same axis, and there is no torque. When the loop is in the xy-plane ($\theta = 0°$), the torque is a maximum. Finally, when θ changes sign, so does the torque, and the loop will tend to rotate counterclockwise.



We can find the torque about the central axis CC' in Fig. 28–25a by using the results of Chapter 10. From Eq. (10–6), the net torque about this axis is

$$\vec{\tau} = (\vec{r}_2 \times \vec{F}_2) + (\vec{r}_4 \times \vec{F}_4),$$

where $\vec{r}_2$ and $\vec{r}_4$ are the perpendicular vectors from axis CC' to legs 2 and 4, respectively (Fig. 28–25c). Both $\vec{r}_2$ and $\vec{r}_4$ have magnitude $a/2$. Figure 28–25c shows that ψ is the angle between $\vec{r}_2$ and $\vec{F}_2$ and between $\vec{r}_4$ and $\vec{F}_4$. The torque has magnitude

$$\begin{aligned}\tau &= r_2F_2 \sin\psi + r_4F_4 \sin\psi = (a/2)(IbB)\sin\psi + (a/2)(IbB)\sin\psi \\ &= IabB \sin\psi. \end{aligned} \tag{28–21}$$

Here, we have used the values for F_2 and F_4 given by Eq. (28–20). According to the right-hand rule, both terms in the equation for τ point in the $+y$-direction, so the net torque is in this direction.

▲ **FIGURE 28–26** A right-hand rule indicates the direction of the magnetic dipole moment, $\vec{\mu}$, of a current loop.

The torque on a current loop in a magnetic field as given by Eq. (28–21) can be summarized and generalized. For a rectangular loop, the factor ab is the area A of the current loop. We can generalize to *any* planar loop of area A, whatever its shape, by the calculus technique of decomposing a planar loop of any shape into tiny rectangles and then treating each small rectangle in the way we have discussed above. We can neatly handle the vectorial nature of the torque by defining a vector $\vec{\mu}$ perpendicular to the plane of the loop. There are two possibilities for the direction of a vector perpendicular to any plane—which do we choose for $\vec{\mu}$? We choose the direction of $\vec{\mu}$ with a right-hand rule: Curl the fingers of the right hand in the direction of the current around the loop, and the right thumb gives the direction of $\vec{\mu}$ (Fig. 28–26). Try it for Fig. 28–25c, where we have indicated $\vec{\mu}$. The angle between $\vec{\mu}$ and $\vec{B}$ is ψ. We have thus shown that the direction and magnitude of the *torque on a current loop* are given by

$$\vec{\tau} = \vec{\mu} \times \vec{B}, \tag{28–22}$$

TORQUE ON A CURRENT LOOP

provided that the magnitude of $\vec{\mu}$ is taken to be

$$\mu = IA. \tag{28–23}$$

From these equations, the magnitude of the torque is $\tau = \mu B \sin\psi$, exactly as in Eq. (28–21), and the direction of the torque is the $+y$-direction. A torque in this direction acts to align $\vec{\mu}$ and $\vec{B}$. It is generally true that the torque tends to rotate a current loop or coil in such a way that $\vec{\mu}$ and $\vec{B}$ become aligned.

The torque on a current loop in a uniform magnetic field is completely analogous to the torque on an electric dipole (a pair of equal and opposite electric charges) in a uniform electric field, discussed in Chapter 21. The electric dipole was described by the *electric dipole moment* $\vec{p}$, a vector aligned with the two charges and equal in magnitude to the charge times the distance of charge separation. In terms of the response to an external magnetic field, the current loop is in all measurable respects a **magnetic dipole**. We therefore call $\vec{\mu}$, which plays a role analogous to $\vec{p}$, the **magnetic dipole moment** of the loop. One of the measurable properties—the defining property—of a dipole, magnetic or electric, is the characteristic field that the dipole itself *produces*. We deal with the calculation of the magnetic dipole field in Chapter 29.

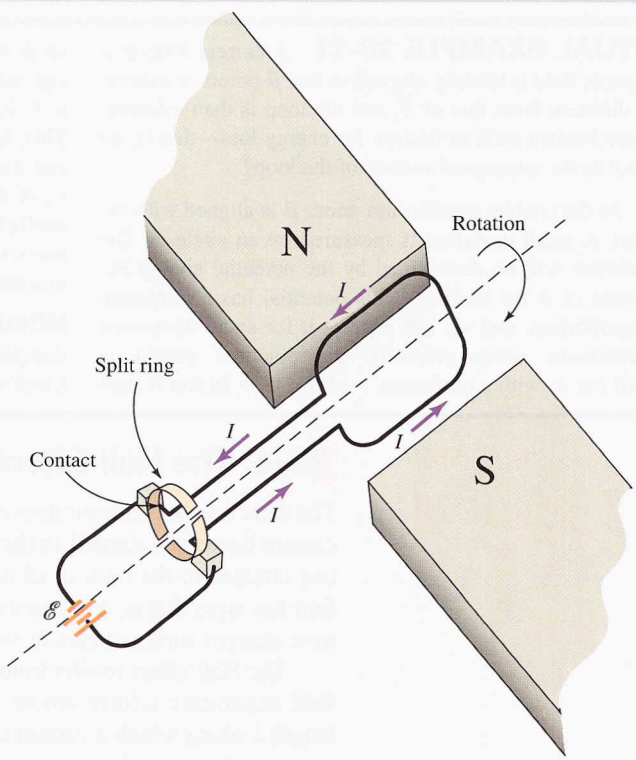
CONCEPTUAL EXAMPLE 28–10 Suppose instead of one turn of wire we take N turns of wire, each surrounding the same plane area, thus creating a *coil*. What is the magnetic moment of the coil?

Answer Each turn of the coil experiences the forces we have described, and the torque is multiplied by N. This factor is included with the other factors intrinsic to the coil, so the magnetic dipole moment will now be multiplied by the factor N:

$$\mu = INA. \qquad (28\text{–}24)$$

MAGNETIC DIPOLE MOMENT OF A COIL

We have seen another system that aligns itself with external magnetic fields: the iron filings we used to make our preliminary definition of magnetic fields. These iron filings behave like little bar magnets that are rotated by magnetic fields. Bar magnets react to fields just like current loops do. As we shall see in Chapter 29 when we find the magnetic fields *produced* by magnetic dipoles, bar magnets are themselves magnetic dipoles. We can explain this by looking at the microscopic level, where we find that metals contain the quantum-mechanical equivalent of circulating currents. We shall study this behavior in more detail in Chapter 31.



Galvanometers

In Chapter 27 we encountered the *galvanometer*—a device that measures currents. The principle behind a galvanometer is the fact that a magnetic field exerts a torque on a current loop. For example, we can attach a spring to a loop to balance the torque due to a known magnetic field, and the amount the spring stretches is a measure of the torque on the loop and hence of the current that passes through it.

THINK ABOUT THIS. . .

HOW DO ELECTRIC MOTORS WORK?

In one fundamental type of electric motor, we have a permanent magnet to supply a magnetic field and an emf to supply a current. The current is run through a loop that is placed in the magnetic field. With the apparatus shown in Fig. 28–25a, as soon as the wire loop rotates past the position in which it is aligned with the field due to the poles, the torque on it changes sign and becomes counterclockwise. In fact, the torque changes direction when ψ goes through 0° or 180°. This device oscillates and would not make a motor, which requires a continuous turning motion. However, if we can make the *current* switch directions every time the loop passes $\psi = 0$ or π (180°), then the torque will continuously produce a clockwise rotation. A device that does just this is known as a *split-ring commutator*, a device whose mechanism is visible in Fig. 28–27. With this device, the loop accelerates its rotation, always in the same direction, under the influence of a torque whose sign does not change, and an *electric motor* has been created. Once we have this arrangement, and a continuously turning loop, it is no great step to imagine tranferring this motion to, for example, a set of wheels. But that is another story more properly treated in a chapter on mechanics.

▲ **FIGURE 28–27** A current-carrying loop aligned in a magnetic field is fitted with a split-ring commutator, as shown in a schematic diagram. The torque on the loop serves to turn the loop and makes a motor.

Energy and the Torque on Loops

When a magnetic field rotates a current loop, the field does work. For a constant field, the only variable in the work is the angle of rotation, ψ. We know from Chapter 7 that we can use the concept of potential energy when the force (or the torque) depends only

on position, as here. Accordingly we associate a potential energy $U(\psi)$ with a loop in a magnetic field, where ψ is the angle between $\vec{\mu}$ and $\vec{B}$. As always, only *changes* in the potential energy have physical consequences. The change in potential energy in rotating the coil from some initial angle ψ to a final angle of $\pi/2$ (90°) is given by the negative of the work done by the magnetic field in moving the coil through these angles:

$$U(\psi) - U(\pi/2) = -\int_{\psi}^{90°} \tau \, d\psi' = -\int_{\psi}^{90°} \mu B \sin\psi' \, d\psi'$$
$$= -\mu B \int_{\psi}^{90°} \sin\psi' \, d\psi' = \mu B \cos(\pi/2) - \mu B \cos\psi.$$

The cosine of $\pi/2$ is zero, so

$$U(\psi) - U(\pi/2) = -\mu B \cos\psi. \qquad (28\text{–}25)$$

We choose the location of $U = 0$ for convenience, and it is customary to choose U to be zero at $\psi = \pi/2$; that is, when $\vec{\mu}$ is perpendicular to $\vec{B}$. Setting the term $U(\pi/2)$ in Eq. (28–25) to zero gives *the potential energy of a current loop with a given magnetic dipole moment $\vec{\mu}$ in a constant magnetic field $\vec{B}$*:

$$U(\psi) = -\vec{\mu} \cdot \vec{B}. \qquad (28\text{–}26)$$

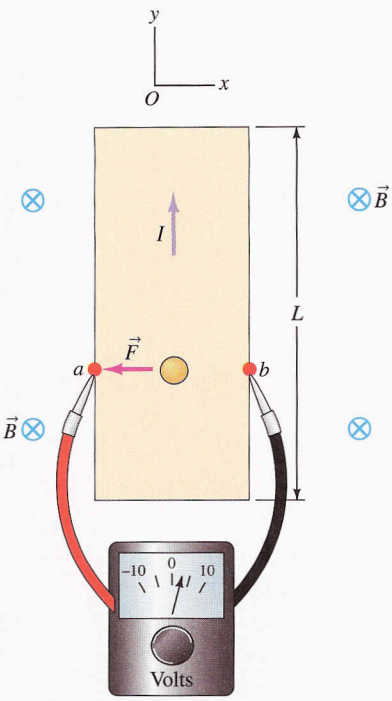
POTENTIAL ENERGY OF A MAGNETIC DIPOLE

The potential energy has a *minimum* when $\vec{\mu}$ is aligned along $\vec{B}$ (that is, when $\psi = 0$). Thus the orientation in which $\vec{\mu}$ is aligned with $\vec{B}$ is a stable equilibrium point. This agrees with our earlier result that the torque tends to rotate the loop to line up $\vec{\mu}$ and $\vec{B}$.

CONCEPTUAL EXAMPLE 28–11 A current loop in a constant magnetic field is initially aligned so that $\vec{\mu}$ points in a direction slightly different from that of $\vec{B}$, and the loop is then released. There is no mechanism such as friction for energy loss—that is, no damping. What is the subsequent motion of the loop?

Answer At the (stable) equilibrium point, $\vec{\mu}$ is aligned with the magnetic field. A small deviation is measured by an angle ψ. The subsequent motion will be determined by the potential energy expressed in terms of ψ for small ψ. This potential has a minimum around the equilibrium, and we can express it for small deviations from the minimum. More precisely, the potential energy is $U(\psi) = -\mu B \cos\psi$, with a minimum $-\mu B$ for $\psi = 0$, and it rises as ψ moves away from the minimum value, independent of the sign of ψ. Any such curve varies as $C\psi^2/2$ for ψ close enough to $\psi = 0$, where C is a constant that depends on the potential energy. This, however, is just the potential energy for a harmonic oscillator, and we may therefore expect that the motion will be simple harmonic, of the general form $\psi = \psi_m \sin(\omega t + \delta)$, where ω involves the coefficient C as well as the rotational inertia of the loop (see Problem 64). In Chapter 13 we saw that this is a general property of motion around stable equilibrium points.

What Do You Think? What is the behavior of an undamped compass needle slightly displaced from the direction of Earth's magnetic field?



28–6 The Hall Effect

The direction of a current does *not* itself determine the sign of the charge carriers in that current because a current to the right can be produced by the movement either of positive charges to the right or of negative charges to the left. The Hall effect allows us to find this sign, that is, whether a current is formed of moving electrons or of moving positive charges such as holes in semiconductors (see Section 26–6).

The Hall effect results from the fact that charges moving along a wire in a magnetic field experience a force whose sign depends on their charge. Consider a metal strip of length L along which a current flows. The strip is placed in a uniform magnetic field that is perpendicular to the strip, as in Fig. 28–28. As a result, there will be a potential difference between points a and b whose cause and qualitative nature we now describe. Equation (28–19) gives the total force on the strip, $\vec{F} = I\vec{L} \times \vec{B}$. This force, by the right-hand rule, is directed in the $-x$-direction—it acts to the *left* in Fig. 28–28. By using the equivalent force law $\vec{F} = q\vec{v} \times \vec{B}$, we can show that the force on the charge carriers acts to the left, *whatever the sign of the charge carriers*. If the moving charges are positive (ions) and the current flows in the $+y$-direction, then the velocity of the charges is also in the $+y$-direction. According to the right-hand rule, $\vec{F} = q\vec{v} \times \vec{B}$ is then directed toward point a in Fig. 28–28. If the moving charges are negative (electrons), however, then the

velocity of the charges is in the $-y$-direction. The vector product $\vec{v} \times \vec{B}$ is directed to the right, but q is negative, and $q\vec{v} \times \vec{B}$ again points to the left, moving these negative charges toward a. Either way, there is a buildup of the charge carriers at the left side of the strip. This buildup cannot continue indefinitely: Once enough charge carriers have moved to the left, they will supply a repulsive Coulomb force against the movement of other charge carriers that is large enough to stop the process. An equilibrium is established in which an electric potential is set up between points a and b that prevents further leftward drift of charge carriers. Charges then move up the strip as they would if there were no magnetic field. (The charge separation has led to an electric field between points a and b. We have crossed $\vec{E}$ and $\vec{B}$ fields, with the value of the electric field such that the charges travel undeflected up the strip just as in the velocity selector discussed in Section 28–3.)

The **Hall effect** is that *the sign of the potential difference between points a and b determines the sign of the charge carriers*. If the charge carriers are negative, negative charges build up on the left side of the metal strip, and point a is at a lower potential than point b. Conversely, if the carriers are positive, positive charges build up on the left side of the strip, and point a is at a higher potential than point b. The first measurement of the sign of this *Hall potential* was performed by the American physicist Edwin H. Hall in 1879. His measurement proved that the carriers of current in metals are negatively charged.

▲ **FIGURE 28–28** A conducting strip perpendicular to a constant magnetic field develops a potential called the Hall voltage between points a and b when the strip carries a current I.

THINK ABOUT THIS. . .

DOES THE HALL EFFECT HAVE TECHNOLOGICAL USE?

Our discussion of the Hall effect shows that the potential across the strip is proportional to the strength of the magnetic field. Potential changes are easy to measure accurately, and in a Hall strip they signal changes in the magnetic field. In particular, they can be used to sense the change in distance of a magnet from the Hall strip. This makes the Hall effect useful in the detection of the motion of magnets, even slow motion.

An example is in the computer keyboard. Constant and heavy use would wear out the keyboard rather rapidly if the use involved establishing direct contact between two solid pieces. The Hall effect is used to signal the application of force to a key on a keyboard without this type of contact. A small, permanent magnet is attached to the bottom of each key on the keyboard, and underneath it there is a Hall probe. Modern probes consist of a thin layer of a conductor deposited on a rigid substrate. Because of the spatial dependence of the magnetic field, the change in the position of the magnet relative to the conducting layer can change the magnetic field at the probe by an order of magnitude. Such a change leads to changes in a Hall potential that is then communicated to the computer, signaling that a given key has been pressed. In an electronic piano this application can be carried further. The rate of change in the Hall potential signals the speed at which a key is depressed, so that the keyboard can signal whether the key has been pressed rapidly or gently, and produce a loud or soft sound in response. ■

EXAMPLE 28–12 Figure 28–28 shows a Hall strip whose width is 1.0 cm in a magnetic field of 2.0 T with a voltage of magnitude 7.2 μV across the strip. What is the speed v of the charge carriers in the strip?

Strategy The velocity of the charge carriers is that of charges passing through a crossed electric and magnetic field. We are given the magnetic field B and can find the electric field in terms of the strip width d and the voltage V across the strip. The charge flow is that of a velocity selector, with $v = E/B$. The electric field is determined from the potential difference and the strip width to be $E = V/d$.

Working It Out Combining the equations above, the velocity is

$$v = \frac{V}{Bd} = \frac{7.2 \times 10^{-6}\ \text{V}}{(2.0\ \text{T})(1.0 \times 10^{-2}\ \text{m})} = 3.6 \times 10^{-4}\ \text{m/s}.$$

This is a measurement of an electron's speed in a current, what we earlier called the drift speed.

What Do You Think? The width of the strip is doubled. Which of the following is true: the voltage (a) is doubled, (b) is halved, (c) remains the same?

Summary

Magnets, moving electric charges, and electric currents all experience magnetic forces. These forces can be described in terms of a magnetic field, $\vec{B}$, whose spatial dependence can be mapped out with iron filings or by observing its effect on a moving electric test charge or a test current element. In terms of this field, the magnetic force on an electric charge q depends on the charge's velocity according to the magnetic force law,

$$\vec{F} = q\vec{v} \times \vec{B}. \qquad (28\text{–}1)$$

The SI unit of magnetic field is the tesla, T: $1\ \text{T} = 1\ \text{kg}/(\text{C}\cdot\text{s})$. When both magnetic and electric fields are present, the Lorentz force law holds:

$$\vec{F} = q(\vec{E} + \vec{v} \times \vec{B}). \tag{28–4}$$

In a static magnetic field, the component of a charged particle's velocity parallel to the field is unaffected by that field. The magnitude of the force on the particle due to the field is proportional to the component of the velocity perpendicular to the field, and the direction of the force is perpendicular to this component of the velocity and to the field itself. It follows that the kinetic energy of a charged particle in a magnetic field is unchanging. When the field is constant, a charged particle traveling perpendicular to the field moves in a circle of radius

$$R = \frac{mv}{qB}. \tag{28–5}$$

The frequency of the particle's circular motion is the cyclotron frequency,

$$f = \frac{qB}{2\pi m}, \tag{28–7}$$

which is independent of the particle's velocity. The general path followed by a moving charge is a spiral around the magnetic field lines.

When a charged particle has a particular velocity perpendicular to constant crossed electric and magnetic fields, the electric and magnetic forces cancel, and the particle passes through the fields undeflected. The magnitude of this special velocity is

$$v = \frac{E}{B}. \tag{28–9}$$

With the help of a velocity selector, an apparatus based in part on this phenomenon, the charge-to-mass ratio of the electron can be measured.

The infinitesimal magnetic force on an infinitesimal length of thin wire $d\ell$ that carries a current I in the presence of a constant magnetic field is

$$d\vec{F} = I\, d\vec{\ell} \times \vec{B}. \tag{28–14}$$

To find the net force on a wire of finite length in a magnetic field, Eq. (28–14) is integrated. For example, the force on a straight wire of length L in a uniform magnetic field is given by Eq. (28–19), $\vec{F} = I\vec{L} \times \vec{B}$. Another important example is a wire that carries a current and is formed into a loop (or coil) of N turns; the area of the face of the loop is A. When it is placed in a constant magnetic field, such a loop experiences a torque

$$\vec{\tau} = \vec{\mu} \times \vec{B}. \tag{28–22}$$

The loop reacts as a magnetic dipole with magnetic dipole moment $\vec{\mu}$. For a coil of N turns, $\vec{\mu}$ has magnitude

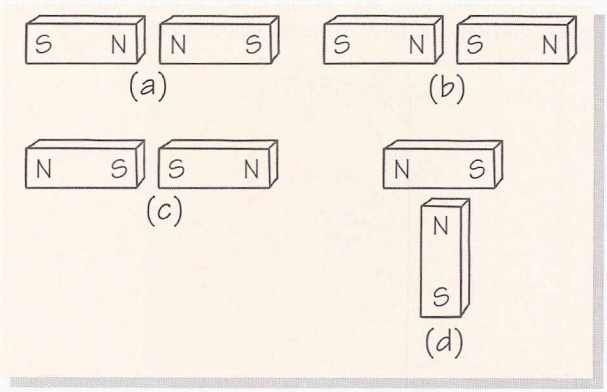
$$\mu = INA \tag{28–24}$$

and direction perpendicular to the face of the coil, oriented by a right-hand rule on the current. The torque tends to rotate the loop so that $\vec{\mu}$ and $\vec{B}$ become aligned. The potential energy of the loop in a constant magnetic field can be expressed as

$$U(\psi) = -\vec{\mu} \cdot \vec{B}. \tag{28–26}$$

The Hall effect exploits the equivalence between the force on a moving charge and the force on a current-carrying wire. This effect proves that the current carriers in metals are negatively charged.

Understanding the Concepts



1. A wire carrying a current is electrically neutral, yet a magnetic field acts on it. Why?
2. Explain how you might define and measure a magnetic field if magnetic monopoles existed.
3. An electron beam in an oscilloscope is deflected to the right on the screen. Could this be caused by an electric field *or* by a magnetic field? Explain how you could distinguish these possibilities.
4. An electron beam makes a spot in the center of the screen of a cathode-ray tube. A bar magnet is brought in from the left side (as seen from the front of the tube), with the S pole nearest to the beam. Which way will the spot move? Suppose that the N end of the bar magnet is brought near the beam from above. Which way will the spot move?
5. Much of the description of magnetic forces depends on the use of a right-hand rule. Does the magnetic force depend fundamentally on the fact that we have chosen the right rather than the left hand?
6. Currents flow in two parallel wires. Wire 1 carries 2 A to the right, and wire 2 carries 1 A to the left. (a) What is the direction of the magnetic field near wire 2 due to wire 1? (b) What is the direction of the magnetic force on wire 2?
7. If you have just used a velocity selector for electrons and you wish to use it to choose positrons with the same speed, do you have to change any settings on the selector? Positrons are like electrons, but positively charged.

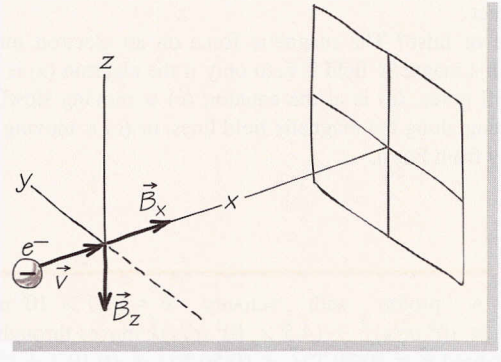
8. Induced charges give rise to electric forces even between electrically neutral objects. How do we know that the forces between bar magnets are not induced electric forces?
9. The aurora is a manifestation of Earth's magnetic field. Why do these lights occur frequently near Earth's poles and only rarely elsewhere?
10. Imagine that an electrically neutral wire carrying a current moves in the presence of an external magnetic field. Do you expect that there will be an additional force on the wire due to the movement?
11. You have a fixed length of wire and want to use it to make a magnetic dipole with the largest possible magnetic dipole moment. Into what shape should you wind it? Are you better off making a single loop or N loops?
12. A small bar magnet forms a magnetic dipole; a current-carrying wire in the shape of a small loop also forms a magnetic dipole. If that is the case, the current loop should give rise to a magnetic field. Use this analogy to sketch the magnetic field lines that would be generated by such a current loop.
13. Consider two small circular current loops. Suppose the two loops are placed flat on a table close to each other (but not touching) and the two currents both flow in a counterclockwise direction. Will the two loops attract or repel? What happens if the directions of the currents are opposite?
14. A proton coming from outer space reaches Earth and is now traveling across the magnetic north pole parallel to Earth's surface. Will it be deflected (a) up, (b) down, (c) to the left, (d) to the right, or (e) not at all?
15. Consider two small circular current loops. Suppose one loop is placed above the other (but not touching), with their areas oriented similarly. If the currents flowing in the two loops are both in the same direction, will the loops attract or repel?
16. Is it possible for an electron to move in a straight line through a magnetic field? If so, how?
17. Suppose that the coil of a direct-current electric motor consists of many turns rather than one turn of wire that carries a current I. Does the coil rotate faster than a single loop would? Does the split-ring commutator still work?
18. You have a large pail of water, a bar magnet with its N and S ends unmarked, a straight pin, and a cork. How could you make a compass? One of the things you need to know to construct this compass is how to distinguish north from south; you are allowed to watch the Sun to help with this part of the question.
19. Do magnetic north poles repel positive electric charges?
20. A classmate tells you that 1 T is 1 N/A · m. Is your classmate correct?
21. True or false? The magnetic force on an electron moving in Earth's magnetic field is zero only if the electron (a) is at the N and S poles, (b) is at the equator, (c) is moving slowly, (d) is moving along the magnetic field lines, or (e) is moving radially away from Earth.

Problems

28–1 Magnets and Magnetic Fields

1. (II) Sketch the magnetic fields for the arrangements of bar magnets shown in Fig. 28–29.

▲ FIGURE 28–29 Problem 1.



2. (II) Consider the magnetic field generated by a current-carrying wire, as depicted in Fig. 28–2. Assuming that a reversal in the direction of the current also reverses the direction of the magnetic field, sketch the magnetic field due to two wires that are parallel to each other, and whose currents flow in the same direction. You may assume that the magnetic fields add vectorially, just like electric fields. Repeat the sketch for the situation in which the currents flow in opposite directions. Your sketches should show the field lines as seen by someone looking along the wires.

28–2 Magnetic Force on an Electric Charge

3. (I) An electron moving in the $-y$-direction enters a region of constant magnetic field and is observed to deflect to the $-x$-direction. What is the direction of the magnetic field?
4. (I) A proton with velocity $\vec{v} = (1.7 \times 10^6\ \text{m/s})\hat{i} + (0.8 \times 10^6\ \text{m/s})\hat{j} - (4.5 \times 10^5\ \text{m/s})\hat{k}$ moves through a magnetic field $\vec{B} = (0.70\ \text{T})\hat{i} - (0.50\ \text{T})\hat{j} + (0.10\ \text{T})\hat{k}$. Calculate the force on the proton.
5. (I) A proton of energy 100 keV moving in the $+x$-direction enters a region of uniform magnetic field perpendicular to the x-axis. Upon entry into that region, the proton experiences an acceleration of $3 \times 10^{12}\ \text{m/s}^2$ in the $+y$-direction. What are the magnitude and direction of the magnetic field?
6. (I) A pith ball charged to $+1\ \mu\text{C}$ falls vertically at the equator. At this location, the magnitude of Earth's magnetic field is 0.5 Gauss (0.5×10^{-4} T) and the field points to the north. When the ball reaches a speed of 5 cm/s, what is the magnetic force (magnitude and direction) on it?
7. (I) A proton moving with speed v enters a narrow (1.0 cm wide) region of magnetic field perpendicular to the direction of the proton's motion. As a result, the proton acquires a small component of speed perpendicular to its original direction of motion. This speed is much less than the original speed, and it is measured to be 3.3×10^5 m/s. What is the strength of the magnetic field?
8. (II) A cork ball carrying charge q has a mass of 0.4 g and is set in straight-line motion perpendicular to a uniform magnetic field of 0.007 T. What is the value of q if its direction of motion changes by 0.05° in 3.0 s?
9. (II) (a) A rapidly moving charged particle of charge e, mass m, and speed v passes through a region of magnetic field $\vec{B}$, which points in a direction perpendicular to the motion. The particle spends a time interval Δt in the region. Estimate the angle θ through which it will be deflected during Δt, assuming that θ is small. (b) The particle is a proton, with $m = 1.7 \times 10^{-27}$ kg, and $e = 1.6 \times 10^{-19}$ C, and the speed is 1.4×10^7 m/s. The size of the magnetized region is 0.1 m across. How large must B be to give rise to a deflection of 0.1 rad?

10. (II) In an oversimplified model of Earth's magnetic field, the field is parallel to the rotation axis, has a constant magnitude of 10^{-4} T up to a height of 100 km, and then quickly drops to zero. A cosmic-ray particle with charge 1.6×10^{-19} C and mass 9.5×10^{-26} kg moves at a speed of 10^8 m/s directly toward the equatorial region from above. (a) In what direction is the particle deflected? (b) Estimate how much it will be deflected from the point of impact it would have if it were uncharged. (In fact, this is not a realistic example. Cosmic-ray particles as massive as this have greater charge.)

11. (II) Electrons travel at a speed of 6.0×10^7 m/s in a television tube. The electrons are affected by Earth's magnetic field. The tube, which is 0.40 m long, is located at a region where the magnetic field has a vertical component of 18 μT and a horizontal component of 24 μT (Fig. 28–30). If the initial direction of the electron beam is in the same direction as the horizontal component of Earth's magnetic field, in which direction, and by how much, is the electron beam deflected?

▲ FIGURE 28–30 Problem 11.

28–3 Consequences of the Magnetic Force on a Charge

12. (I) A proton is sent into a region of constant magnetic field, oriented perpendicular to the proton's path. There the proton travels at a speed of 3×10^6 m/s in a circular path of radius 240 cm. What is the magnitude of the magnetic field?

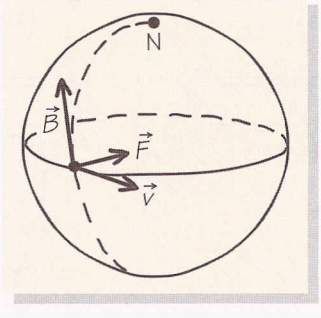
13. (I) (a) Suppose that electrons from an electron gun with a voltage of 1600 V are injected into a region of constant magnetic field perpendicular to the electrons' velocity. What magnetic field will give the electrons a radius of curvature of 6 cm? (b) A magnetic field of what magnitude is necessary to give an alpha particle (charge $q = 2e$ and mass $m_\alpha = 7360$ times the mass of an electron) with a kinetic energy of 1200 eV a path with radius of curvature of 20 cm?

14. (I) Show that the radius of curvature of a proton moving at a velocity of 25 km/s in a magnetic field of 10^{-10} T is small compared to interplanetary distances. The protons therefore spiral around interplanetary magnetic field lines; we say that the protons are "tied to the magnetic field lines" in cosmic magnetic fields.

15. (I) The magnetic field at the surface of a neutron star has magnitude 3×10^7 T. What is the radius of the circular orbit of an electron that moves there at 0.1 percent of the speed of light? What is the magnitude of the magnetic force on the electron?

16. (I) With what frequency will deuterons, which have the same charge as protons but twice the mass, circulate in a cyclotron with a magnetic field of 0.65 T?

17. (I) If we want to triple the cyclotron frequency associated with a proton accelerator from an initial value of 6.1 MHz, what quantity must we change, and from what initial value to what final value?



18. (I) In a certain region, the average radius of curvature of the trajectory of electrons trapped in the Van Allen belt is 300 m and the average electron energy is 100 keV. What is the value of Earth's magnetic field in this region?

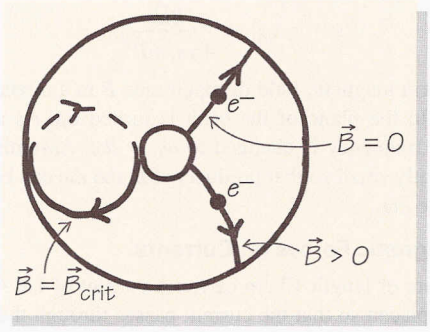
19. (I) Electrons of speed 10^6 m/s and protons of speed 10^4 m/s perpendicularly enter a region of constant magnetic field 10^{-5} T above Earth. What are the radii of their orbits? Why is the proton's radius greater? If the proton's speed were the same as that of the electron (10^6 m/s), what would be the radius of its orbit?

20. (II) An accelerator designer envisages circulating protons moving in a ring of radius 17 km by means of magnetic fields of magnitude 7.0 T. What is the magnitude of the momentum of a proton that moves in this way? For protons with this momentum, the energy is given to excellent accuracy by the formula $E = pc$, where c is the speed of light, about 3×10^8 m/s. Calculate the energy of the proton in megaelectron-volts; 1 MeV $= 1.6 \times 10^{-13}$ J.

21. (II) Assume that the electrons in a television picture tube have an energy of 10 keV and move perpendicularly to Earth's magnetic field (see Table 28–1). (a) Calculate the final velocity (vector) of an electron when it hits the screen if the horizontal distance the electron travels is 40 cm. (b) What is the deflection (distance) of the electron perpendicular to its original direction?

22. (II) Earth acts as a giant magnet whose field lines are like those of a bar magnet, running from the magnetic north pole to the magnetic south pole. The magnetic field at the equator is approximately constant, of magnitude 5×10^{-5} T, and runs from the geographic South Pole to the geographic North Pole (Fig. 28–31). If we ignore air resistance and the gravitational force, a charged object could orbit Earth at the equator as a result of the magnetic force if it has just the right velocity. Suppose that such an object has a charge of -1 mC and a mass of 1.0 g. (a) What would its velocity have to be for it to travel in such an orbit? (b) Suppose that the gravitational force acts on this object as well. What is the ratio of the gravitational force to the magnetic force?

▲ FIGURE 28–31 Problem 22.



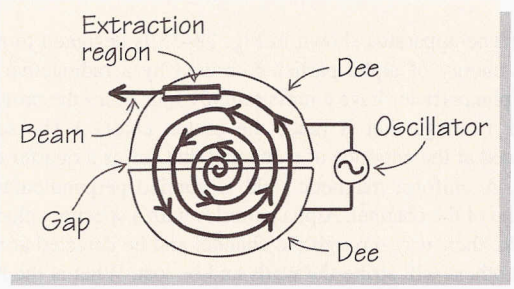
23. (II) In Section 28–3, we calculated the critical momentum for an electron to stay within the galaxy. (a) Given that the energy of a high-energy particle is related to its momentum by $E = pc$ (see Problem 20), what is the energy of an electron with the critical momentum? What are the critical momentum and energy for (b) an alpha particle (charge $2e$ and mass four times the mass of a proton) and (c) an ion of uranium, with charge e and mass 240 times the proton mass?

24. (II) A proton moves horizontally perpendicular to a constant magnetic field oriented so as to deflect the proton instantaneously upward. The magnitude of the field is 0.7×10^{-2} T. What is the speed of the proton so that the magnetic force just cancels the gravitational force on the proton, leaving it in horizontal flight? This problem illustrates how very weak the gravitational force is compared to electromagnetic forces.

25. (II) An electron moves at a speed $v = 3.0 \times 10^5$ m/s in a region of constant magnetic field of magnitude 0.12 T. The direction of the electron when it enters this region is at 40° to the field, and the electron follows a helical path. When you look along the direction of the magnetic field, the path is a projected circle. How far has the electron traveled along the direction of $\vec{B}$ when one projected circle has been completed?

26. (II) An electron enters a bubble chamber that contains a constant magnetic field of strength 0.035 T and follows a helical path. The spacing between the turns of the path is 8.5 mm, as is the radius of the circular part of the path. Find the components of the velocity parallel and perpendicular to the field.

27. (II) A vacuum tube contains two axial cylinders (Fig. 28–32). The potential difference between these cylinders is 500 V. Some electrons are released from the inner cylinder and are accelerated by the electric field toward the outer cylinder; a small current thereby travels through the tube. Suppose that a uniform magnetic field is set up parallel to the axis of the tube. This curves the trajectories of the electrons, and at a critical magnetic field, the electrons will no longer reach the outer cylinder, and the current ceases to flow. What is the kinetic energy of the electrons that hit the outer cylinder at a magnetic field just below the critical value?



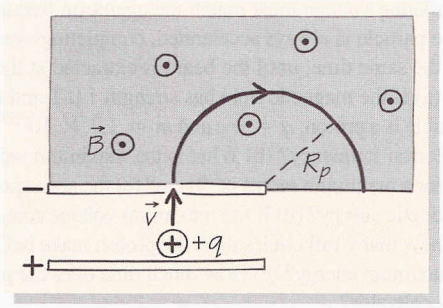
▲ FIGURE 28–32 Problem 27.

28. (II) A proton and an alpha particle, which has twice the charge and four times the mass of the proton, are each accelerated through the same potential difference and enter a region of constant magnetic field perpendicular to their paths. (a) What is the ratio of the radii of their orbits? (b) What is the ratio of the frequencies of their orbits?

29. (II) An electron is injected at $t = 0$ s with velocity $\vec{v}_0 = (2 \times 10^6 \text{ m/s})\hat{i}$ into a region with parallel electric and magnetic fields $\vec{E} = (1500 \text{ V/m})\hat{j}$ and $\vec{B} = (-0.2 \text{ T})\hat{j}$, respectively. Calculate the subsequent motion.

30. (II) You want to be able to tune a velocity selector such that you have the capacity to select electrons that have been accelerated from rest by a potential that runs from 1500 V to 15,000 V. If the magnetic field, B, is fixed at 0.40 T, what range of electric field strengths must be available? If the electric field strength were fixed at 15 V/cm, what range of magnetic field strengths must be available?

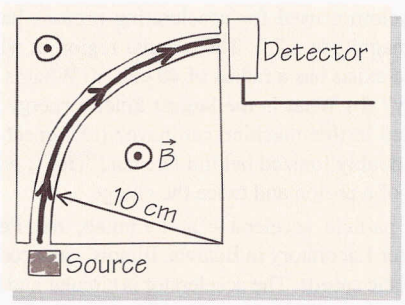
31. (II) Figure 28–33 is a schematic diagram of a cyclotron. A charged particle starts out at the central point and, for a given magnetic field perpendicular to the plane of motion, follows a circular path. The cyclotron takes advantage of the fact that the time for the particle to execute a half-circle is independent of the particle's velocity. An alternating voltage is applied across the gap between the two "dees" (the semicircular regions), so that when the particle crosses the gap, the voltage acts to accelerate it. When the particle gets to the gap again after having completed a half-circle, the voltage has changed sign, and the particle is once again accelerated. The frequency of the oscillating voltage must match the cyclotron frequency. In this way, the particle is always accelerated, completing ever bigger circles in the same time, until the beam is extracted at the maximum radius. (a) If the magnetic field has strength 1.0 T and the circulating particle is a proton, $q = +e$ and $m = 1.7 \times 10^{-27}$ kg, what is the cyclotron frequency? (b) What is the maximum velocity of the proton for a maximum radius of 50 cm? (c) the corresponding maximum kinetic energy? (d) If the maximum voltage across the gap is 50 kV, how many full circles does the proton make before it reaches its maximum energy? (e) How much time does the proton spend in the accelerator?



▲ FIGURE 28–33 Problem 31.

32. (II) A cyclotron used for accelerating protons has a magnetic field of magnitude 1.7 T. The circular region in which the magnetic field exists has a radius of 40 cm. (a) What is the cyclotron frequency? (b) What is the largest kinetic energy that a proton accelerated in this machine can have? (c) Repeat parts (a) and (b) for a doubly ionized helium nucleus, $^4\text{He}^{++}$, with four times the mass of a proton and twice the charge.

33. (II) The particle accelerator at Fermilab, the Fermi National Accelerator Laboratory in Batavia, Illinois, can accelerate protons to relativistic speeds. The accelerator is circular and holds the protons in circular paths by increasing the strength of a magnetic field perpendicular to this path as the protons' momentum increases. (The momentum increases because the protons pass repeatedly through regions of electric potential.) The radius of the main Fermilab accelerator is 6.2 km, and the magnets are capable of maintaining magnetic field strengths between 1 T and 4.5 T. Given that the magnitude of a proton's electric charge is 1.6×10^{-19} C, what range of momenta can be accommodated in this accelerator? Because protons of such momenta are highly relativistic, their energies are given by the approximate relativistic formula $E = pc$. What range of energies can be reached at Fermilab? What would the speed of a baseball, mass 0.15 kg, be if it had the energy of the most energetic protons at Fermilab? (For the baseball, use the normal nonrelativistic formulas that relate energy and speed.)



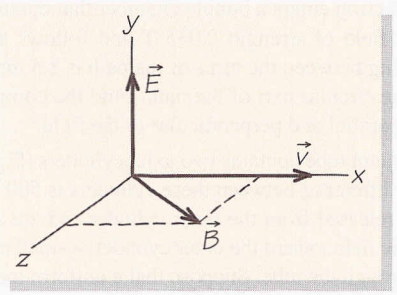
34. (II) A proton, with charge $q_p = +e$ and mass m_p, is accelerated through an electric potential V. The proton then enters a region of constant magnetic field $\vec{B}$ oriented perpendicular to its path. In this region, the proton's path is circular with radius of curvature R_p. Another particle with the same charge as the proton but with mass m_x follows under the same conditions. Its radius of curvature in the magnetic field, R_x, is 1.4 times as large as R_p. What is the ratio of m_x to m_p?

The device we have described is a type of *mass spectrometer*, which can be used to identify a material by the masses of that material's constituent molecules (Fig. 28–34, see next page). Sometimes, instead of a simple electrostatic potential as in our example, a velocity selector of crossed $\vec{E}$ and $\vec{B}$ fields is used to select particles of a given speed.

▲ **FIGURE 28–34** Problem 34.

35. (II) The apparatus shown in Fig. 28–35 is designed to measure the energy of alpha particles emitted by a radioactive source. (Alpha particles have a mass roughly four times the proton mass and a charge that is twice the proton charge.) The source is placed at the entrance of a channel that forms a quarter of a circle. A uniform magnetic field is applied perpendicular to the plane of the channel. Alpha particles with a specific velocity will make their way through the channel and be detected at the exit. All others will strike the walls and be lost. What is the range of values of B necessary to analyze alpha particles whose energies range up to 6 MeV?

▲ **FIGURE 28–35** Problem 35.



36. (II) A 150-MeV proton, moving in the x-direction, enters a region in which there is a magnetic field. The proton experiences an acceleration of 7.0×10^{12} m/s^2 in the y-direction. What can you say about the magnetic field?

37. (II) A 2.3-keV electron is moving horizontally and passes perpendicular to the Earth's magnetic field at a location where the field magnitude is 0.52 Gauss. What is the magnetic force on the electron? What is the ratio of this force to the gravitational force on the electron? What energy electron would be needed to make the magnetic and gravitational forces equal?

38. (II) The 88-inch (diameter) cyclotron was put into operation at the Lawrence Berkeley Laboratory in 1962 and for 40 years produced significant scientific results. It was able to produce protons up to 55 MeV energy, and heavier ions of mass A up to 5 MeV/A. (a) What was the maximum magnetic field of the magnet? (b) If a ^{86}Kr ion with charge $+19e$ is accelerated in this cyclotron, what maximum energy can be expected?

39. (II) Constant electric and magnetic fields are perpendicular to each other, the electric field pointing from left to right on the page, the magnetic field from the bottom to the top of the page. A proton with charge q and speed v moves into the region of the fields in the direction out of the page. (a) What are the directions of the magnetic and electric forces? (b) What is the magnitude of the resulting force on the proton? (c) When could this force ever be zero?

40. (III) You have an apparatus that can form an electric field of 2000 N/C and a magnetic field of 0.3 T. You want to build a velocity selector to select electrons of speed 2×10^4 m/s. (a) Draw the orientation of your apparatus, showing $\vec{E}$, $\vec{B}$, and $\vec{v}$. (b) What are the minimum and maximum values of v that you can select? [*Hint*: Set the apparatus up so that $\vec{v}$ and $\vec{B}$ are not perpendicular to each other (Fig. 28–36).]

▲ **FIGURE 28–36** Problem 40.

41. (III) A particle of mass m and charge $-q$ moves in a circular orbit of radius R about a fixed charge Q. The angular frequency for the orbit is given by

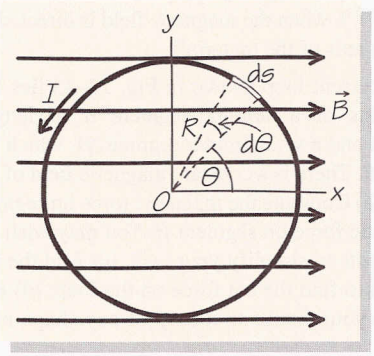
$$\omega_0^2 = \frac{qQ}{4\pi\varepsilon_0 mR^3}.$$

A uniform magnetic field of magnitude B in a direction perpendicular to the plane of the orbit is turned on. As a result, the angular frequency is changed to $\omega_0 + d\omega$. Assuming that B is sufficiently small so that products of B and $d\omega$ can be neglected, calculate $d\omega$.

28–4 Magnetic Forces on Currents

42. (I) A wire of length 12 cm carries a current of 1.3 A. When the wire is placed so that the current passes through the wire along the x-direction, the force on the wire due to an external magnetic field B is measured to be $-(0.02\text{ N})\hat{j}$. When the wire is moved so the current through the wire moves along the y-direction, the force is measured to be $(0.02\text{ N})\hat{i}$. What is the magnetic field?

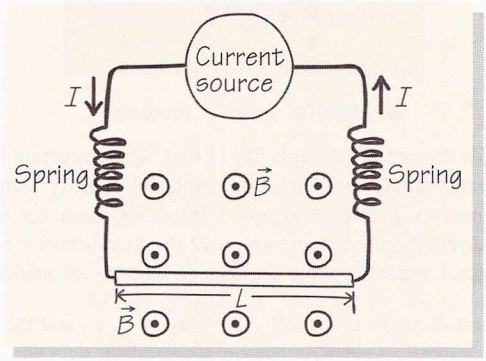
43. (I) A straight wire segment is placed in a region known to contain a constant magnetic field of unknown strength. A current of 6 A runs through the wire, which can be turned in various directions until the force per unit length acting on it takes on a maximum value of 0.18 N/m. What is the value of the magnetic field?



44. (I) A long wire carries a current of 6.5 A. A bar magnet is brought near the wire so that the charge carriers, of speed 1.7×10^{-4} cm/s, experience a magnetic field of 0.50 T perpendicular to their direction of motion. Calculate the force (a) on each moving charge carrier (electron) and (b) on a 1-m length of the wire.

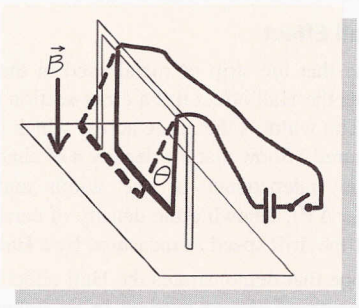
45. (I) A thin, straight wire carries a current of 10 mA and makes an angle of 60° with a constant magnetic field of magnitude 10^{-6} T. The portion of the wire in this field has a length of 10 cm. Calculate the force, both direction and magnitude, on this segment of the wire.

46. (I) The length of a vertical lightning conductor from roof to ground is 20 m. A lightning stroke leads to a current of 10^4 A flowing through the conductor. Given that Earth's magnetic field is horizontal and of magnitude 0.5×10^{-4} T at the location of the building, what is the force on the conductor during the period the current flows?



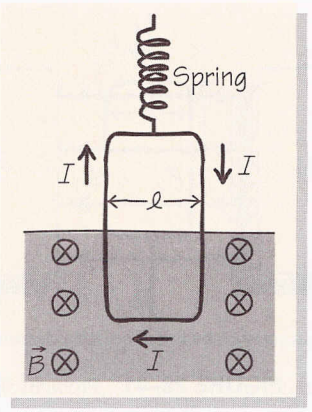
47. (I) A straight wire is placed in a uniform magnetic field of magnitude 0.010 T. The direction of the field makes an angle of 30° with that of the wire, which carries a current of 10 A. What is the force on a 1.0-m segment of the wire?

48. (II) A current I flows through a circular wire loop of radius R that lies in the xy-plane (Fig. 28–37). Consider a constant magnetic field of magnitude B that points in the x-direction. Calculate the force on an element of the loop formed by an angle $d\theta$, located at an angle θ from the $+x$-axis.



▲ FIGURE 28–37 Problem 48.

49. (II) A wire of length L is suspended from two springs of spring constant k attached to a current source (Fig. 28–38). A magnetic field B, in a horizontal direction perpendicular to the wire (out of the page), is turned on; a current I then flows in the wire, which moves to a new equilibrium position. Which way will the wire move, and by how much?



▲ FIGURE 28–38 Problem 49.

50. (II) In a physics lecture demonstration, a thick copper wire of length 0.8 m and mass 70 g is attached to two thin wires and suspended so that it is horizontal (Fig. 28–39). A 0.03-T magnetic field pointing in the downward direction is turned on. What angle will the supporting wires make with the vertical if a current of 0.5 A flows through the wire?

▲ FIGURE 28–39 Problem 50.

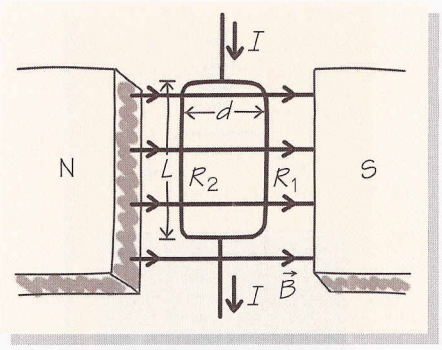
51. (II) Figure 28–40 shows a possible device for measuring magnetic fields. A loop carrying a current I is dipped into a region of magnetic field. The loop is suspended from a spring of spring constant k that stretches if the magnetic field points in a certain direction. Here the loop has width $\ell = 1.2$ cm, $I = 100$ mA, the spring stretches 0.6 cm, $k = 5 \times 10^{-2}$ N/m, and the magnetic field is uniform. What is the magnitude of the field? How could such a device be used, or modified, to measure fields that are not uniform?

▲ FIGURE 28–40 Problem 51.

28–5 Magnetic Force on Current Loops

52. (I) A wire coil of area 20 cm^2 with 180 turns experiences a maximum torque of 2×10^{-2} N · m when placed in a magnetic field of 0.3 T. What is the current through the coil?

53. (I) A rectangular wire loop of height 5 cm and width 3 cm consists of 60 turns and carries a current of 1.2 A. What are the magnitude and direction of the magnetic dipole moment? If a uniform magnetic field of 0.5 T is applied to the loop, and the field's direction makes an angle of 26° with the normal to the current loop, what is the torque (magnitude and direction) that acts on the loop?

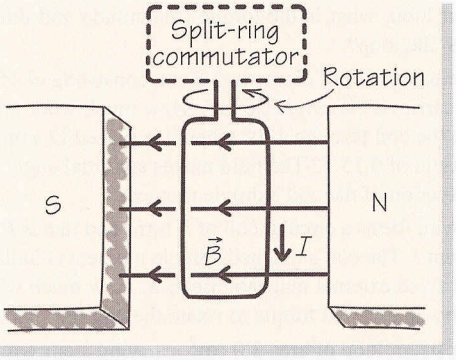


54. (I) A circular coil of diameter 2.5 cm, consisting of 1500 turns of wire, carries a current of 50 mA. How much work must be done to flip the coil through 180° when it is placed in a uniform magnetic field of 0.75 T? The field makes an initial angle of 50° with the direction of the coil's dipole moment.

55. (I) A wire forms a circular coil of N turns and radius R and carries a current I. The coil's magnetic dipole moment is initially aligned with a fixed external magnetic field, $\vec{B}$. How much work must be done by an external torque to rotate the coil through an angle θ?

56. (I) A current loop of area 3.0 cm^2, carrying a current of 5.0 A, is placed in a uniform magnetic field of 0.25 T such that the normal to the loop is perpendicular to the direction of the magnetic field. There is a torque, and the loop changes direction. Because of friction in the bearings, it settles to the minimum energy orientation. How much energy was dissipated in the process?

57. (I) An atom can have a magnetic dipole moment of 10^{-23} J/T. Such an atom is placed in a magnetic field of 10 T. What is the range of potential energies involved?

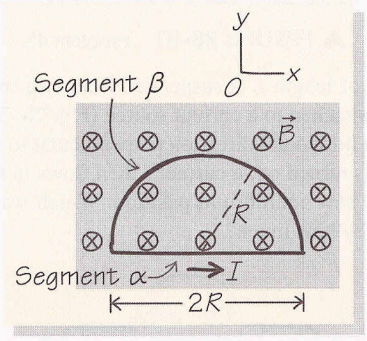


58. (II) A wire carrying a current I splits into two channels of resistance R_1 and R_2, respectively, forming a circuit. The wire enters the space between the two poles of a magnet with a uniform magnetic field that runs from one pole piece to the other (Fig. 28–41, see next page). The circuit forms a loop; the field lies in the plane of the loop. What is the torque on the circuit about the wire axis, given that the wires are a distance d apart and that the length of the split is L?

▲ FIGURE 28–41 Problem 58.

59. (II) A circular wire coil of area 6 cm^2 has 50 turns. When the coil is placed in a magnetic field of 0.2 T, the maximum torque is 3×10^{-5} N · m. (a) What is the current in the coil? (b) What work is required to rotate the coil 180° in the magnetic field? Does the work depend on the initial angle?

60. (II) An electric motor consists of a current-carrying wire loop in a constant magnetic field $\vec{B}$ (Fig. 28–42). The field produces a torque that tends to rotate the loop so that the loop's magnetic dipole moment, $\vec{\mu}$, and $\vec{B}$ become aligned. When that happens, a split-ring commutator reverses the current direction, so that $\vec{\mu}$ changes its orientation by 180°, and the torque acts to continue the rotation. Suppose that $\vec{\mu}$ and $\vec{B}$ start out almost antiparallel. Plot the magnitude of the torque as a function of the angle between $\vec{\mu}$ and $\vec{B}$, as this angle runs from $-\pi$ to 0. At 0° the commutator reverses the current. Plot the torque through another half turn. What is the average value of the torque through a full turn if the current in the motor is 6.2 A, the magnitude of $\vec{B}$ is 0.45 T, and the area of the loop is 54 cm^2?



▲ FIGURE 28–42 Problem 60.

61. (II) An electron, of charge $q = -1.6 \times 10^{-19}$ C, has a "size" of about 3×10^{-15} m, called its classical radius. The magnetic dipole moment of the electron is roughly 10^{-23} A · m^2. (a) Suppose that this magnetic moment were due to the entire charge q orbiting at the classical radius. What would the speed of the charge be to generate this magnetic moment? (b) Suppose that the electron's magnetic moment were perpendicular to a magnetic field of magnitude 1 T. What is the torque on the electron?

62. (II) (a) Calculate the magnetic dipole moment of a single atom, based on the following model: One electron travels at speed 2.2×10^6 m/s in a circular orbit of diameter 10^{-10} m. (b) The individual atomic magnetic dipoles of magnetic materials (such as iron) are preferentially lined up to point in the same direction. If a fraction f of the dipoles are so aligned along the long axis (with the rest oriented randomly so that their magnetic dipole moments add vectorially to zero), what is the net magnetic dipole moment of a piece of such material 1 cm^2 in area and 10 cm long? (The material may be viewed as an array of cubes, each of which contains one atom and is 10^{-10} m on a side.) (c) What is the torque experienced by the piece of material in part (b) in a field of 10^{-3} T when the magnetic field is directed at right angles to the long axis of the material?

63. (III) The current loop shown in Fig. 28–43 lies in the xy-plane and consists of a straight segment α of length $2R$ in the x-direction and a semicircular segment β, which has a radius of curvature R. There is a constant magnetic field of strength B into the page. (a) Compute the magnetic force on segment α. (b) Find the magnetic force on segment β. You may wish to use symmetry arguments to simplify your task. (c) Add the results of parts (a) and (b) to find the net force on the loop. (d) How could you generalize your results to a loop of any shape in the xy-plane?

▲ FIGURE 28–43 Problem 63.

64. (II) We showed in Example 28–11 that, when a current loop with magnetic dipole moment $\vec{\mu}$ is displaced slightly from perfect alignment of $\vec{\mu}$ and a magnetic field $\vec{B}$, the rotational motion of the current loop due to the torque of the field is harmonic. Given the usual expression for the kinetic energy associated with a rotation of angle ψ, namely $K = \frac{1}{2} I_M \left(\frac{d\psi}{dt}\right)^2$, and the approximate expression $\cos\psi \cong 1 - \psi^2/2$, calculate the angular frequency of the harmonic motion.

65. (III) A coil carrying current $I = 50$ mA has a moment of inertia $I_M = 7.5 \times 10^{-7}$ kg · m^2 about a rotational axis and an area of 6.0×10^{-4} m^2. The coil is placed in a magnetic field of magnitude 0.6 T, displaced 5° from alignment between its magnetic dipole moment, μ, and the field, and released from rest. Describe the subsequent motion. What is the maximum angular speed of the coil in that motion?

28–6 The Hall Effect

66. (II) Suppose that the strip of metal used in the apparatus that demonstrates the Hall effect has a cross section of width w and depth d_0. (The width is the space across which the Hall voltage ΔV is measured.) Show that the density n of charge carriers with charge e is independent of the width and is given by $n = IB/(d_0 e\,\Delta V)$. Knowing the density of carriers, find an expression for the drift speed as measured by a Hall apparatus.

67. (II) The probe that demonstrates the Hall effect is used to measure the density of charge carriers in an unknown sample of metal. A sample of the material 1.5 mm thick is placed in a magnetic field of 1.2 T. When a current of 1.8 A passes through the material, a Hall voltage of 6.2 μV is measured. What is the density of charge carriers?

68. (II) A Hall-effect probe can be used to measure the magnitude of a magnetic field. A researcher has lost the instruction booklet and forgotten the calibration procedure. However, when she places the Hall probe inside a known magnetic field of 7500 G, she measures a Hall voltage of 165 mV. What is the field of a magnet with a Hall voltage of 390 mV?

General Problems

69. (II) The wire coil of a galvanometer has an area of 2 cm^2 and 500 turns. The coil is placed in a magnetic field of magnitude 0.18 T and oriented so that its plane is initially parallel to the field. The restoring torque of the galvanometer spring is proportional to the angular deflection, with a proportionality constant of 10^{-8} N · m/° (see Example 28–9). What current corresponds to a deflection of 70°?

70. (II) The masses of atomic ions of known charge can be precisely measured by finding the time an atom takes to complete a circular trajectory in a known magnetic field. With a magnetic field of magnitude 3.0 T and an apparatus capable of measuring times to an accuracy of 10^{-9} s, how accurately can the mass of an ion with charge $+e$ be measured in 1 rev? If the mass is to be measured to an accuracy of 5×10^{-31} kg, how many revolutions must be measured?

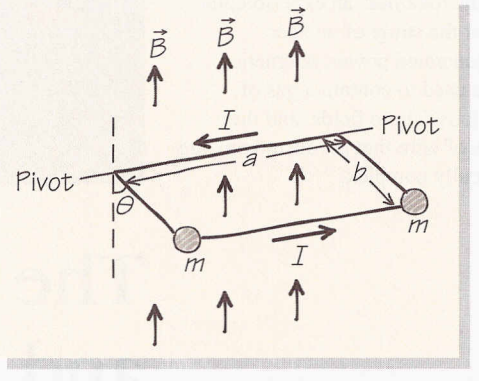
71. (II) When an electron orbits a proton, the smallest circular orbit is one with a radius of about 0.5×10^{-10} m, the Bohr radius. The proton's electric field must have what magnitude to make the electron follow this orbit? Compare the magnitude of the magnetic field that would be required to make an electron move in a circle of the same radius at the speed it would have if it were orbiting a single proton.

72. (II) A massive charge Q is fixed at the origin of a coordinate system. A magnetic field $\vec{B}$ points in the $+z$-direction. A light particle of charge q and mass m moves in a circular orbit of radius r about the origin. For what value of $\vec{B}$ (as a function of r) is such motion possible if Q and q have the same sign and if the angular momentum of the motion is a fixed constant L?

73. (II) Consider a parallel-plate capacitor with charge density $\pm 8.0 \times 10^{-7}$ C/m^2 on the two plates and an electric field that points in the $+z$-direction. What magnetic field is necessary to provide a velocity selector for 60-keV deuterons that move in the $+y$-direction? A deuteron has a mass of 3.2×10^{-27} kg and a charge of 1.6×10^{-19} C; 1 keV = 1.6×10^{-16} J.

74. (II) A narrow beam of particles of mass m and charge q travels in free space at speeds between v_1 and v_2. It enters a region of length L with a constant magnetic field that points perpendicular to the beam direction and parallel to the boundary between the field-free region and the region with the field. There, it follows a circular path with radius of curvature R until it exits that region. Show that the beam widens when it emerges from the region with the field, and calculate the spread in terms of a range of angles.

75. (II) An electron moving in the xy-plane is subject to forces due to a constant magnetic field $\vec{B}$ that points in the $+z$-direction. Assuming that the electron loses 10 percent of its energy after 20 turns, as a consequence of frictional forces, what will the fractional change in the radius of the orbit be after 20 turns?



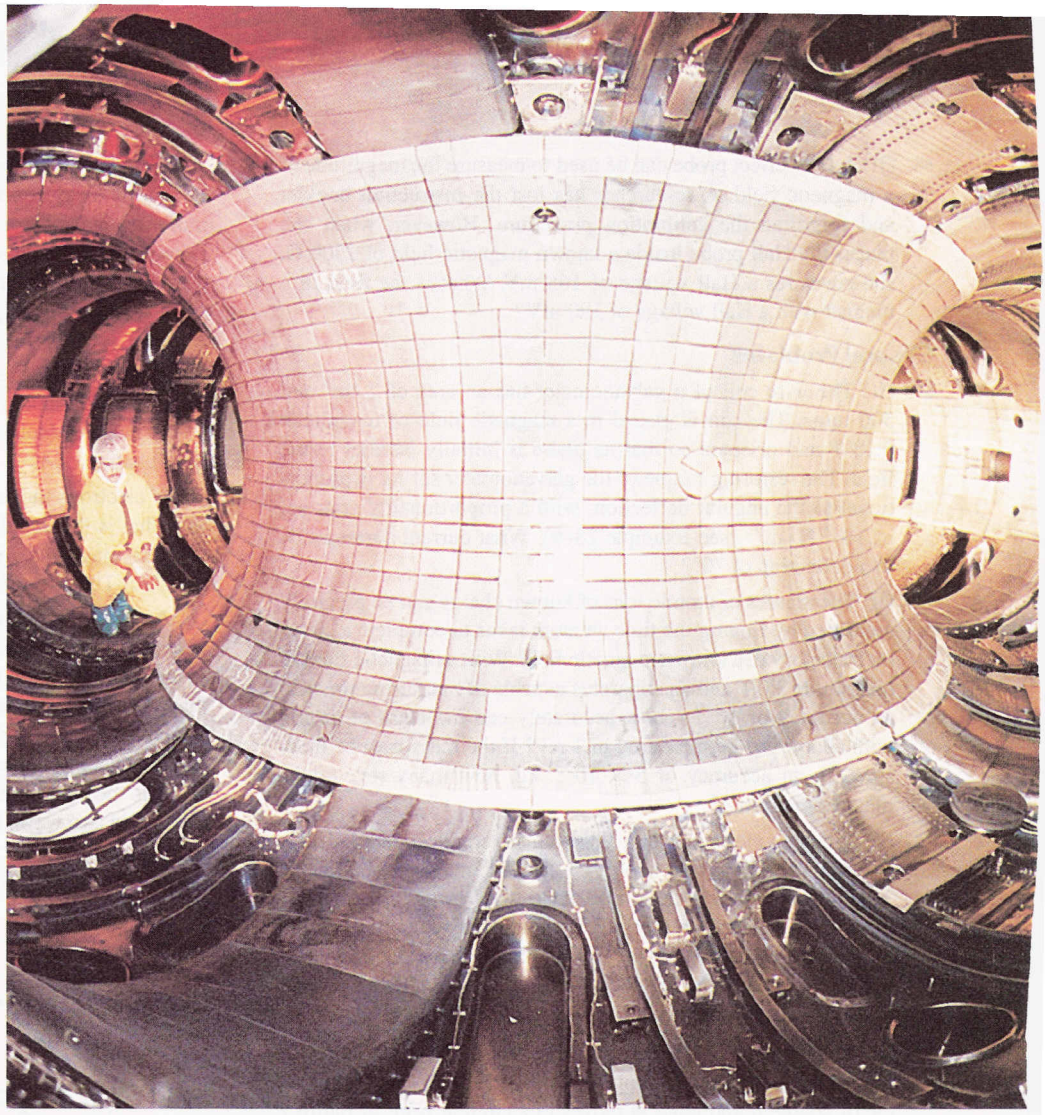
76. (II) For the motion described in Problem 75, (a) what will the fractional angular-momentum change be during the 20 turns? (b) What is the torque exerted by the frictional forces in terms of the initial kinetic energy?

77. (II) Electrons are injected into a region with a constant magnetic field $\vec{B}$ by an electron gun with known voltage V. The electrons move in a plane perpendicular to $\vec{B}$ and follow an arc of radius R. Determine the charge-to-mass ratio e/m for the electrons in terms of the given parameters.

78. (II) Particles with mass $M_A = A(1.6 \times 10^{-27}\ \text{kg})$ and charge $q = 1.6 \times 10^{-19}$ C are accelerated by a potential difference of 6.0×10^4 V and directed perpendicularly into a region of uniform magnetic field of strength 2.2 T. The region with the field is 35 cm deep. Calculate the angular deflection of the particles, θ, as a function of A.

79. (II) N electrons move at speed v in a circular orbit of radius R. (a) What is the angular momentum of the system of electrons? (b) The magnetic dipole moment associated with the current loop? (c) The ratio of the quantities in parts (a) and (b)?

80. (II) A rectangular wire loop of width a and height b is connected to a current source that, when turned on, gives rise to a current I in the wire. The loop is suspended in a uniform magnetic field $\vec{B}$ that points in a vertical direction (Fig. 28–44), and it would hang vertically if there were no current. We assume that the wire is massless, but two masses m are suspended at the lower corners. What is the angle θ at which the loop is in equilibrium? Calculate this in two ways: by using torques, and by expressing the potential energy as a function of θ and minimizing it. What happens if the direction of the current is reversed?



▲ FIGURE 28–44 Problem 80.

81. (III) A particle of charge q and mass m is subject to gravity acting downward on the page, and a magnetic field of magnitude B acting in a direction perpendicular to the page, pointing into the page. We assume that the initial velocity of the particle is zero. (a) Show that the motion will only be in the plane of the page; (b) if there are many such particles, and their mutual Coulomb repulsion is negligible, what is the direction of the average current? (c) Check your conclusions by writing out the form of Newton's second law for the three components of the motion.

82. (III) Suppose that an experimental apparatus can have both electric and magnetic fields constant in magnitude and direction. In this apparatus a proton moving at a speed of 5.0×10^4 cm/s in the $+z$-direction does not accelerate, whereas a proton moving at a speed of 8.0×10^4 cm/s with no x-component at an angle of 42° with respect to the z-axis experiences an initial acceleration of magnitude 3.5×10^8 m/s^2 in the $-x$-direction. A proton moving in the xy-plane has a circular orbit. Find the values of $\vec{E}$ and $\vec{B}$ in the apparatus.

Chapter 29

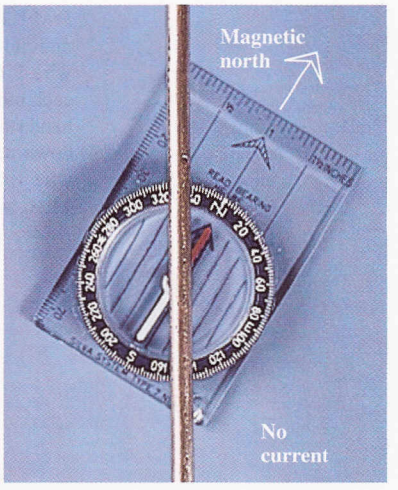
▶ In the tokamak, an experimental device for the study of nuclear fusion–generated power, magnetic fields are used to contain a gas of positive ions. These fields, and the windings of wire that produce them, are topologically complex.

The Production and Properties of Magnetic Fields

We have seen how magnetic fields influence moving charges and current-carrying wires. But where do the magnetic fields themselves come from? We have seen that an electric charge creates an electric field, and that an electric field exerts a force on a charge. Similarly, a *moving* charge or a current *creates* a magnetic field, just as we know that a magnetic field exerts a force on a *moving* charge or a current. In other words, currents and moving charges exert magnetic forces on each other. In this chapter, we will describe and explore the ways in which magnetic fields are produced, and learn the properties of these fields, some quite different from those of electric fields. We shall also continue to explore the close relation between electric and magnetic fields.

29–1 Ampère's Law

Over the winter of 1819–1820, Hans Christian Oersted discovered that electric currents influence compass needles (Fig. 29–1). Until this discovery, there was only a suspicion of a connection between electricity and magnetism. Oersted, as well as André-Marie Ampère, soon showed that *current-carrying wires exert forces on each other*. Because



such wires are everywhere electrically neutral, these forces are not electric. As we saw in the previous chapter, a current-carrying wire aligns iron filings on a plane perpendicular to the wire in a circular pattern (Figure 28–2c). This suggests that a current-carrying wire creates the magnetic field.

The Magnetic Field of a Straight Wire

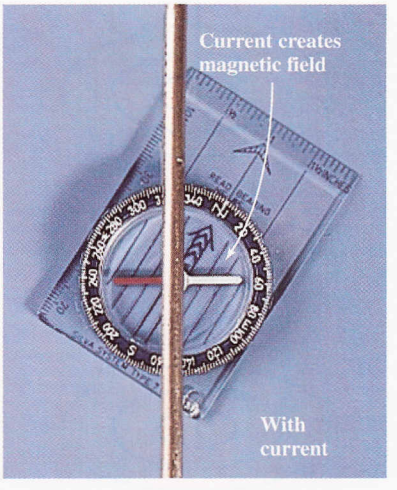


Figure 29–2 shows a set of experiments that tell us much about the nature of the magnetic fields produced by a current-carrying wire. To start with, in Figs. 29–2a and 29–2b two parallel wires with current flowing in the same direction are attracted to each other, while in Figs. 29–2c and 29–2d we see that if the currents flow in opposite directions, the parallel wires repel. If we interpret the force between the two current-carrying wires in Fig. 29–2 as a magnetic force on one wire due to the magnetic field produced by the other and perform some measurements, we can determine the magnetic field of a straight wire. In Fig. 29–3a we redraw the situation with wire segments that are long, $L \gg d$, where L is the wire length and d their separation. In this limit all other segments of the wires are distant and can be ignored, because the forces between the wires weaken considerably as the separation between the wires increases. Only the relatively close long, parallel segments come into the picture. In Fig. 29–3a, the force on wire 2, which is directed to the left, is due to the magnetic field of wire 1. Equation (28–19) describes the force on a segment of current-carrying wire. Using this equation, the force on wire 2 is of the form

$$\vec{F}_2 = I_2 \vec{L}_2 \times \vec{B}_1, \tag{29–1}$$

provided only that the field $\vec{B}_1$ due to wire 1 is the same all along wire 2, an assumption that is justified for arbitrarily long wires. Here the vector $\vec{L}_2$, of magnitude L, is oriented along the direction of I_2.

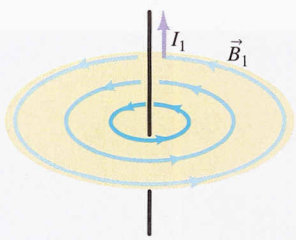
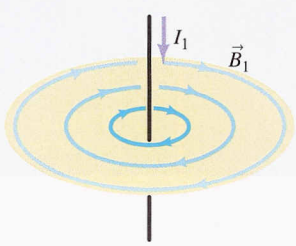
(d)

◀ **FIGURE 29–2** Two parallel wires that carry currents exert forces on one another; these forces are larger when the wires are closer. (a) and (b) The currents are parallel, and the forces are attractive. (c) and (d) The currents are antiparallel, and the forces are repulsive.



(a)

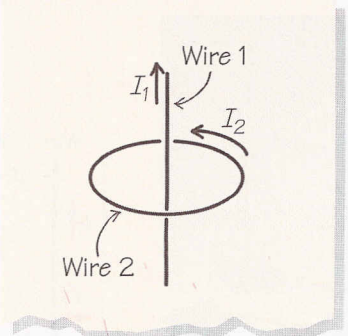


(b)

▶ **FIGURE 29–3** Determining the direction of the magnetic field due to wire 1. Currents I_1 and I_2 are parallel to each other. (a) According to the right-hand rule, $\vec{B}_1$ due to wire 1 is directed down when wire 2 is to the right of wire 1. (b) $\vec{B}_1$ due to wire 1 is directed up when wire 2 is to the left of wire 1.

(a)

(b)

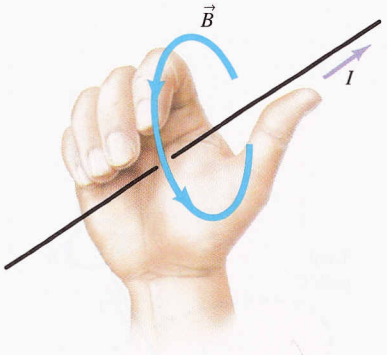


▲ **FIGURE 29–4** (a) The magnetic field due to wire 1, $\vec{B}_1$, traces out a circle around the wire in the direction shown. (b) If the current in wire 1 were reversed, the orientation of $\vec{B}_1$ would change.

If we move wire 2 around wire 1 in such a way that the wires remain parallel and at the same separation (moving from the position in Fig. 29–3a to that in Fig. 29–3b), we find that the force remains attractive and does not change in magnitude. This observation and Eq. (29–1) are consistent with the interpretation that *the magnetic field $\vec{B}_1$ due to wire 1 follows a circle around wire 1*. Application of a right-hand rule in Eq. (29–1) shows that $\vec{B}_1$ must be directed down when wire 2 is in its original position to the right of wire 1 (Fig. 29–3a). If wire 2 is moved to the left of wire 1, however, field $\vec{B}_1$ at wire 2 will be directed up because the two wires continue to attract each other (Fig. 29–3b). By using this argument for other positions, we find that the magnetic field lines due to wire 1 make circles about wire 1 (Fig. 29–4a; see also Fig. 28–2c). Equation (29–1) shows that force $\vec{F}_2$ is insensitive to any component of $\vec{B}_1$ that is *parallel* to the wires, because the vector product of two parallel vectors is zero—there may be a component of $\vec{B}_1$ parallel to the wire, but due to Eq. 29–1, we can't tell from the experiments that we have so far discussed. We have to resort to another argument—see Conceptual Example 29–1—to rule out a component of $\vec{B}_1$ parallel to wire 1.

If we reverse the current in wire 1 as we did in Fig. 29–2b, we find that the force on wire 2 is also reversed—the wires repel—and we interpret this as a change in direction of the magnetic field around wire 1 (Fig. 29–4b). The field lines again form circles around the wire, but in the opposite direction.

CONCEPTUAL EXAMPLE 29–1 In an experiment, a wire (wire 2) is wrapped in a circle around a straight wire (wire 1), as in Fig. 29–5. Measurements show that when constant currents run through them, there are no forces between them, and it is claimed that this shows that wire 1 produces no component of magnetic field parallel to itself. Is this correct?



Answer Yes. Symmetry tells us that any component of $\vec{B}_1$ oriented parallel to wire 1 will be the same all the way around wire 1, so that every segment of the circle formed by wire 2 will be in the presence of the same field $\vec{B}_1$. But then an application of the right-hand rule shows that a component of $\vec{B}_1$ parallel to wire 1 would cause a force to be exerted on wire 2. As Eq. (29–1) indicates, such forces would tend to expand or contract the circle traced by wire 2, and this effect would be measurable. Wire 1 does not produce a component of the magnetic field parallel to itself.

▲ **FIGURE 29–5** If wire 2 traced a circle around wire 1, it would react to any components of $\vec{B}_1$ due to wire 1 that are parallel to wire 1. No such forces are found.

We can summarize the results above by saying that the direction of the magnetic field produced by a straight wire is determined by a right-hand rule (Fig. 29–6):

If the thumb of the right hand is oriented along the direction of current flow in a wire, the fingers curl in the direction of the magnetic field.

▲ **FIGURE 29–6** A right-hand rule determines the direction of the magnetic field around a current-carrying wire.

We have found the direction of the magnetic field produced by the current. How do we find its magnitude? We do this by measuring the magnitude of the force between the wires, and such measurements show that the magnitude of the force between two parallel, straight segments of wire is

$$F = \frac{CI_1I_2L}{d},$$

where I_1 and I_2 are the currents in wires 1 and 2, respectively, d is the separation between the wire segments, and L is their length. The proportionality constant C depends on how we define the units of current. Conversely, if we use a *defined* proportionality constant, the force between two current-carrying wires determines the units of current. This latter alternative is the one used in the SI: C is defined according to

$$F = \frac{\mu_0 I_1 I_2 L}{2\pi d}, \tag{29–2}$$

where the constant μ_0, called the **permeability of free space**, is

$$\mu_0 \equiv 4\pi \times 10^{-7}\ \mathrm{T \cdot m/A}. \tag{29–3}$$

With this definition of C (that is, of μ_0) 1 A is defined as the current that travels in two long, parallel wires of length L that are 1 m apart, such that the attractive force between them is $(2 \times 10^{-7}\ N/m)\ L$. Is this result consistent with previous definitions of the current? In Chapter 21, we defined the coulomb as the charge on two pointlike objects such that there is a certain force between them, and we provisionally defined 1 A as 1 C/s in Chapter 26. The definition of the coulomb in terms of a force between charges depends on another constant, ε_0, in exactly the same way that the definition of the ampere depends on μ_0. Thus, for our relations to be consistent, ε_0 *must be a measured constant*. If both μ_0 and ε_0 are known, the same must be true for their product, which is given by

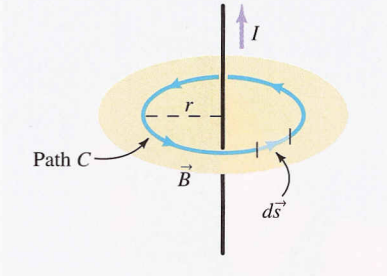
$$\mu_0\varepsilon_0 \equiv c^{-2} = (2.99792458 \times 10^8\ \mathrm{m/s})^{-2}. \tag{29–4}$$

The constant c is precisely the speed of light! We shall see in Chapter 34 why this is so.

Comparison of Eqs. (29–1) and (29–2) shows that a long, straight wire that carries a current I gives rise to a magnetic field whose magnitude at a distance r from the wire is

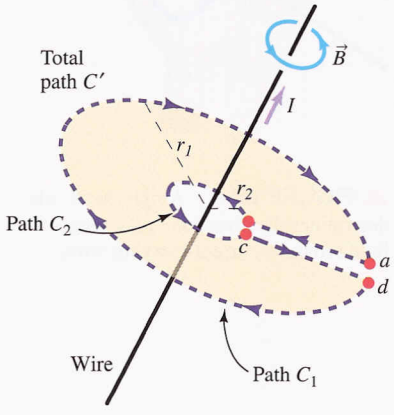
$$B = \frac{\mu_0 I}{2\pi r}. \tag{29–5}$$

Ampère's Law



We can find a more universal form for the magnetic field produced by a current by expressing Eq. (29–5) in a different form, one that relates the magnetic field along a closed path to the electric current that the closed path encloses. This relation is what is known as Ampère's law. We'll see that we can use it to find the magnetic field in symmetric situations much as we use Gauss' law to find the electric field in symmetric situations.

To arrive at Ampère's law, imagine a line integral over the magnetic field $\vec{B}$ that follows a circular path of radius r all the way around a long wire, as in Fig. 29–7. The integration path, labeled C, thus follows the direction of $\vec{B}$. The path is broken into infinitesimal distance elements $d\vec{s}$ that are parallel to the magnetic field, so $\vec{B} \cdot d\vec{s} = B\,ds$. Finally, B is a constant when the distance r from the wire is constant and we can remove it from the integral:



$$\oint \vec{B} \cdot d\vec{s} = B \oint ds = B(2\pi r). \tag{29–6}$$

(The sign $\oint$ indicates that the path of the line integral is closed, going all the way around the circle.) The factor $2\pi r$ is the length of the path, the circumference of the circle of radius r. If we use Eq. (29–5), we find that

$$\oint \vec{B} \cdot d\vec{s} = \frac{\mu_0 I}{2\pi r} 2\pi r = \mu_0 I. \tag{29–7}$$

▲ **FIGURE 29–7** Path C circles a current-carrying wire at a constant distance r from the wire and follows the direction of the magnetic field, $\vec{B}$, around the wire.

▲ **FIGURE 29–8** This path does not form a closed path around the wire. Path C' consists of a clockwise circle C_1 of radius r_1, a leg from a to b that moves inward to a distance r_2 from the wire, a counterclockwise circle C_2 of radius r_2, and a leg from c to d that moves outward to r_1.

Equation (29–7) includes a right-hand-rule convention in which path C must be in the direction of the fingers of the right hand when the thumb is oriented along I. Equation (29–7) is the first step in the development of Ampère's law.

A current "pierces" the closed path C described above (or more properly pierces a surface whose edge is formed by the path C). Now let us consider a similar integral, but this time over a closed path *not* pierced by a current, for example path C' shown in Fig. 29–8. We thus wish to compute $\oint_{C'} \vec{B} \cdot d\vec{s}$. This time we shall see that the integral vanishes. We first break the path C' into the segment from a to b, the nearly full circle C_2, the segment from c to d, and the nearly full circle C_1. The total contribution of the two paths from a to b and c to d is zero, because $\vec{B}$ is perpendicular to the path there. Thus in the limit that the "nearly" full circles get arbitrarily close to closing,

$$\oint_{C'} \vec{B} \cdot d\vec{s} = \int_{C_1} \vec{B} \cdot d\vec{s} + \int_{C_2} \vec{B} \cdot d\vec{s} = -B_1(2\pi r_1) + B_2(2\pi r_2). \qquad (29\text{–}8)$$

Here B_1 is the magnitude of the magnetic field at a distance r_1 from the wire, and B_2 is the magnitude of the field at a distance r_2. The first term is negative because $\vec{B}$ is oriented opposite to the path direction on segment C_1. From Eq. (29–5) we see that the two terms on the right of Eq. (29–8) cancel:

$$\oint_{C'} \vec{B} \cdot d\vec{s} = -\frac{\mu_0 I}{2\pi r_1}(2\pi r_1) + \frac{\mu_0 I}{2\pi r_2}(2\pi r_2) = -\mu_0 I + \mu_0 I = 0. \qquad (29\text{–}9)$$

The difference between the integral over path C and that over path C' arises from the fact that path C encloses current I, whereas path C' encloses no current. This is the first step toward the following generalization. Let the quantity I_{enclosed} be the total current enclosed by *any closed path*. Then

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 I_{\text{enclosed}}, \qquad (29\text{–}10)$$

AMPÈRE'S LAW

where the integral is taken around that closed path. Equation (29–10), which was formulated by Ampère in the 1820s during his extensive work on magnetism, is known as **Ampère's law**. The direction of the loop integral must be specified: If the fingers of the right hand curl in the same sense as the integral path, the thumb points in the direction a positive current takes in passing through the loop. The total current can include both positive and negative contributions, and *the path does not have to be circular, just closed.*

Ampère's law includes an experimental result that is worth pointing out: *The magnetic fields produced by different currents add, or superpose*, just as the electric fields of different charges add according to the superposition principle.

▲ **FIGURE 29–9** This clip-on ammeter uses Faraday's law to measure the current through the wire it surrounds, here 5.0 A. The jaws of the ammeter can be opened to allow its positioning.

THINK ABOUT THIS. . .

CAN YOU MEASURE A CURRENT WITHOUT ENTERING THE CIRCUIT?

It is not always easy to insert an ammeter directly into a circuit wire, for example a wire from your car's battery. If we want to measure the current carried by one or more wires in a bundle of many wires without physically entering the circuit, we can use a device known as a clip-on ammeter, shown in Fig. 29–9. It works by measuring the magnetic field that the current in the wire produces; Ampère's law then gives the current. In its simplest form the magnetic field is measured with a permanent dipole magnet pointer mounted on a center point bearing much like a magnetic compass. When a current is present in the wire, the magnetic field generated deflects the pointer. The deflection angle depends on the torque induced by the magnetic field—and hence the current. In more sophisticated versions of the clip-on ammeter, the magnetic field sensor is a Hall effect sensor (see Chapter 28). Clip-on ammeters can be found in automobile parts stores; mechanics use them to measure the current through a starter motor.

Using Ampère's Law to Find the Magnetic Field

If there is some symmetry that suggests that the integral over a particular path is simple, then Ampère's law [Eq. (29–10)] can be used to *find* the magnetic field, in analogy with the way we use Gauss' law to find electric fields. In the case of Gauss' law, the integral is taken over a closed surface, and $\vec{E}$ is related to the electric charge enclosed. In the case of Ampère's law, the integral taken is along a closed path, and $\vec{B}$ is related to the electric current enclosed by the path.

EXAMPLE 29–2 The current I within a wire that has a circular cross section of radius R is known to be distributed uniformly over that cross section. (Real currents in real wires would show some variance from this.) What is the magnetic field as a function of the distance r from the wire's axis outside the wire, and what is it within the wire?

Setting It Up We show current moving through the wire in Fig. 29–10. The wire has cylindrical symmetry—it looks the same as we move around it at a fixed distance.

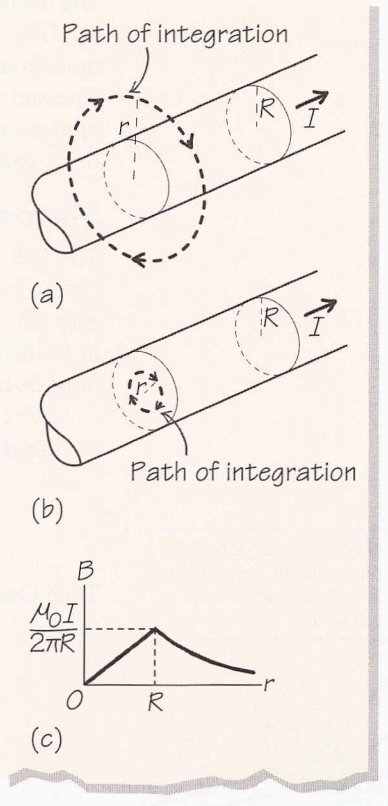
Strategy The cylindrical symmetry means that any magnetic field will not vary with the angle around the wire; the field is a function only of the radial distance r from the central axis. We can apply Ampère's law—Eq. (29–10)—for a circular path of radius r centered on the middle of the wire, and use the fact that $\vec{B}$ will be the same all along this path. This will allow us to pull the magnitude of the magnetic field from the integration of Ampère's law. In turn, we can then use information about the current enclosed by the path to solve for the field as a function of r. The amount of current enclosed depends on whether the path lies outside or inside the wire. Figure 29–10a shows a path *outside* the wire that will determine the field outside, and Fig. 29–10b shows a path *inside* the wire that determines the field inside.

Working It Out By the right-hand rule, $\vec{B}$ is oriented in the direction of the path, so $\vec{B} \cdot d\vec{s} = B\,ds$. The magnetic field magnitude is constant over the chosen path and thus comes out of the integral, leaving just the circumference of the path. If the circular path is outside the wire, the current enclosed is the *total* current carried by the wire. Thus Ampère's law becomes

$$\oint \vec{B} \cdot d\vec{s} = \oint B\,ds = B \oint ds = B(2\pi r) = \mu_0 I.$$

We can solve for B to find that

$$B = \frac{\mu_0 I}{2\pi r},$$



the same result we found for a thin wire. Note that the magnetic field outside the wire is independent of the size of the wire, just as the electric field outside a spherically symmetric charge distribution is independent of the size of the distribution.

We continue to use symmetry to find the field inside the wire, but this time we take our circular path *inside* the wire (Fig. 29–10b). The current enclosed by the path is I times the ratio of the area of the circle of radius r to the area of the wire:

$$I_{\text{enclosed}} = I\frac{\pi r^2}{\pi R^2}.$$

As before, Ampère's law gives

$$\oint \vec{B} \cdot d\vec{s} = B(2\pi r) = \mu_0 I\left(\frac{\pi r^2}{\pi R^2}\right).$$

▲ **FIGURE 29–10** (a) A circular path of radius r is used to determine the magnetic field outside a wire that carries a current I. (b) A similar path inside the wire. (c) The magnitude of the magnetic field versus r.

If we solve for B, we find that

$$B = \frac{\mu_0 I}{2\pi R^2} r.$$

By analogy with Gauss' law for electricity, any current outside a circle of radius r makes no contribution to the net magnetic field at radius r. Inside the wire, the magnetic field decreases linearly to zero as r approaches zero. As a check, we see that the results for outside and inside the wire agree at $r = R$. Figure 29–10c is a graph of the magnitude of the magnetic field.

What Do You Think? Would this method give us the same magnitude and direction for the magnetic field if the current were reversed? *Answers to **What Do You Think?** questions are given in the back of the book.*

29–2 Gauss' Law for Magnetism

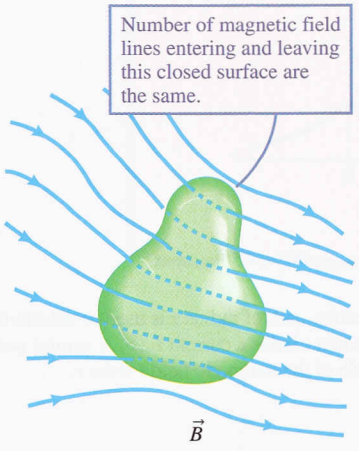
We have already studied Gauss' law for electricity. Is there a Gauss' law for magnetism similar to that for electricity? In this section, we shall see in what sense such a law holds.

There is an important difference between electricity and magnetism that determines the form of Gauss' law for magnetism: Despite much experimental effort, *magnetic charges* (**monopoles**) *have never been observed.* A magnetic monopole would be a source of magnetic field analogous to electric charges as sources of the electric field. Finding magnetic monopoles would be the equivalent of being able to isolate the N or S poles of a bar magnet. The bar magnet's magnetic field looks from the outside like the electric field of an electric dipole, and we can of course separate the plus and minus charges that form the electric dipole. But when we try to separate the N and S poles of a bar magnet by cutting the magnet in two, we end up with two smaller bar magnets.

The consequence of these observations for the magnetic field is that if magnetic monopoles analogous to electric charges existed, then magnetic field lines would originate and terminate on magnetic monopoles, just as electric field lines originate and terminate on electric charges. But since there are no magnetic monopoles, *magnetic field lines, unlike electric field lines, must form closed curves.*

Magnetic Flux and Gauss' Law for Magnetism

The fact that there are no magnetic charges means that a relation similar in form to Gauss' law for electricity holds for magnetism, but with the electric charge replaced by zero. In other words, Gauss' law for magnetism is equivalent to the statement that if field lines are continuous, then the number of field lines entering any closed surface must be the same as the number leaving.



We come to the explicit statement of the law by defining the **magnetic flux** Φ_B for a magnetic field $\vec{B}$ over a surface S, open or closed, by

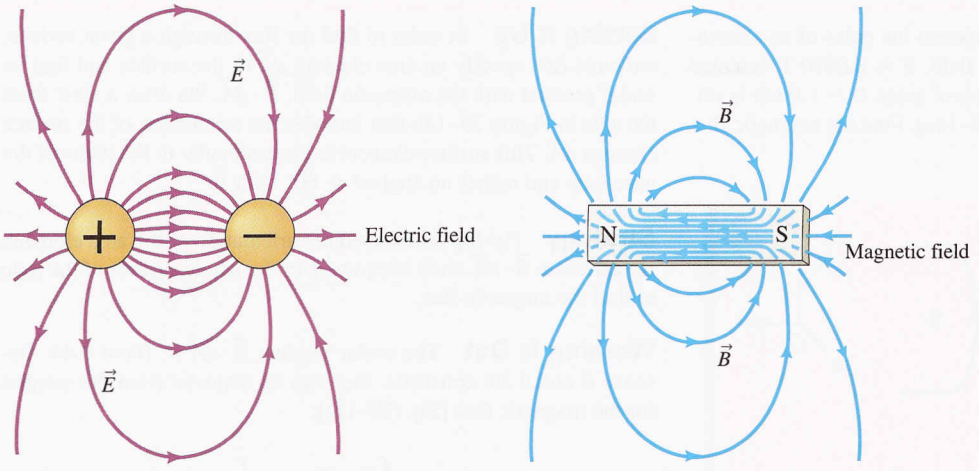
$$\Phi_B(S) \equiv \int_{\text{surface } S} \vec{B} \cdot d\vec{A}. \tag{29–11}$$

Then **Gauss' law for magnetism** is

$$\text{for a closed surface: } \Phi_B = \int_{\text{closed surface}} \vec{B} \cdot d\vec{A} = 0. \tag{29–12}$$

GAUSS' LAW FOR MAGNETISM

▲ **FIGURE 29–11** Magnetic field lines are everywhere parallel to the magnetic field; their density measures the field's strength. There are no magnetic charges, so magnetic field lines do not end, as there is nothing for them to originate or end upon, and the magnetic flux through a closed surface is zero. This is Gauss' law for magnetism.



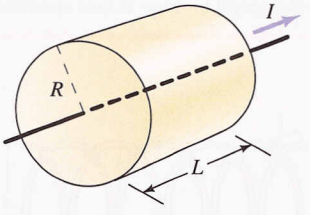
As for the electric flux, infinitesimal surface elements $d\vec{A}$ are perpendicular to the surface and, for a closed surface, are oriented outward. We can easily see why this holds by thinking in terms of field lines and noting that the field lines for a magnetic field do not terminate. The magnetic flux is a measure of the number of field lines that go out of a surface minus the number of lines that go in. But since magnetic field lines are continuous, the number of magnetic field lines that enter a closed surface minus the number that leave the surface is zero (Fig. 29–11). Any magnetic field line entering a closed surface must leave it somewhere because there are no magnetic monopoles inside on which magnetic field lines can begin or end.

The SI unit for magnetic flux is the unit of magnetic field times area, that is, tesla times square meters ($\text{T} \cdot \text{m}^2$). This unit occurs often enough to be given its own name in SI, the **weber** (Wb), after Wilhelm Eduard Weber:

$$1\ \text{Wb} \equiv 1\ \text{T} \cdot \text{m}^2. \tag{29–13}$$

The Field Lines of a Bar Magnet

When we drew the magnetic field lines for a bar magnet in Chapter 28, it may have seemed natural to think of the field lines as starting on the north pole and ending on the south pole. In light of what we have just learned, we now realize that magnetic field lines never start or stop—they are *continuous*. Therefore, we must reconsider our view of the



▲ **FIGURE 29–12** Although electric field lines outside an electric dipole resemble magnetic field lines outside a bar magnet, the fields within are quite different. The electric field lines begin and end on the electric charges, whereas the magnetic field lines are continuous.

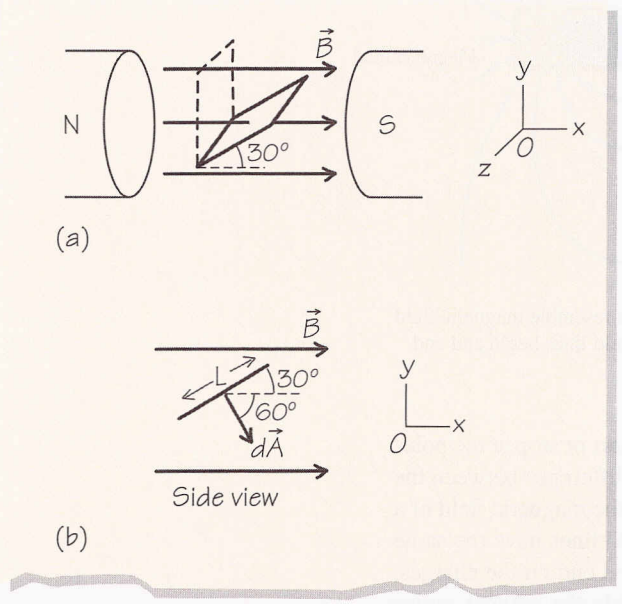
magnetic field lines for a bar magnet. In fact, the field lines do not start or stop at the poles *but pass through the bar magnet*. This remark underlines a critical difference between the electric field of an electric dipole (equal and opposite charges) and the magnetic field of a bar magnet, both shown in Fig. 29–12. "Outside" the ends, the field lines have the same form. However, while the field lines for the electric dipole begin and end on the charges, the field lines that run from the north pole to the south pole outside the magnet *return within the magnet to form closed loops*. This view is consistent with Gauss' law for magnetism, Eq. (29–12), because for any closed surface that can be drawn in and around a bar magnet, the same number of field lines enter the surface as leave it.

Using Gauss' Law to Find Magnetic Fields

Gauss' law for magnetism is useful for limiting the forms a magnetic field may take. As an example, let's use Gauss' law for magnetism to show that the magnetic field around a straight current-carrying wire can have no radial component, as we concluded in Section 29–1. We need a suitable closed (imaginary) surface to construct about the wire in order to exploit any symmetries, and for a straight wire cylindrical symmetry is appropriate. Our closed surface will therefore be a cylinder of radius R and length L whose central axis lies on the wire (Fig. 29–13). The wire looks the same from any point on the surface of the cylinder, so the magnetic field cannot depend on the angle around the axis of the cylinder. Thus, if there were a radial component B_r at some fixed radial distance, it would have to be the same all around the wire.

▲ **FIGURE 29–13** A Gaussian surface that exploits the symmetry of a long, straight wire.

To find the net magnetic flux through the closed cylinder, Φ_B, we must consider contributions from its ends and sides. Only a longitudinal component of the field (along the wire) contributes to the flux at the ends. But the contribution from one end must cancel the contribution from the other end—if the longitudinal component enters the surface at one end, it must leave the surface at the other end. The net flux through the ends is therefore zero.



The contribution to the magnetic flux from the sides is due to the radial component of the field, B_r. We have for the net flux

$$\Phi_B = \int_{\text{end}} \vec{B}\cdot d\vec{A} + \int_{\text{side}} \vec{B}\cdot d\vec{A} = \int_{\text{side}} \vec{B}\cdot d\vec{A} = B_r(2\pi RL),$$

where $2\pi RL$ is the area of the cylinder's sides. This must equal zero by Gauss' law and, because the area of the cylinder sides is not zero, B_r must be zero. We have shown by Gauss' law that there can be no radial component of the magnetic field.

We shall see in later chapters that the magnetic flux plays an important role in other fundamental laws of electromagnetism, and it is important to know how to calculate the magnetic flux for both closed and open surfaces. Example 29–3 is an exercise of this type.

EXAMPLE 29–3 The region between the poles of an electromagnet[†] contains a constant magnetic field, $B = 0.0030$ T, oriented in the $+x$-direction. A square wire loop of sides $L = 1.0$ cm is oriented at a 30° angle to the field (Fig. 29–14a). Find the magnetic flux through the loop.

▲ **FIGURE 29–14** (a) A tabletop electromagnet for which $\vec{B}$ is oriented in the $+x$-direction. (b) The surface element $d\vec{A}$ of the square wire loop is oriented perpendicular to the surface.

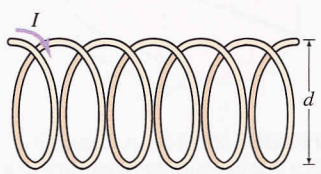
Setting It Up In order to find the flux through a given surface, we must first specify an area element $d\vec{A}$ of the surface and find its scalar product with the magnetic field, $\vec{B} \cdot d\vec{A}$. We draw a view from the side in Figure 29–14b that includes the orientation of the surface element $d\vec{A}$. This surface element is perpendicular to the plane of the wire loop and makes an angle $\theta = 60°$ with $\vec{B}$.

Strategy Having established the orientation of the area element, we calculate $\vec{B} \cdot d\vec{A}$, then integrate over the whole surface of the loop to find the magnetic flux.

Working It Out The scalar product $\vec{B} \cdot d\vec{A} = B \cos\theta \, dA$. Because B and θ are constants, they can be removed from the integral for the magnetic flux [Eq. (29–11)]:

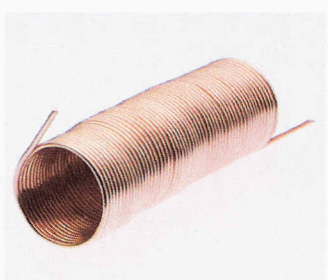
$$\Phi_B(S) = \int_{\text{surface } S} \vec{B} \cdot d\vec{A} = \int_{\text{surface } S} B \cos\theta \, dA$$

$$= B \cos\theta \int_{\text{surface } S} dA = BL^2 \cos\theta.$$



The numerical value is

$$\Phi_B(S) = (0.0030 \text{ T})(1.0 \times 10^{-2} \text{ m})^2(\cos 60°)$$

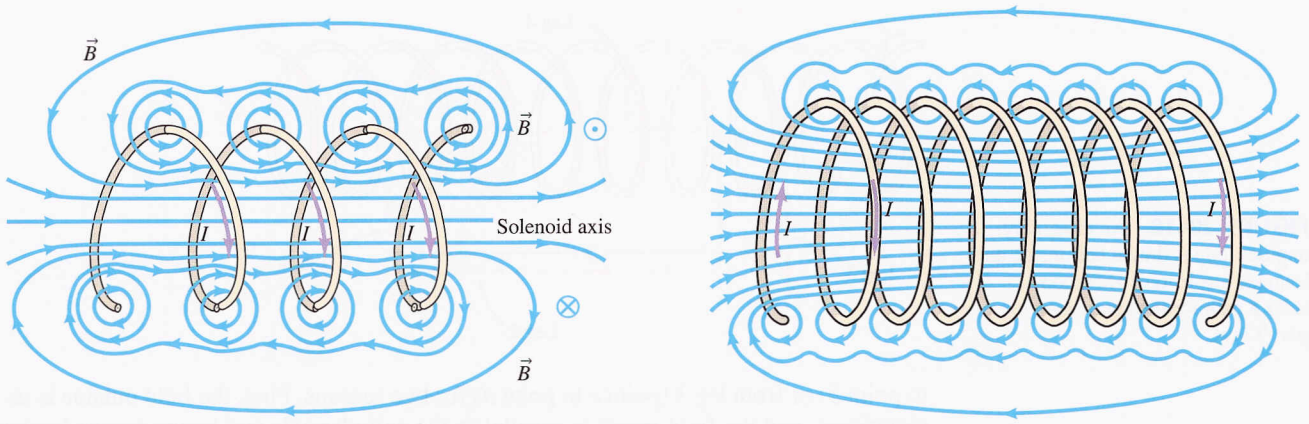


$$= 1.5 \times 10^{-7} \text{ Wb}.$$

What Do You Think? For what orientation of the loop will the flux be a maximum?

[†]An electromagnet is a magnet whose field is produced by appropriately circulating electric currents. It is typically set up so that there are two parallel flat faces separated by a space, with a roughly constant magnetic field running from one face (the N pole) to the other (the S pole)—in the next section, we'll describe how this might be done. It thus resembles a horseshoe magnet whose tips have been formed into the two flat faces.

(a)

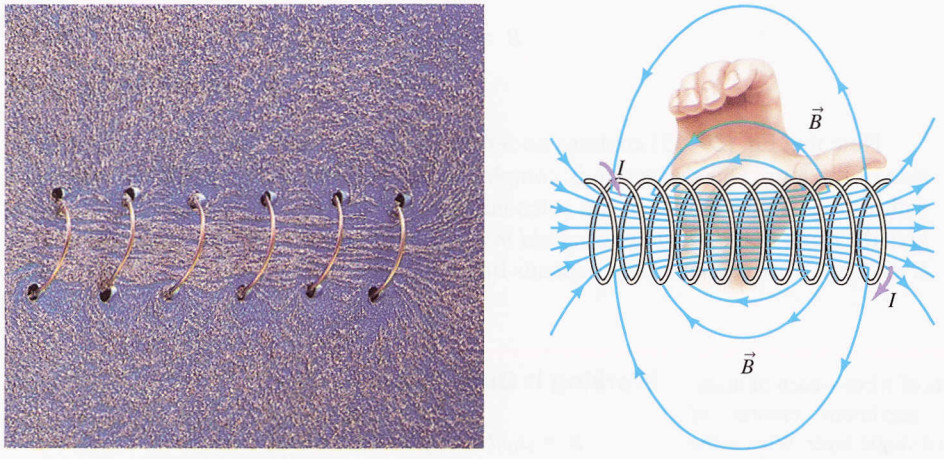


(b)

▲ **FIGURE 29–15** (a) An ideal solenoid is an infinitely long cylinder made from a uniformly wound coil carrying current I (view shown is exaggerated). (b) A real solenoid.

29–3 Solenoids

A parallel-plate capacitor produces a uniform, constant electric field between its plates. The equivalent device for magnetic fields, a **solenoid**, is a length of wire coiled uniformly into a long cylinder, ideally infinitely long (Fig. 29–15). A solenoid generates a constant magnetic field in the interior of the cylinder it forms just as a parallel-plate capacitor sets up a constant electric field in the space between its plates. In Chapter 32 we'll see that, like capacitors, solenoids play an important role in circuits. We mention one use as a mechanical switch: An iron piece near an end of a solenoid moves in response to a magnetic force that appears when a current starts to run through the solenoid.

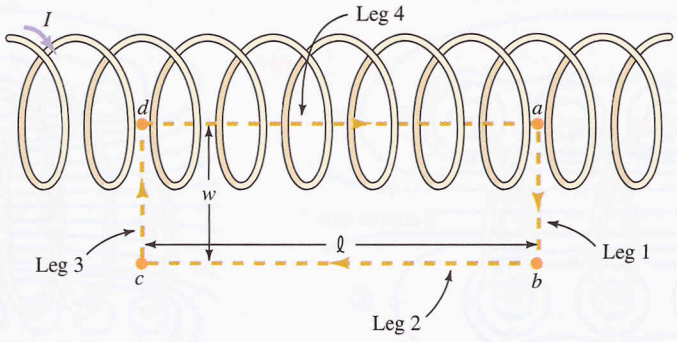


Let's sketch what the magnetic field of a solenoid might look like. Consider a solenoid whose cylinder diameter is d carrying current I, with the wires wound so that there are n turns per unit length, where the length is measured along the axis of the solenoid. In Fig. 29–15a we have exaggerated the spacing between the wires, which normally are tightly wound. Figure 29–16a is a cross-sectional view of several loops of the solenoid, which are again spaced more widely than in reality. Very near the wire, the magnetic field lines form circles around the wire because the field approximates that of a single straight wire. Figure 29–16a shows that *between* adjacent turns of the wire where two segments of wire are near one another, the fields tend to cancel. *Within* the solenoid, the fields from adjacent turns add together to form a large component that points to the right along the axis of the solenoid. *Outside* the solenoid the fields from the bottom of the wire loop tend to cancel the fields from the top of the wire loop, so that as the number of loops becomes large, the field outside is small (Fig. 29–16b).

(a) (b)

▲ **FIGURE 29–16** (a) One three-turn section of a solenoid, showing the superposed magnetic fields (view shown is exaggerated). (b) As the winding density increases, the magnetic field takes on a simpler form.

To summarize, the fields from the different loops of the coil reinforce inside the cylinder to create a net magnetic field that is parallel to the cylinder axis (Fig. 29–17a) and whose direction is determined by a right-hand rule: If the fingers curl around the solenoid in the direction of the current, the thumb shows the direction of the magnetic field (Fig. 29–17b). Outside the cylinder, the field points primarily in the opposite direction and is much weaker. A quantitative analysis shows that *even though the magnetic field is not exactly zero outside a real solenoid, to a good approximation the field there is insignificant.*



(a) (b)

◀ **FIGURE 29–17** (a) Magnetic field lines of a solenoid, as shown by iron filings that align with the field. (b) A right-hand rule gives the direction of the magnetic field within a solenoid.

Using Ampère's Law to Find the Magnetic Field in a Solenoid

Now that we understand qualitatively that a long solenoid has a large magnetic field inside—parallel to the solenoid axis—and a weak field outside, we can apply Ampère's law to calculate quantitatively the magnetic field inside an ideal solenoid—one so long that the field outside can be taken to be zero. Figure 29–18 shows a solenoid that carries a current I, and an *imaginary* closed area, bounded by a loop consisting of four legs in a rectangle of length ℓ and height w, on which to apply Ampère's law. The wire of the solenoid passes N times from above through the imaginary loop. The path about the imaginary loop is taken to be clockwise, so the net current into the imaginary loop, NI, is positive by the right-hand rule. We now calculate the line integral on the left-hand side of Eq. (29–10). There is only a very small contribution from leg 2 (point b to point c), because the field outside is insignificant. There is no contribution from leg 1 (point a

▶ **FIGURE 29–18** An imaginary rectangular loop is drawn half inside and half outside a solenoid. This loop provides a path for the application of Ampère's law.

to point b) or from leg 3 (point c to point d) for two reasons. First, the field outside is insignificant, and the field inside is parallel to the cylinder axis and hence perpendicular to the path. Second, any contributions from these two legs would cancel each other because they are in opposite directions. From point d to point a (leg 4), the field is parallel to the path. Along this portion of the path, the field has a constant unknown value B. The contribution to the integral is $B\ell$, and thus Ampère's law gives

$$\oint \vec{B} \cdot d\vec{s} = B\ell = \mu_0 I_{\text{enclosed}} = \mu_0 NI. \tag{29–14}$$

We can eliminate the explicit dependence on ℓ in Eq. (29–14) by noting the total number of turns $N = n\ell$, where n is the *turn density* of the solenoid, the number of turns per unit length. We have

$$B\ell = \mu_0 n\ell I,$$

and the *interior magnetic field of a long solenoid* has magnitude

$$B = \mu_0 nI. \tag{29–15}$$

MAGNETIC FIELD WITHIN A SOLENOID

Note that Eq. (29–15) contains no reference to the distance from the axis on the inside of the loop. Our derivation is completely independent of how close the imaginary path in Fig. 29–18 comes to the solenoid axis, and any choice of this distance would give the same field. *The magnetic field inside a long solenoid, not too close to the ends, is uniform.* The magnetic field depends linearly on the current.

EXAMPLE 29–4 A solenoid consists of wires—each of diameter $d = 0.6$ mm—that can carry a maximum current of $I = 0.03$ A; the wires are tightly wound in a single layer. What is the maximum magnitude of the field inside the solenoid?

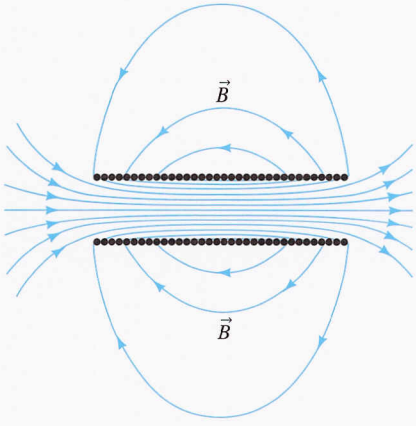
Strategy Equation (29–15) gives us the magnitude of the unknown magnetic field inside the solenoid in terms of the current I and the turn density, n. We are given I, but we must calculate n. If the wire has diameter d, and the wires are tightly wound in a single layer, then we have one turn every length d, and $n = 1/d$.

Working It Out We have

$$B = \mu_0 nI = \frac{\mu_0 I}{d} = \frac{(4\pi \times 10^{-7}\ \text{T}\cdot\text{m/A})(0.03\ \text{A})}{0.6 \times 10^{-3}\ \text{m}}$$
$$= 0.6 \times 10^{-4}\ \text{T}.$$

This is comparable in magnitude to Earth's field.

What Do You Think? What would happen to the magnetic field if we double the number of turns of wire by wrapping another row on top of the existing one?



CONCEPTUAL EXAMPLE 29–5 Assume that the maximum current a wire can carry in the previous example is proportional to the area of the wire, and that the wire's diameter is the only variable under consideration. The winding will continue to be in a single layer. How should we change the diameter of the wire to double the magnetic field inside?

Answer If B is to double, then the product nI must double according to Eq. (29–15). Let's see how these factors depend on the diameter d. Because the solenoid is tightly wound, the turn density $n \propto 1/d$. The maximum current is proportional to the wire area, which in turn is proportional to the wire diameter squared. Thus $I \propto d^2$. Combining our results, $nI \propto (1/d)d^2 \propto d$. If the field is to be doubled, the diameter of the wire used in the solenoid should also be doubled.

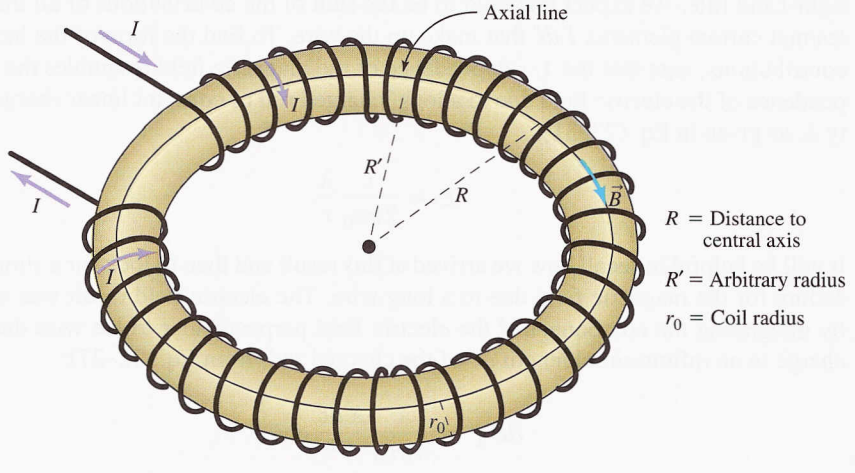
We have used Ampère's law to calculate the magnetic field inside a long, cylindrical solenoid, and we can also apply the law in the same way to noncylindrical geometry—say, a solenoid with square cross section—with exactly the same results. Equation (29–15) holds *even if the winding does not form a cylindrical tube*. We require only that the solenoid be long and that the cross-sectional area be constant.

Our results for the ideal solenoid hold rather well for a solenoid of finite length. Figure 29–19 shows the magnetic field lines, numerically calculated, of a solenoid in a plane that cuts through the center of the solenoid, whose length is four times its diameter.

The exterior field of the solenoid of finite length illustrated in Fig. 29–19 looks just like the magnetic field of a bar magnet, Fig. 28–2a. Does this mean that the field of a bar magnet has the same physical origin as that of a solenoid? As Ampère himself suggested, the answer is yes. A bar magnet is made of the equivalent of aligned current loops of atomic size. In fact, the interior field of a bar magnet is also the same as the interior field of a solenoid. The origin of magnetism in matter is discussed further in Chapter 31.

▲ **FIGURE 29–19** The magnetic field of a solenoid of finite length. (After E. M. Purcell, *Berkeley Physics Course: Electricity and Magnetism*, McGraw-Hill, 1990, p. 229.)

A Toroidal Solenoid



A real solenoid has finite length, and therefore its magnetic field departs from its constant value as one approaches either end. These end effects can be eliminated by making the solenoid into a doughnut shape, or *torus* (Fig. 29–20). This shape does, however, introduce some variation in the magnetic field within the solenoid. To look at this variation, consider a toroidal solenoid whose coil radius is r_0 and whose overall radius—the distance from the center to the circular axial line—is R. Symmetry implies that the magnetic field within the coil must be parallel to the cylinder walls. The same arguments that we gave for the straight solenoid imply that this field is oriented in the direction of the thumb when the fingers of the right hand are curled in the direction of the current. Ampère's law can then be used to find the magnitude of $\vec{B}$. Take a circular path for Ampère's law that lies within the coil a distance R' from the center (Fig. 29–20). The magnitude of the field is the same all along the path, so

$$\oint \vec{B} \cdot d\vec{s} = B(2\pi R') = \mu_0 NI.$$

Here, N is the total number of loops in the coil. We solve to find the field magnitude at a distance R',

$$B = \frac{\mu_0 NI}{2\pi R'}. \qquad (29\text{–}16)$$

Although there are no end effects, the field does depend on R'—it is not constant across the cross-sectional area of the torus. But if the coil's radius r_0 is much less than the overall radius R of the torus, the possible values of R', from $R - r_0$ to $R + r_0$, do not vary much, and the magnetic field within the torus will not vary very much either.

◀ **FIGURE 29–20** A torus wrapped with a wire that carries a current I has a magnetic field inside, which we can calculate by using Ampère's law. The overall radius of the torus is R, whereas the radius of the coil is r_0. The distance R' is not equal to R.

THINK ABOUT THIS. . .

WHAT CAUSES EARTH'S MAGNETIC FIELD?

In the regions outside Earth itself, Earth's field is that of a magnetic dipole, which is the form of the magnetic field due to a bar magnet or to a current loop or coil. The field's origin is in Earth's high-temperature core, which is mainly composed of iron, with a solid inner core and a fluid outer core. In fact, Earth's core cannot be a gigantic bar magnet, which is formed by the alignment of microscopic magnetic dipoles in substances like solid iron (Section 31–3), because when a bar magnet is too hot, the alignment is spoiled by the high temperature, and Earth's core is far too hot to maintain such an alignment. It is rather associated with the convective motion of the fluid iron, as well as with the rotation of the solid core at a slightly greater speed than Earth's surface. These motions effectively carry current that result in magnetic field lines with the same form as that of a bar magnet or current loop. The behavior of this system is too complex to yield an analytic solution, but it has been successfully modeled. The best mathematical model, which requires large supercomputers to run, has some surprising features. This model confirms the speed of rotation of Earth's solid core. It also explains the hitherto puzzling fact that Earth's magnetic field reverses rather suddenly every hundred thousand years or so (although the reversal is not entirely regular). These reversals are obvious in the geological rock record, because molten rock solidifies with a record of Earth's magnetic field frozen within it. (The Sun reverses its magnetic field every 11 years, the difference with Earth being that the Sun does not have a solid core.)

29–4 The Biot–Savart Law

Ampère's law is a general one, but its usefulness as a tool for calculating magnetic fields depends on the symmetry of the system of currents that create the magnetic field. Here we find a direct expression known as the *Biot–Savart law* for the magnetic field produced by a current, one that can be applied even when there is no symmetry. There is a simple analogue to this procedure in electrostatics. When there is symmetry in a charge distribution, Gauss' law provides a powerful tool for finding the electric field. When there is no symmetry, we can always find the net electric field by using the superposition of the electric fields of point charges (as determined by Coulomb's law). Similarly, the Biot–Savart law gives us the magnetic field due to an infinitesimal distribution of current segments. We then use the superposition principle to determine the magnetic field of a finite arrangement of currents.

Let's start with a result we already know. The magnitude of the magnetic field at a radial distance r from a long, straight wire that carries a current I is

$$B = \frac{\mu_0 I}{2\pi r},$$

Eq. (29–5). The field lines form circles around the wire with the direction given by the right-hand rule. We expect this field to be the sum of the contributions of all the infinitesimal current elements $I\,d\ell$ that make up the wire. To find the form of the individual contributions, note that the $1/r$ dependence of the magnetic field resembles the $1/r$ dependence of the electric field due to a long, charged rod of constant linear charge density λ, as given in Eq. (22–31):

$$E = \frac{1}{2\pi\varepsilon_0}\frac{\lambda}{r}.$$

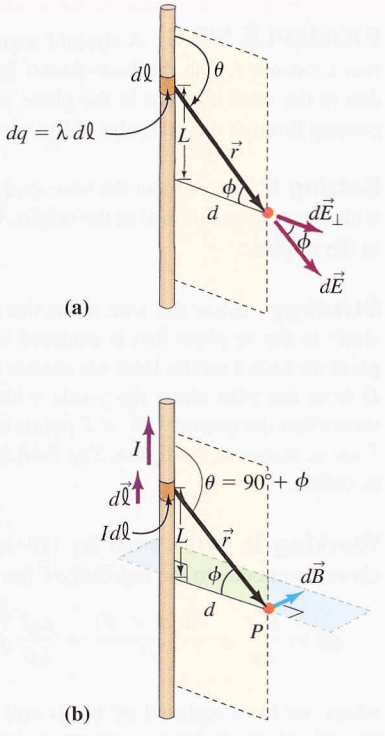
It will be helpful to recall how we arrived at this result and then to look for a similar procedure for the magnetic field due to a long wire. The electric field result was obtained by integrating the component of the electric field perpendicular to the wire due to the charge in an infinitesimal length $d\ell$ of the charged rod, from Eq. (22–27):

$$dE_\perp = \frac{1}{4\pi\varepsilon_0}\frac{\lambda\,d\ell}{r^2}\cos\phi.$$

Here, the particular element of the charged rod is a distance $r = \sqrt{L^2 + d^2}$ from the point where the field is measured, and ϕ is as shown in Fig. 29–21a. The factor $\frac{\lambda\, d\ell}{4\pi\varepsilon_0 r^2}$ is just the electric field strength for a point charge $dq = \lambda\, d\ell$. The second factor, $\cos\phi$, is present only because we are looking at the perpendicular component. If we compare Eqs. (22–31) and (29–5), we see that they have the same form, but with $1/\varepsilon_0$ replaced by μ_0 and λ replaced by I. This suggests that the individual contribution to the magnetic field of a length $d\ell$ of a wire that carries a current I can similarly be found by taking the contribution to the electric field from an element of the charged wire, Eq. (22–27), and replacing $1/\varepsilon_0$ with μ_0 and λ with I:

$$dB = \frac{\mu_0}{4\pi}\frac{I\, d\ell}{r^2}\cos\phi. \tag{29–17}$$

There is, however, a difference in the vectorial aspect of the electric and magnetic fields. The electric field is directed radially away from the charge element, whereas the magnetic field lines form circles. The direction of $\vec{B}$ is shown in Fig. 29–21b for point P and follows the right-hand rule. The direction of the current is indicated by making the infinitesimal length $d\ell$ a vector $d\vec{\ell}$ whose direction is along I. We see that $\vec{B}$ is perpendicular to both $d\vec{\ell}$ and $\vec{r}$. You should recall that there is a direct way to produce a vector that is perpendicular to two other vectors, and that is by using the vector product (see Chapter 10). Using trigonometry, we can see that if $\theta = \phi + 90°$ (as in Fig. 29–21b), then $\cos\phi = \cos(\theta - 90°) = \cos\theta\cos 90° + \sin\theta\sin 90° = \sin\theta$. Equation (29–17) becomes



$$dB = \frac{\mu_0}{4\pi}\frac{I\, d\ell\sin\theta}{r^2} = \frac{\mu_0}{4\pi} I\frac{r\sin\theta}{r^3}\, d\ell \tag{29–18}$$

in the direction perpendicular to $d\vec{\ell}$ and $\vec{r}$. *The magnetic field $d\vec{B}$ produced by a segment of wire $d\ell$ that carries a current I at a displacement $\vec{r}$ from the segment is*:

$$d\vec{B} = \frac{\mu_0}{4\pi}\frac{I\, d\vec{\ell}\times\vec{r}}{r^3}. \tag{29–19}$$

THE BIOT–SAVART LAW

The vector product $d\vec{\ell}\times\vec{r}$ has a magnitude $d\ell\, r\sin\theta$, and for the situation in Fig. 29–21 the direction is as drawn there. Note that there is no ambiguity as to the vector $d\vec{\ell}$; if the segment is short enough, it may be treated as a straight line, and that has a definite direction. Equation (29–19) is the **Biot–Savart law**, named after the two physicists who first formulated it, Jean-Baptiste Biot and Félix Savart. This law is analogous to Coulomb's law in electricity. It even has the same overall distance dependence of $1/r^2$—note that the magnitude r appears in the numerator of Eq. (29–19). The angular factors are quite different, however.

▲ **FIGURE 29–21** (a) A rod that carries a net charge density λ can be broken up into segments that contribute an electric field at any point. Integration over the contributions from the segments gives the net electric field. (b) A wire carrying current I similarly has a magnetic field that can be calculated by integrating the contributions of segments of the wire. For a segment of length $d\vec{\ell}$, the vector $d\vec{\ell}$ is oriented along the segment in the direction of I.

Using the Biot–Savart Law

We can use the Biot–Savart law to find the magnetic field due to nonsymmetric current distributions, in just the same way that Coulomb's law is used to find the electric field. The net magnetic field is found by integrating over $d\vec{B}$:

$$\vec{B} = \int d\vec{B} = \frac{\mu_0}{4\pi}\int\frac{I\, d\vec{\ell}\times\vec{r}}{r^3}. \tag{29–20}$$

Evaluation of this expression depends on the details of the currents. For most cases Eq. (29–20) is too complicated to give an analytic expression. In that case it is always possible to make a numerical evaluation of the integral. Sophisticated computer programs exist that allow one to design the form of the windings of wire needed to produce a desired field. Such programs superpose infinitesimal field contributions $d\vec{B}$, each given by the Biot–Savart law. Finally it is of course always possible to measure the magnetic fields due to nonsymmetric current distributions experimentally.

EXAMPLE 29–6 A straight segment of wire of length L carries a current I. Use the Biot–Savart law to find the magnetic field due to the wire segment in the plane perpendicular to the wire and passing through the midpoint of the wire segment.

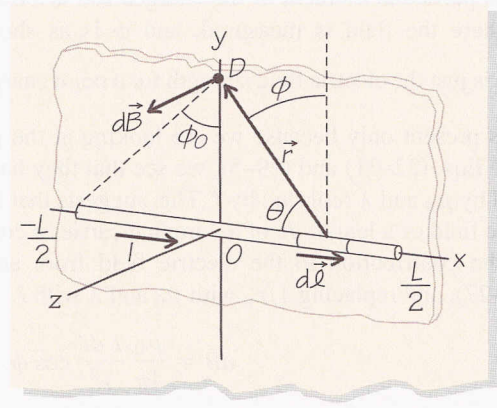
Setting It Up Orient the wire along the x-axis, as in Fig. 29–22, with its center positioned at the origin. We then wish to find the field in the yz-plane.

Strategy Since the wire looks the same from anywhere on any circle in the yz-plane that is centered on the wire, we can pick any point on such a circle. Here we choose to find the field at a distance D from the wire along the y-axis with $z = 0$. The right-hand rule shows that the quantity $d\vec{\ell} \times \vec{r}$ points out of the plane where $d\vec{\ell}$ and $\vec{r}$ are as shown in the figure. The field forms circles around the wire, as before.

Working It Out From Eq. (29–18), the magnetic field at the chosen point due to the segment $d\vec{\ell}$ has magnitude

$$dB = \frac{\mu_0 I}{4\pi}\,dx\,\frac{\sin(\pi - \theta)}{r^2} = \frac{\mu_0 I}{4\pi}\,dx\,\frac{\sin\theta}{r^2} = \frac{\mu_0 I}{4\pi}\,dx\,\frac{\cos\phi}{r^2},$$

where we have replaced $d\ell$ by dx and used the angle ϕ defined in Fig. 29–22. To find the net magnetic field, we sum over the contributions of segments from $x = -L/2$ to $x = L/2$:



$$B = \frac{\mu_0 I}{4\pi}\int_{-L/2}^{L/2}\frac{\cos\phi}{r^2}\,dx.$$

Both ϕ and r depend on x. The integral is computed most simply if we use trigonometric variables; we therefore change variables from x to ϕ. We have by simple geometry $x/D = \tan\phi$. Hence

$$dx = D\,d(\tan\phi) = D(\sec^2\phi)\,d\phi = \frac{D}{\cos^2\phi}\,d\phi.$$

In addition, $r = D/\cos\phi$, so the combination that appears in the integral becomes

$$\frac{\cos\phi}{r^2}\,dx = \cos\phi\,\frac{1}{(D/\cos\phi)^2}\,\frac{D}{\cos^2\phi}\,d\phi = \frac{1}{D}\cos\phi\,d\phi.$$

▲ **FIGURE 29–22** A straight segment of wire of length L, carrying a current I, is oriented on the x-axis and centered at the origin.

Thus

$$B = \frac{\mu_0 I}{4\pi D}\int_{-\phi_0}^{+\phi_0}\cos\phi\,d\phi,$$

where $\pm\phi_0$ is the limit of integration—the largest values taken on by ϕ. The integral of the cosine is the sine, and so

$$B = \frac{\mu_0 I}{4\pi D}[\sin\phi_0 - \sin(-\phi_0)] = \frac{\mu_0 I}{2\pi D}\sin\phi_0.$$

We can reexpress this result in terms of L and D by using the geometrical relation

$$\sin\phi_0 = \frac{L/2}{\sqrt{(L/2)^2 + D^2}}$$

to find that

$$B = \frac{\mu_0 I}{4\pi}\,\frac{L}{D\sqrt{(L/2)^2 + D^2}}. \qquad (29\text{–}21)$$

This form shows that the field depends not only on the distance D from the wire but also on the relative magnitudes of D and L.

What Do You Think? Find the magnetic field when $L \gg D$. Compare your result with Eq. (29–5), which is the field of an infinitely long wire.

What is the numerical significance of the fact that the wire of Example 29–6 has finite length? Suppose that the current is 1 A and that the wire segment is 10 cm long. Then, 1 cm from the wire, Eq. (29–21) gives a field of 1.96×10^{-5} T, whereas the magnetic field of the infinitely long wire carrying the same current [Eq. (29–5)] is 2.00×10^{-5} T. In this case, we are a distance from the wire of one-tenth the length of the wire and the field is only 2 percent less than the infinite length result. But let's now move away from the wire so that we are one wire's length away: $L = 0.1$ m, and $D = 0.1$ m. In this case, the field from the wire has a value some 2.2 times smaller than the field of the wire of infinite length.

EXAMPLE 29–7 A wire forms a circular loop of radius $R = 12$ cm. A current $I = 8.0$ A flows counterclockwise in the wire. Find the magnetic field at the center.

Setting It Up We show the wire loop and an element of the wire $d\vec{\ell}$ in Fig. 29–23 along with an appropriate coordinate system.

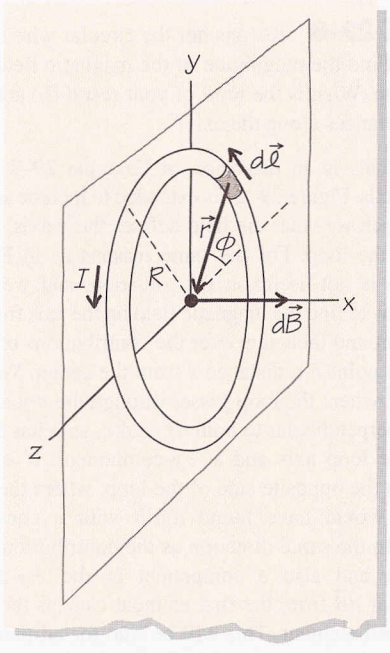
Strategy There is no path along which the magnetic field is constant, so we cannot use Ampère's law. We must use the Biot–Savart law and integrate over the contributions $d\vec{B}$ of the different elements of the wire to find the unknown total field $\vec{B}$. Vector $\vec{r}$ runs from the current element $d\vec{\ell}$ to the center of the circle, the point where we want to find $\vec{B}$. The quantity $d\vec{\ell} \times \vec{r}$ for the current element shown

in Fig. 29–23 is directed along the x-axis, and this will be true for all the current elements that make up the loop. The net magnetic field at the center is thus directed along the x-axis.

Working It Out The magnitude of the field due to the element shown is [Eq. (29–18)]

$$dB = \frac{\mu_0}{4\pi}\frac{I\,d\ell}{R^2}.$$

There is no sine factor here because $d\vec{\ell}$ is perpendicular to $\vec{r}$. The integral of $d\vec{\ell}$ around the circle is the circumference $2\pi R$, so the net field at the center has magnitude



$$B = \int dB = \int \frac{\mu_0}{4\pi}\frac{I\,d\ell}{R^2} = \frac{\mu_0 I}{4\pi}\frac{1}{R^2}\int d\ell = \frac{\mu_0 I}{4\pi}\frac{2\pi R}{R^2} = \frac{\mu_0 I}{2R}. \tag{29–22}$$

The numerical value is

$$B = \frac{(4\pi \times 10^{-7}\ \text{T}\cdot\text{m/A})(8.0\ \text{A})}{2(0.12\ \text{m})} = 4.2 \times 10^{-5}\ \text{T}.$$

This is roughly the size of Earth's magnetic field at Earth's surface.

What Do You Think? Is the orientation of the magnetic field we have calculated consistent with a right-hand rule?

▲ **FIGURE 29–23** An integration is required to find the net magnetic field at the center of the loop.

Problem-Solving Techniques

In the examples of this chapter and Chapter 28, we have studied two aspects of problems on static magnetic fields: We may need to find the magnetic fields produced by a given time-independent set of currents, or we may need to find the magnetic forces on currents or on moving charges. Two sets of key laws contain all that is generally necessary to approach such problems, and you should understand the symbols in these formulas and what the laws mean. First, we have the laws that determine the magnetic field due to currents, which can be written in the two forms

$$\text{Ampère's law: } \oint \vec{B}\cdot d\vec{s} = \mu_0 I_{\text{enclosed}}; \tag{29–10}$$

$$\text{Biot–Savart law: } d\vec{B} = \frac{\mu_0}{4\pi}\frac{I\,d\vec{\ell}\times\vec{r}}{r^3}. \tag{29–19}$$

Second, we have the laws that express the force on a moving charge or a current due to a given magnetic field, namely,

$$\vec{F}_B = q\vec{v}\times\vec{B}, \tag{28–1}$$

$$d\vec{F} = I\,d\vec{\ell}\times\vec{B}. \tag{28–14}$$

Each set of laws involves a right-hand rule. For Ampère's law, if the thumb of the right hand follows the current, the fingers curl in the direction of the integration path. For the force laws and the Biot–Savart law, the right-hand rule for a vector product applies.

Based on these laws, we can suggest a list of habits to develop when solving static magnetic field problems. Many of these are the very same habits that are useful for solving *any* problem in physics.

1. Draw a figure that indicates the physical situation with the quantities known; include directions if appropriate.
2. Write down what is known and what is to be determined. Are you dealing with moving charges or with currents?
3. What physical principles connect the unknown quantities to the known ones?
4. If the problem concerns a force, do you have sufficient information to determine the force directly from the force laws? If not, you may need to compute a magnetic field or integrate an infinitesimal force.
5. In a situation with enough symmetry (for example, for long, straight wires), we can use Ampère's law to calculate a magnetic field. When it is applicable, Ampère's law will usually give the answer more easily than the Biot–Savart law.
6. If the system is not sufficiently symmetric to use Ampère's law, the Biot–Savart law is always available. In using it, be sure that the infinitesimal element $d\vec{\ell}$ and the position vector $\vec{r}$ are identified properly. A partial symmetry may rule out one or more directions for the magnetic field. If only one direction is indicated by symmetry, then the other components will cancel in the calculation of the integral over $d\vec{\ell}$, and you need only integrate for the component desired.
7. Superposition can be a useful tool; the field due to a complex system of currents can sometimes be found by adding the fields due to pieces of the current. For example, the field due to a wire that has an angle bend in it can be found by adding the fields due to the two straight segments.
8. It is always useful to check dimensions and units.
9. Substitute numbers only at the last stage. Any checks you can find of limits or special cases are always helpful.

EXAMPLE 29–8 Reconsider the circular wire loop of Example 29–7. (a) Find the magnitude of the magnetic field all along the axis of the loop. What is the limit of your result (b) at the center and (c) at large distances along the axis?

Strategy This is an extension of Example 29–7 to include all points on the axis. Figure 29–24 is extended to include such points; the axis along which we want the field defines the x-axis, with $x = 0$ at the center of the loop. For the same reasons as in Example 29–7, Ampère's law is not useful in this situation, and we must use the Biot–Savart law to find the magnetic field on the axis from a particular current element and then sum over the contributions of the elements.

Consider a point P a distance x from the center. We have chosen an element $d\vec{\ell}$ where the loop passes through the $+y$-axis. Its contribution $d\vec{B}$ is perpendicular to both $d\vec{\ell}$ and $\vec{r}$, so it has *both* a component along the loop axis and a $+y$-component. If we had chosen an element on the opposite side of the loop, where the loop cuts the $-y$-axis, we would have found a $d\vec{B}$ with a component along the loop axis in the same direction as the contribution from the first loop element, and also a component in the $-y$-direction. The y-component of $d\vec{B}$ from the first element cancels the y-component from the second element. This will be true for all pairs of elements around the loop, so we must calculate only the component of $d\vec{B}$ along the loop axis, which is the x-component. This understanding of the role played by symmetry is important, and a moment or two spent looking for such symmetries is time well spent.

From Fig. 29–24, we see that the vectors $d\vec{\ell}$ and $\vec{r}$ are perpendicular, so the cross product $d\vec{\ell} \times \vec{r} = (d\ell)(r)$. Then

$$dB_x = \frac{\mu_0}{4\pi}\frac{I\,d\ell}{r^2}\cos\gamma.$$

We sum these elements to find the net field. Notice that the x-dependence of the field is contained both in the distance r and in the angle γ.

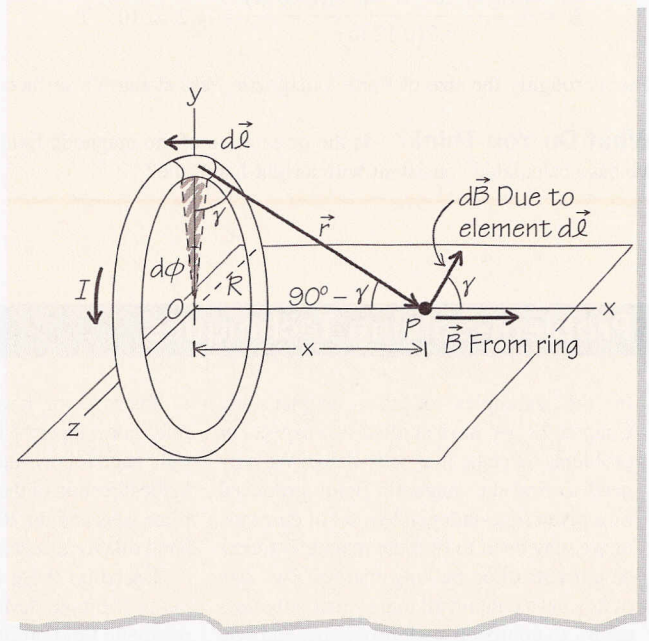
Parts (b) and (c) simply require substitutions and limits of the more general result.

Working It Out

(a) From Fig. 29–24 we can use trigonometry for the following simplifications: $d\ell = R\,d\phi$, $\cos\gamma = \dfrac{R}{\sqrt{R^2 + x^2}}$, and $r = \sqrt{R^2 + x^2}$, so that

$$dB_x = \frac{\mu_0}{4\pi}\frac{IR^2\,d\phi}{(R^2 + x^2)^{3/2}}.$$

The net field is then



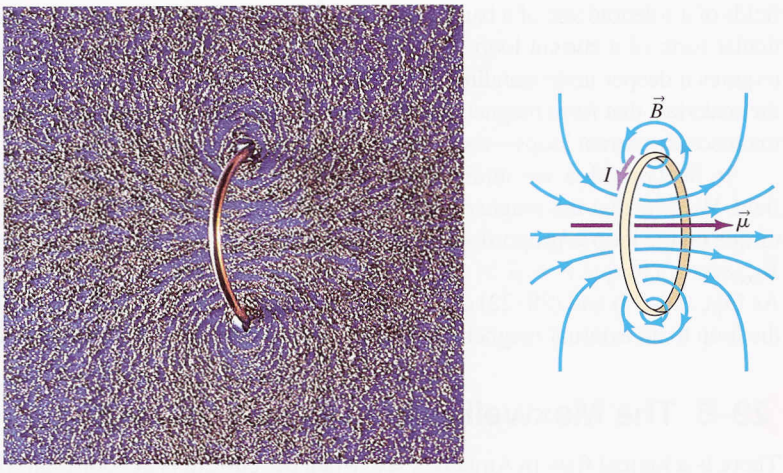
$$B_x = \int dB_x = \frac{\mu_0 IR^2}{4\pi(R^2 + x^2)^{3/2}}\int_0^{2\pi} d\phi = \frac{\mu_0 IR^2}{2(R^2 + x^2)^{3/2}}. \tag{29–23}$$

(b) At the center of the loop, $x = 0$ in Eq. (29–23). The result of substituting $x = 0$ correctly gives Eq. (29–22).

(c) At large distances, $x \gg R$, the axial magnetic field in Eq. (29–23) reduces to

$$B = \frac{\mu_0 I}{2}\frac{R^2}{x^3} = \frac{\mu_0}{2\pi}\frac{I\pi R^2}{x^3}. \tag{29–24}$$

What Do You Think? Does the $1/r^3$ (i.e. $1/x^3$ in this case) behavior of the magnetic field remind you of the electric field of (a) a point charge or (b) an electric dipole?



▲ **FIGURE 29–24** The net magnetic field along the loop axis due to a current loop carrying a current I is oriented along the axis, according to a right-hand rule. The contribution from an infinitesimal element $d\vec{\ell}$ has components along its axis and in other directions as well.

Magnetic Dipoles

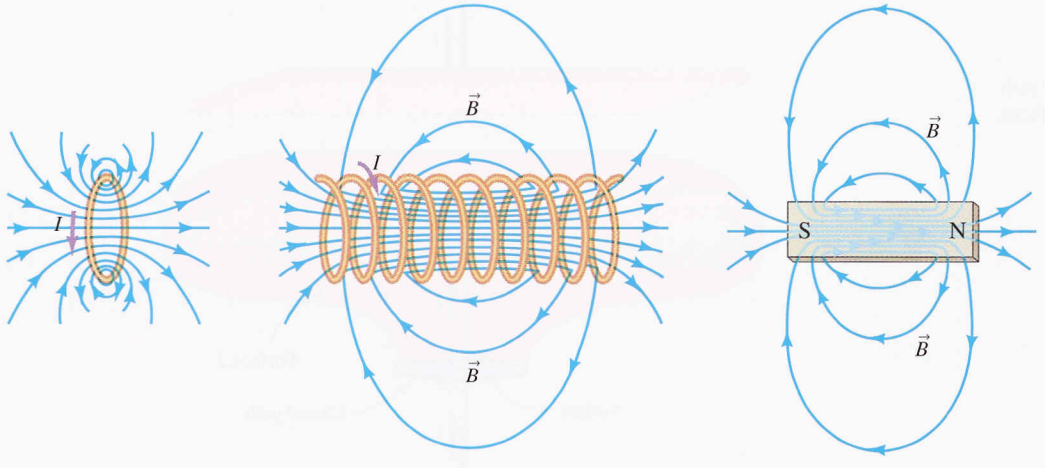
Calculation of the magnetic field over all space due to the current-carrying loop of Examples 29–7 and 29–8 shows that the magnetic field lines shown in Fig. 29–25 are just like the electric field lines of the electric dipole (Fig. 22–12), apart from the region between the two electric charges of the electric dipole. In fact, it is the form of the field, not how that field is produced, that labels the magnetic field of the current loop as a *magnetic dipole field*. The loop forms a magnetic dipole whose strength is characterized by a magnetic dipole moment, μ. The magnetic dipole moment μ plays the same role for the magnetic dipole that the electric dipole moment p plays for the electric dipole. (Don't confuse μ with the permeability of free space, μ_0!) By looking at Eq. (29–24), we see that a sensible definition is

$$\text{for a circular current loop: } \mu \equiv I\pi R^2. \tag{29–25}$$

(a) (b)

◀ **FIGURE 29–25** (a) Magnetic field lines for a circular loop of current, as shown by iron filings. (b) The field for such a loop is a magnetic dipole field.

From Eq. (29–24) we know that at a distance x far from the loop the magnitude of the magnetic field along the axis is



$$\text{along the axis: } B = \frac{\mu_0}{2\pi}\frac{\mu}{x^3}. \tag{29–26}$$

In fact, for *any* closed loop of area A that carries a current I, there is a similar result: The magnetic field decreases as $1/r^3$ far from the loop. The strength of the field is proportional to a dipole moment μ that is equal to the product of the current in the loop and the area of the loop:

$$\mu = IA. \tag{29–27}$$

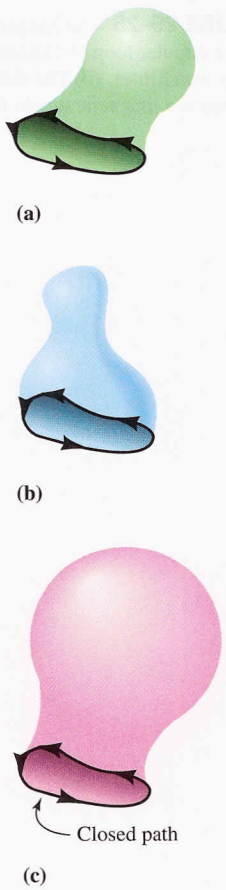
The magnetic dipole moment, like the electric dipole moment, forms a vector $\vec{\mu}$: For any plane loop, $\vec{\mu}$ is perpendicular to the plane of the loop according to a right-hand rule—curl the fingers of the right hand around the direction of current flow in the loop, and the thumb points in the direction of $\vec{\mu}$. The vectorial aspect of the magnetic dipole moment ensures that the magnetic field of the current loop has an appropriate directionality.

One feature of this discussion is quite striking. The electric dipoles that we know about are formed by a pair of equal and opposite electric charges, while the magnetic dipole above is formed by a current loop. Magnetic charges do not exist; the magnetic dipole *cannot* be formed from a pair of equal but opposite magnetic charges, rather it is formed from a closed loop of current. The magnetic field of a current loop (Fig. 29–26a) has the same form as the

(a) (b) (c)

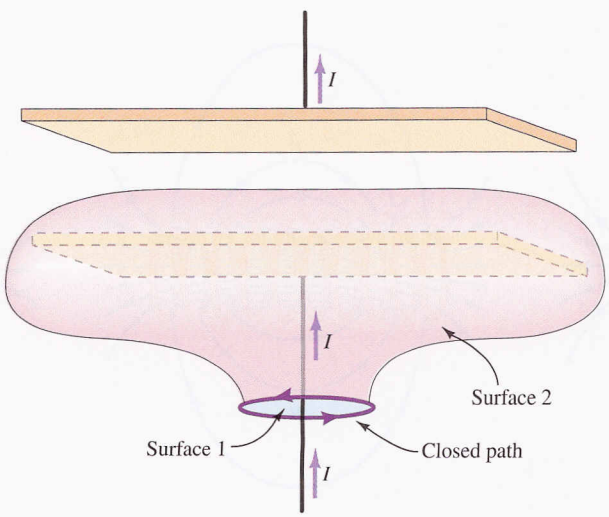
▲ **FIGURE 29–26** (a) The magnetic field lines of a circular loop of current have the same form as the magnetic field lines of (b) a solenoid and of (c) a bar magnet.

fields of a solenoid and of a bar magnet (Figs. 29–26b, c). A solenoid is of course just a particular form of a current loop. The bar magnet is another story, and to understand it fully requires a deeper understanding of materials at the atomic level. But we can say here that the materials that form magnets behave at a microscopic level as if they were composed of microscopic current loops—see Chapter 31 for more on this subject.



In Section 28–5 we studied the *response* of a current loop to an external magnetic field. We saw that the magnetic dipole responds to an external field by rotating, and the torque on the loop is proportional to the magnetic dipole moment. In more detail, the field $\vec{B}_{\text{ext}}$ exerts a torque $\vec{\tau} = \vec{\mu} \times \vec{B}_{\text{ext}}$ on the loop that tends to line up the vector $\vec{\mu}$ with $\vec{B}_{\text{ext}}$. As Eqs. (29–27) and (28–22) show, both the magnetic field of the loop and the reaction of the loop to an external magnetic field are given in terms of the dipole moment.

29–5 The Maxwell Displacement Current

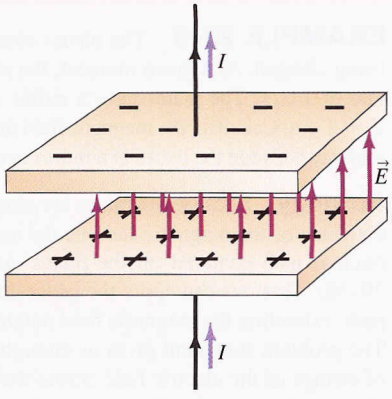


There is a logical flaw in Ampère's law when the current is not constant. In 1865, James Clerk Maxwell modified the law to remove this flaw. This modification was crucial to the completely unified theory of electricity and magnetism that will be discussed in Chapter 34.

Ampère's law is applied with an integration over some closed path. The right-hand side of Ampère's law, Eq. (29–10), contains what we called the current enclosed by a path. By "the current enclosed by a path," we mean the rate of charge flow through a surface whose boundary is the closed path. Such a surface can be chosen in many different ways (Fig. 29–27), but *when the current is continuous, the current that crosses any one of these surfaces must be the same as the current that crosses any other*. For constant current, the freedom to choose a surface therefore presents no problem. There is a situation, however, in which the freedom to choose the surface presents a difficulty, and this situation arises, for example, when the current deposits charge on the plates of a capacitor. Figure 29–28 shows two surfaces with the same loop as their boundary. A current I crosses surface 1 in the positive sense, while no current crosses surface 2, as the charge collects and remains at the capacitor plate. Ampère's law is ambiguous in this situation, because either surface is allowed in its expression.

Maxwell noted that even if no current passes through surface 2, there is a distinguishing feature for this surface: *There is a changing electric flux through it*. As the charge builds up on the plates of the capacitor, the resulting electric field between the plates also builds up, and hence so does the electric flux in the space between the plates.

▲ **FIGURE 29–27** A closed path defines an infinite number of surfaces.



▲ **FIGURE 29–28** Two surfaces bounded by the same closed path. A current passes through surface 1 but not through surface 2.

Suppose that we have a capacitor with large, planar plates of area A (Fig. 29–29). As the current I flows, it deposits a charge $+q$ on one of the plates. We can then use the results of Chapters 22 and 25: The field $\vec{E}$ of such a capacitor is uniform between the plates and small outside the region between the plates. The field points from the plate with positive charge (where the charge accumulates) to the plate with negative charge. The electric flux associated with a surface that passes between the plates, Φ_E, is then just EA. The magnitude of the electric field is given by $E = (1/\varepsilon_0)(q/A)$. Because $\Phi_E = EA$ in this case, this result is equivalent to

$$\varepsilon_0 \Phi_E = q. \tag{29–28}$$

If we take a time derivative, we find the relation

$$\varepsilon_0 \frac{d\Phi_E}{dt} = \frac{dq}{dt} = I. \tag{29–29}$$

▲ **FIGURE 29–29** The electric field between two parallel plates that carry charges $+q$ and $-q$, respectively, is uniform inside and small outside the region between the plates.

Equation (29–29) implies that whatever the value of the current that passes through the wire that leads to the capacitor, that current equals the quantity $\varepsilon_0 \, d\Phi_E/dt$ between the plates. Therefore, if we replace I in Ampère's law by the *sum* of the two terms in Eq. (29–29),

$$I + \varepsilon_0 \frac{d\Phi_E}{dt}.$$

Ampère's law would be satisfied for *any* surface we could draw for the path of Fig. 29–28. For surface 1, only the term I in this sum applies; for surface 2, only the changing flux term applies. The second term, $\varepsilon_0 \, d\Phi_E/dt$, is written in a way that does not refer explicitly to the plane geometry. Indeed, Maxwell was able to show that if the sum of these two terms is used, any surface gives the same answer in Ampère's law. Maxwell called the changing flux term the **displacement current**, I_d:

$$I_d \equiv \varepsilon_0 \frac{d\Phi_E}{dt}. \tag{29–30}$$

DISPLACEMENT CURRENT

The term "current" is used here because the displacement current has the same dimensions as, and appears in the place of, the current composed of moving charge. Note that the displacement current is present only when there are changing electric fields.

Maxwell's insight that changing electric flux gives rise to a magnetic field, and his quantification of the magnetic field that results, allows Ampere's law to be extended to cover all situations, including those in which there is varying current. Even though the current is not continuous when capacitors are present, *the sum of the ordinary current and the displacement current is continuous.*

Maxwell's generalized form of Ampère's law is accordingly

$$\oint \vec{B} \cdot d\vec{s} = \mu_0(I + I_d) = \mu_0 I + \mu_0 \varepsilon_0 \frac{d\Phi_E}{dt}. \tag{29–31}$$

GENERALIZED AMPÈRE'S LAW

Here, the sum $I + I_d$ is calculated with reference to *any* surface that spans the closed path defining the line integral of the magnetic field. We have concluded from this generalization that changing electric flux produces magnetic field just as moving charges do.

That a changing electric flux produces a magnetic field has great importance for electromagnetic waves, as we shall see in Chapter 34. It may also be of importance when a very large capacitor discharges very quickly, but as Example 29–9 shows, it may otherwise have very little practical effect.

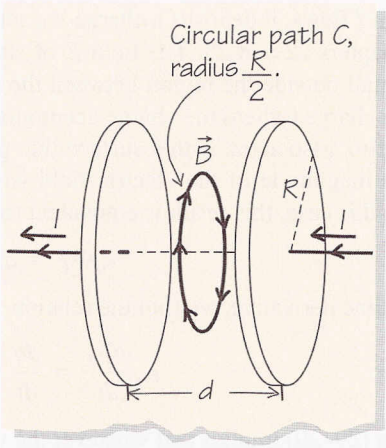
EXAMPLE 29–9 The planar circular plates of a capacitor are being charged. At a given moment, the charge is being built up at the rate of 1 C/s. The plates have a radius $R = 0.1$ m and a separation $d = 1$ cm. Calculate the magnetic field due to the displacement current midway between the plates at a radius equal to half the plate radius.

Strategy Because the plates are circular, symmetry requires that the value of the magnetic field be the same everywhere on path C, a circular path centered on the plates' axis and of radius $R/2$ (Fig. 29–30). Then we can apply the generalized Ampère's law using this path, extracting the magnetic field magnitude B from the integration. The problem statement gives us enough information to find the rate of change of the electric field across the plates and hence the rate of change of electric flux through our path. We can then solve for B.

Working It Out The line integral in Ampère's law is taken in the sense drawn. Because $\vec{B}$ has constant magnitude on this path and points along the path, we can remove it from the integral. The remaining integral is the circumference of the path, $2\pi(R/2)$:

$$\oint \vec{B} \cdot d\vec{s} = B \oint ds = B\left(2\pi \frac{R}{2}\right).$$

To calculate the displacement current, we note that, in terms of the charge q on the plates, the electric field, which is uniform across the region between the plates, has magnitude



$$E = \frac{1}{\varepsilon_0} \frac{q}{\pi R^2}.$$

We must now calculate the electric flux through the area bounded by path C (and not the *total* electric flux in the capacitor). The flux through path C is E times the area $\pi(R/2)^2$:

$$\Phi_E = \frac{1}{\varepsilon_0} \frac{q}{\pi R^2} \pi\left(\frac{R}{2}\right)^2 = \frac{1}{4\varepsilon_0} q.$$

Thus the displacement current is

$$I_d = \varepsilon_0 \frac{d\Phi_E}{dt} = \varepsilon_0\left(\frac{1}{4\varepsilon_0} \frac{dq}{dt}\right) = \frac{1}{4} \frac{dq}{dt}.$$

▲ **FIGURE 29–30** Symmetry requires that the value of the magnetic field be the same everywhere on path C.

We can find the magnitude of the magnetic field $\vec{B}$ by using Eq. (29–31):

$$B\left(2\pi \frac{R}{2}\right) = \mu_0 I_d = \frac{\mu_0}{4} \frac{dq}{dt};$$

then

$$B = \frac{\mu_0}{4\pi} \frac{1}{R} \frac{dq}{dt}.$$

Numerically, $dq/dt = 1$ C/s $= 1$ A and $R = 0.1$ m, so

$$B = \frac{4\pi \times 10^{-7}\ \text{N/A}^2}{4\pi} \frac{1}{0.1\ \text{m}} (1\ \text{A}) = 10^{-6}\ \text{T}.$$

This is a small field; for comparison, recall that Earth's magnetic field at Earth's surface is around 10^{-4} T.

What Do You Think? What happens if the distance d between the plates is halved?

Summary

Magnetic fields are produced by electric currents. The magnetic field lines about a long, straight wire that carries a constant current form circles around the wire in the plane perpendicular to the wire. The direction of the field lines in these circles is determined when the thumb of the right hand points along the direction of the current flow: The fingers then curl in the direction of the magnetic field. The magnitude of the field at a radial distance r from the wire is

$$B = \frac{\mu_0 I}{2\pi r}. \tag{29–5}$$

The defined constant $\mu_0 = 4\pi \times 10^{-7}$ T · m/A is the permeability of free space.

The magnetic fields produced by unchanging currents obey Ampère's law:

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 I_{\text{enclosed}}. \tag{29–10}$$

Here, the line integral follows any closed path through which the current I_{enclosed} passes. A second law obeyed by the magnetic field results from the absence of magnetic equivalents to the electric charge. Because there are no magnetic charges on which magnetic field lines begin or end, magnetic field lines must close on themselves. This fact is expressed by Gauss' law for magnetism:

$$\text{for a closed surface: } \Phi_B = \int_{\text{closed surface}} \vec{B} \cdot d\vec{A} = 0. \tag{29–12}$$

This law states that the magnetic flux, Φ_B, through any closed surface is zero; equivalently, the number of magnetic field lines that enter a closed surface is the same as the number of lines that leave the surface.

Ampère's law is an important practical tool for determining magnetic fields when there is enough symmetry to allow a path choice in which the integral simplifies, as in the determination of the interior field of a long solenoid. A solenoid is a wire wound uniformly into a coil to form a tube. When current flows, a magnetic field is produced within the tube that has a constant magnitude and is aligned with the tube axis. The magnitude of the interior field is

$$B = \mu_0 nI, \tag{29–15}$$

where n is the number of windings of wire per unit length of the solenoid. Because its interior magnetic field is constant, a solenoid is to magnetism what a capacitor is to electricity.

When there is not enough symmetry to allow Ampère's law to be used to determine the magnetic field produced by a given configuration of currents, the Biot–Savart law can be used instead. According to this law, the magnetic field $d\vec{B}$ produced by a segment of wire $d\vec{\ell}$ that carries a current I at a displacement $\vec{r}$ from the segment is given by

$$d\vec{B} = \frac{\mu_0}{4\pi}\frac{I\,d\vec{\ell}\times\vec{r}}{r^3}. \tag{29–19}$$

The magnetic field from an infinitesimal segment can be integrated to find the net magnetic field due to a finite segment of wire.

Application of the Biot–Savart law shows that the magnetic field due to a ring of current, or the exterior field of a solenoid of finite length, is a magnetic dipole field. The form of this magnetic dipole field is the same as that of a bar magnet or, equivalently, has the same form as the exterior electric field produced by an electric dipole. The current loop forms a magnetic dipole, characterized by a magnetic dipole moment μ which is aligned perpendicular to the surface of the loop according to a right-hand rule. Its magnitude is

$$\mu = IA, \tag{29–27}$$

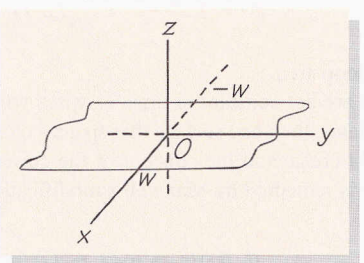
where A is the loop area.

If currents are not constant in time, as when wires are interrupted by the presence of charging capacitor plates, then one surface that spans a closed path might not cross the wire that another surface might cross, and the concept of the current enclosed by a path becomes ambiguous. This ambiguity is remedied by Maxwell's modification of Ampère's law to

$$\oint \vec{B}\cdot d\vec{s} = \mu_0(I + I_d) = \mu_0 I + \mu_0\varepsilon_0\frac{d\Phi_E}{dt}. \tag{29–31}$$

The quantity I_d, proportional to the rate of change of electric flux, is known as the Maxwell displacement current. The surface through which the sum of I and I_d passes is any surface that spans the closed integration path. We conclude from this modification that a changing electric flux creates a magnetic field.

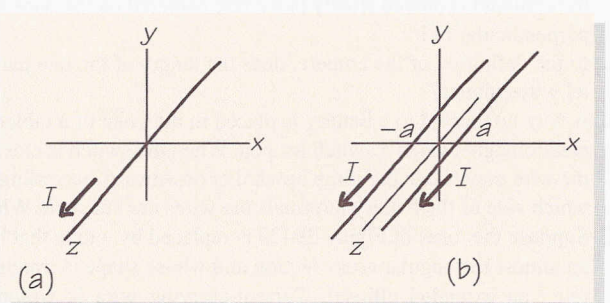
Understanding the Concepts



1. Suppose you move a compass needle near a straight wire that carries a current. Describe how the compass needle reacts when the compass is moved slowly in a circle centered on the wire and perpendicular to it.
2. In the definition of the ampere, does the length of the two parallel wires matter?
3. A wire connected to a battery is placed in the yoke of a tabletop electromagnet when a switch is open. When the switch is closed, the wire may take a big jump upward or downward, according to which side of the battery terminals the wires are attached. Why?
4. Suppose the torus of Figure 29–20 is replaced by a tube that has an almost rectangular cross section and whose shape is irregular (e.g., an extended ellipse). Current-carrying wire is wrapped closely around the tube. What can you say about the magnetic field?
5. In the definition of the ampere, must we worry about the Coulomb forces between the charges in the two wires?
6. Does the statement of the generalized Ampère's law, including displacement current, imply that without the displacement current charge would *not* be conserved?
7. Why is the Biot–Savart law written in differential form? Explain why it cannot be written as in Eq. (29–19) but without the differential signs.
8. Consider the solenoid, length L, of Example 29–4. You increase the number of windings, always using the same wire, so that the magnetic field is doubled. How will the resistance of the coil change?
9. Why is it preferable to define current in terms of the force between two long, parallel wires rather than in terms of the rate at which charge passes a point?

10. Is it possible to arrange a set of electric currents and produce a magnetic field that, at large distances from the apparatus responsible, is everywhere directed radially away from the apparatus? Feel free to choose your apparatus, and give either a proof that it is impossible or a description of the apparatus.
11. Suppose that the space between the plates of the capacitor discussed in Section 29–5 is not empty but is filled with a dielectric. How would the treatment in that section, and the determination of the displacement current, change?
12. Suppose that magnetic charges were discovered. What are some practical consequences?
13. In Example 29–8 we looked at the field along the axis of a loop. Suppose you had two identical loops parallel to one another and aligned along the same axis. Consider the point P that is on the axis and midway between the loops. What, qualitatively, is the field at P if the current travels in the same direction in both loops? If the current travels in opposite directions?
14. What are the SI units of the ratio E/B, where E is an electric field and B is a magnetic field?
15. When two bar magnets are placed side by side, they will (a) attract or (b) repel if the adjacent poles are (a) opposite or (b) the same. If you draw magnetic field lines for the combination of two magnets in both cases, the net magnetic field between the magnets will tend to (a) cancel or (b) be doubled. What conclusions can you draw?
16. A current passes through a helical coil. Which of the following statements is true? (a) The helical coil will tend to get shorter; (b) the helical coil will tend to get longer; (c) the coil will get charged; (d) no magnetic field will get produced.

Problems



29–1 Ampère's Law

1. (I) Sketch the magnetic field lines due to two current-carrying wires that are parallel to each other for the cases that (a) the currents move parallel to each other, and (b) the currents move in opposite directions.
2. (I) Consider an array of parallel, current-carrying wires arranged so that they all lie in a plane and are separated by equal distances. Sketch the magnetic field due to this array. Assume that all the currents point in the same direction.
3. (I) What is the force per meter between two long, parallel wires, each carrying 50,000 A but in opposite directions, if the two wires are 30 cm apart? Such currents are normal in the electrolytic production of aluminum.
4. (I) A long, straight wire carries a current of 17 A. What is the magnetic field at a distance of 35 cm from the wire?
5. (I) A lightning conductor carries a current of 5×10^4 A for a short period. During that time, what is the magnitude of the magnetic force per unit length exerted on a parallel wire 4 m away in which a current of 100 μA flows?
6. (I) Two 12-cm-long parallel wires in a handheld calculator are 1.2 cm apart. The currents are parallel, running in the same direction, and have values 35 μA and 8 μA, respectively. What is the force between the wires due to the currents?
7. (I) Find the dimensions of μ_0 and ε_0, and use your expressions to show that the product $\mu_0\varepsilon_0$ has dimensions of $(1/\text{speed})^2$. Find the value of that speed in SI units.
8. (I) A coaxial cable consists of a central wire that carries current I to the right and a tube centered on the central wire that carries the same current to the left. Find the magnetic field outside the cable.
9. (II) (a) In a thick, straight wire carrying a current that is uniform through its cross section, where is the magnetic field the greatest? (b) If the radius of the wire is R and the current is I, what is the value of the maximum magnetic field? (c) What is the minimum magnetic field, and where does this occur? Consider regions both inside and outside the wire. (d) Plot the magnetic field as a function of the distance from the center of the wire.
10. (II) The current-carrying capacity of superconducting wires is limited by the fact that superconductivity breaks down if a large magnetic field is present. Estimate the largest current that can be transported via a NbTi wire, 0.8 mm in diameter, if the critical (breakdown) magnetic field is 10 T. [*Hint*: What is the wire's own magnetic field?]
11. (II) Plot the curves of constant magnetic field in the xy-plane for values B_0, $2B_0$, $3B_0$, and $4B_0$ of the field about a straight wire that carries current along the z-axis. B_0 is some field value that you can choose. These curves are the intersections with the xy-plane of the surfaces of constant field.
12. (II) A very thin, infinitely long metal sheet lies in the xy-plane, between $x = -w$ and $x = w$. A current of density h A/m flows in the $+y$-direction (Fig. 29–31). What are the magnitude and direction of the magnetic field at a distance $z \ll w$ above and below the sheet? Neglect end effects.

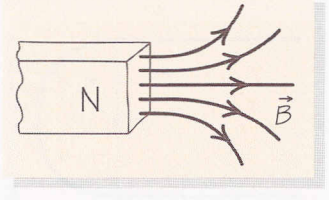
▲ **FIGURE 29–31** Problem 12.

13. (II) Current is carried from a battery to a device by a copper "ribbon" 1 in wide and 1/32 in thick. What is the magnetic field over the surface of the ribbon, if the current it carries is 120 A?
14. (II) Consider two parallel metal sheets, such as the sheet of Problem 12, with currents flowing in opposite directions. What are the magnetic fields between and outside the sheets? What is the situation when the currents are parallel rather than anti-parallel?
15. (II) Consider a wire that passes through the origin along the z-axis and carries a current I (Fig. 29–32a). (a) Calculate the x- and

▲ **FIGURE 29–32** Problem 15.

y-components of the magnetic field at a point whose coordinates are $(x, y, 0)$. (b) Use this result to obtain the magnetic field due to two wires that are parallel to the z-axis, cross the xy-plane at $(a, 0)$ and $(-a, 0)$, and carry current I in the $+z$-direction (Fig. 29-32b). (c) What are the fields when the currents are in opposite directions?

16. (II) A uniform current with current density J A/m flows parallel to the z-axis on a cylindrical metal sheath, where the radius of the cylinder is R. What is the magnetic field outside the sheath? inside the sheath?



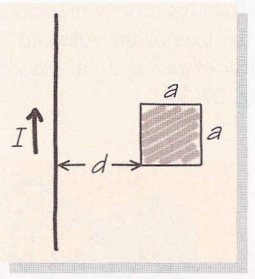
17. (II) Current flows up the inner cylinder of a coaxial cable and returns on the outside cylinder. The radius of the inner cylinder is 0.1 cm, and the radius of the thin outer cylindrical shell is 0.5 cm. Calculate the magnetic field on the cylindrical surface midway between the inner and outer surfaces, given that the current is 10 A. Ignore end effects.

18. (II) Two long, parallel wires carrying a current I in the same direction each have a mass density λ. The wires are initially a distance D apart and are then released. Write a differential equation for the distance between the wires that describes the relative motion of the wires. Ignore all forces other than the magnetic force.

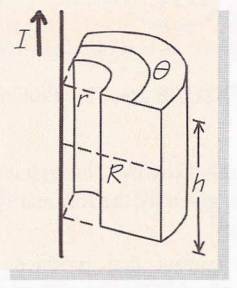
19. (III) An electron beam contains electrons that move along the $+x$-axis at $0.020c$. The beam enters a region of length 1.0 m and runs parallel to a wire that carries a 0.20-A current in the $+x$-direction. The beam is 10.0 cm from the wire. (a) Specify the direction in which the beam is deflected, if at all. (b) Find the deflection of the beam as it passes through the 1-m region by calculating the impulse it receives during its brief passage through that region. (c) After it has passed the wire, does the beam have the same energy it had when it entered the region that contains the wire?

29–2 Gauss' Law for Magnetism

20. (I) Figure 29–33 shows the magnetic field lines that emerge from one pole of a bar magnet; these lines resemble the electric field lines that emerge from one end of an electric dipole. Sketch the magnetic field lines in the region of the pole inside the magnet. For comparison, also sketch the electric field lines in the central region of an electric dipole. What would the magnetic lines look like if the N and S poles of a magnet represented magnetic monopoles, which would be point sources of magnetic field?



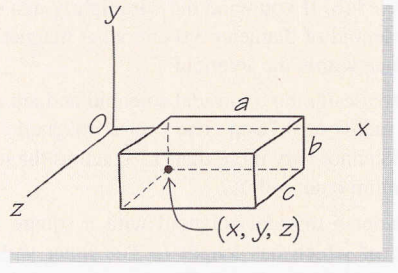
▲ **FIGURE 29–33** Problem 20.



21. (II) A long, current-carrying wire is oriented vertically; next to it is drawn a square whose area lies in the same plane as the wire (Fig. 29–34). Using the distances indicated, find the magnetic flux through the square.

22. (II) Using Gauss' law for magnetism, show that a magnetic field with only an x-component must be constant as x varies.

23. (II) Show that Gauss' law is satisfied for the magnetic field due to a straight wire that carries a current I in the $+z$-direction for a volume that represents a portion of a cylindrical shell of height h, extending from a radius r to a radius R and formed by an angle θ (Fig. 29–35).



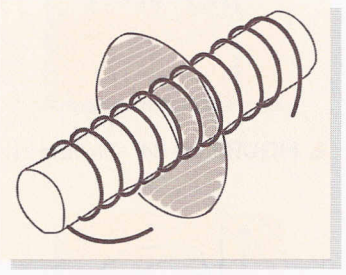
▲ **FIGURE 29–34** Problem 21.

▲ **FIGURE 29–35** Problem 23.

24. (III) Apply Gauss' law for magnetism to a parallelepiped of dimensions a, b, and c, one of whose corners is located at point (x, y, z), as in Fig. 29–36. Assume that the dimensions in the x-, y-, and z-directions $(a, b, \text{and } c)$ are small enough so that $B(x + a, y, z) = B(x, y, z) + a\,\partial B/\partial x$, and so on. Show that Gauss' law leads to the condition $(\partial B_x/\partial x) + (\partial B_y/\partial y) + (\partial B_z/\partial z) = 0$ in this limit.

▲ **FIGURE 29–36** Problem 24.

29–3 Solenoids



25. (I) A solenoid of diameter 5 cm has a length of 25 cm and 320 turns of wire. What is the magnetic field at the center of the solenoid when the current in the coil is 3 A?

26. (I) A long, superconducting solenoid is wound with fine niobium–tin wire so that there are 16×10^4 turns/m. If a power supply produces 12 A, what is the magnetic field inside the solenoid?

27. (I) You are told that a toroidal solenoid, carrying a current of 0.36 A through 2500 turns, produces a magnetic field of 5.1×10^{-4} T at its central axis. What can you conclude about the radius of the circle made by that axis?

28. (I) A wire is wound around a torus with outer radius of 32 cm and inner radius of 30 cm. There are 6400 turns in all and the wire carries a current of 2.2 A. What is the range of the magnetic field inside the torus? What percentage change is there from the center to the outside?

29. (I) The magnetic field inside a cylindrical solenoid of area 4 cm^2 is 0.15 T along the axis of the solenoid. What is the magnetic flux through a disk of radius 3 cm placed perpendicular to the solenoid axis (Fig. 29–37)?

▲ **FIGURE 29–37** Problem 29.

30. (I) Show that the magnetic flux through an ideal cylindrical solenoid of radius R is given by the formula $\Phi_B = \mu_0 nI\pi R^2$, where n is the turn density.

31. (I) What is the current that produces a magnetic field of 0.40×10^{-4} T in the middle of a solenoid that is 1.6 m long and that has 800 turns?

32. (II) A toroidal solenoid consists of a cylinder bent into a circle. The axis of the cylinder is 60 cm from the center of the torus. The cross-sectional area of the cylinder is 70 cm^2, and the coil has 1200 turns. Given that the current in the coil is 25 A, what is the magnetic field inside the solenoid, along the axis of the cylinder?

33. (II) You have 20 m of #16 AWG copper wire (0.051 inch diameter) that can carry a maximum current of 22 A. (a) If you form the wire into a large circle and pass the maximum current through it, what magnetic field would you produce at the center of the circle? (b) If you wind the wire tightly in a single layer to form a solenoid of diameter 3.0 cm, what magnetic field would you produce within the solenoid?

34. (II) You are designing a toroidal solenoid and are constrained to an inner radius of 0.76 m. The central magnetic field must be 3.0 T and cannot vary more than 15% across the toroid. What is the maximum outer radius?

35. (II) Consider a toroidal solenoid with a square cross section, each side of which has length L. The inner wall of the torus forms a cylinder of radius R. The torus is wound evenly with N loops of wire, and a current I flows through the wire. What is the total magnetic flux through the torus?

36. (II) A toroidal solenoid—similar to the one considered in Problem 35—has a square cross section of side length 1.1 cm and an inner radius of $R = 15$ cm. It is wound with 500 turns of 0.25-mm-diameter copper wire. The wire is connected to a 1.5-V battery with negligible internal resistance. (a) Calculate the largest and smallest magnetic field across the cross section of the toroid. (b) Calculate the magnetic flux through the torus. (c) Do you need to cool the solenoid?

29–4 The Biot–Savart Law

37. (I) Two long wires are placed along the y- and z-axes, respectively. They carry the same current I in the positive directions. Calculate the magnetic field along the x-axis.

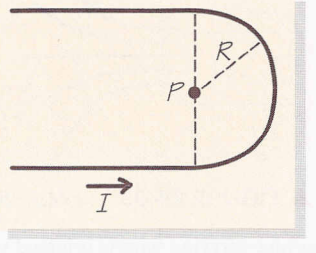
38. (I) A single loop of wire forms a rectangle whose sides have lengths 17 mm and 150 mm. The wire carries a current of 36 mA. What is the magnetic dipole moment of the loop?

39. (II) An infinitely long L-shaped wire is placed so that a current I flows in along the y-axis toward the origin, then out from the origin along the x-axis. What is the magnetic field at a point on the z-axis at a height H above the origin?

40. (II) Consider a straight segment of wire of length L that carries a current I. Use the Biot–Savart law to find the magnetic field along the axis of the wire, beyond the wire itself, due to this segment.

41. (II) A differential length $d\vec{\ell}$ of wire carrying a current of 2 A is positioned at the origin of a coordinate system and points in the $+x$-direction. Find the magnetic field due to this wire segment at the following (x, y, z) positions, given in centimeters: (a) $(0, 0, 3)$, (b) $(0, 6, 0)$, (c) $(3, 0, 0)$, and (d) $(6, 0, 6)$. Give both the magnitude and direction of the magnetic field.

42. (II) Consider a thin dielectric ring 7 cm in diameter that rotates around a stem perpendicular to the plane of the ring and through its center at the rate of 120 rev/s. Assume that the ring is charged uniformly and carries a total charge of 8×10^{-7} C. What is the magnetic field produced at the center of the ring by the rotating charge?

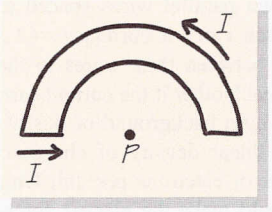


43. (II) Repeat the calculation of Problem 42 for a solid disk 5 cm in diameter, with the same total charge.

44. (II) A wire carries a current of 10 A, starting from $x = -\infty$. The wire is laid along the negative x-axis to the point $x = -15$ cm. The wire then follows in the positive y direction for 10 cm, then continues parallel to the x-axis to the point ($x = 15$ cm, $y = 10$ cm), then drops back in a straight line to the x-axis, and continues along the positive axis. What is the magnetic field at the origin?

45. (II) Calculate the magnetic field at the center of a rectangular wire, with sides a and b respectively, if the current flowing through the wire is I. What happens when $a = b$? What happens when $b \gg a$?

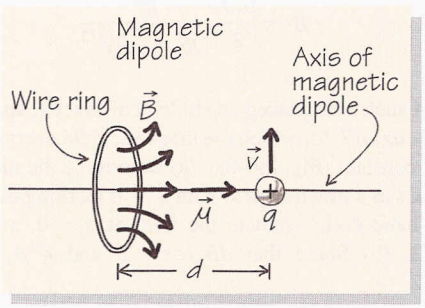
46. (II) A current loop consists of a square with sides of length L. A current I circulates counterclockwise around the loop. Find the direction and magnitude of the magnetic field at the center of the square. Compare this to the field at the center of a circular loop of diameter L that carries the same current.



47. (II) Consider the wire shown in Fig. 29–38. Calculate the magnetic field at point P, the center of the half-circle of radius R around which the wire turns, as a function of R and the current I carried by the wire.

▲ **FIGURE 29–38** Problem 47.

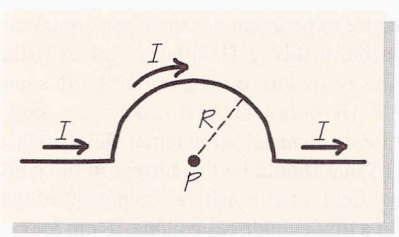
48. (II) A very long wire is aligned along the $+x$- and $+y$-axes, making a right angle at the origin. A current I travels in the $-y$-direction and continues in the $+x$-direction. What is the magnetic field at the point (x, y), where both x and y are positive?



49. (II) Consider the wire shown in Fig. 29–39, see next page, with the inner and outer radii of the semicircle given as 5 cm and 8 cm, respectively. Given that the current in the wire is 12 A, what is the magnetic field at point P, the center of the semicircles?

▲ **FIGURE 29–39** Problem 49.

50. (II) Calculate the magnetic field at the center of a wire square that consists of 80 loops and has sides of length 5 cm and carries a current of 0.7 A.



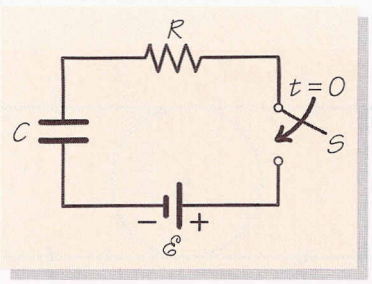
51. (II) A charge q moves at instantaneous speed v when it crosses the axis of a ring of current with a magnetic dipole moment μ. At that instant, q is located a distance d from the center of the ring in the direction of the dipole moment vector and is moving perpendicular to the axis (Fig. 29–40). What is the resulting instantaneous motion of the charge? Find the instantaneous radius of curvature of its motion.

▲ **FIGURE 29–40** Problem 51.

52. (II) A circular current loop of radius R produces a magnetic field. At what distance along the axis of the loop does the field have magnitude 0.5 times the magnitude at the center of the loop? At what distance is the magnitude of the field reduced to 1/100 the value at the center? Give your answer in units of R.

53. (II) Find the magnetic field at point P in Fig. 29–41 if a current of 8 A flows in the infinitely long wire; the radius R of the semicircle is 1.2 cm.

▲ **FIGURE 29–41** Problem 53.

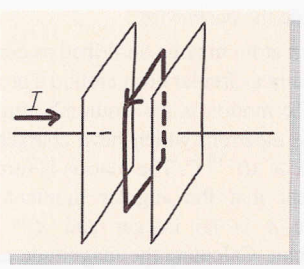


54. (III) A segment of wire forms a straight line of length L and carries a current I. Find the magnetic field due to the wire segment in the plane perpendicular to it and passing through one end.

55. (III) By integration, find the magnetic dipole moment of a spherical shell of radius R that carries a total charge Q, distributed uniformly, if the shell rotates with angular velocity ω oriented along the z-axis.

56. (III) Consider a long, thin-walled metal pipe that carries a total current I distributed evenly along the walls of the pipe. A simple application of Ampère's law indicates that the magnetic field inside the pipe is zero. Show by a simple geometric argument that the same result follows from the Biot–Savart law.

29–5 The Maxwell Displacement Current



57. (I) Consider the RC circuit shown in Fig. 29–42. Switch S is closed at time $t = 0$. Calculate the displacement current in the capacitor as a function of time.

▲ **FIGURE 29–42** Problems 57, 58.

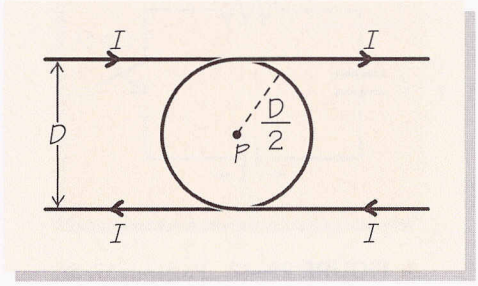
58. (I) Consider the RC circuit shown in Fig. 29–42; this time the switch is closed. At some time, the switch is opened. What is the displacement current?

59. (I) A parallel-plate capacitor is being charged at a rate of $I = 0.2$ A. The plates have an area of 0.25 m^2 and are separated by 1.0 cm (Fig. 29–43). What is the value of $\int \vec{B} \cdot d\vec{\ell}$ for a closed path midway between the plates and covering an area of 5.0×10^{-2} m^2?

▲ **FIGURE 29–43** Problem 59.

60. (II) A 15-μA current starts flowing in a circuit with a 3.5 μF capacitor of area 40 cm^2 at $t = 0$ s. (a) How fast is the voltage across the capacitor plates changing at $t = 0$ s? (b) Use the result of (a) to calculate *explicitly* $d\Phi_E/dt$ and the displacement current at $t = 0$ s.

61. (II) An alternating voltage of the form $V = V_0 \cos(\omega t)$ is connected across a capacitor C. What is the displacement current in the capacitor?



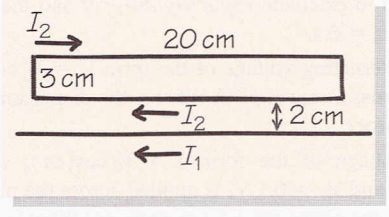
62. (II) A voltage of the form $V = V_0 \cos(\omega t)$, with $\omega = 2 \times 10^4$ rad/s and $V_0 = 0.1$ V, is applied across the plates of a 5-nF capacitor; the plates are 1.5 cm apart. (a) What is the maximum rate of change in electric field between the plates? (b) The maximum value of current leading to the capacitor?

63. (II) A conducting sphere of radius R initially has a uniform surface-charge density σ_0. Beginning at $t = 0$, this charge is drained off over a period t_0 such that $\sigma = \sigma_0[1 - (t/t_0)]$. Find the displacement current at the surface of the sphere as a function of time. Compare the displacement current to the current carried off by the wire.

General Problems

64. (I) Three wires lie in a plane, placed parallel to one another and equally spaced by 0.20 m. If the wires are oriented up and down on the page, the right-hand wire carries 100 A to the top, the middle wire 300 A to the bottom, and the left-hand wire carries 200 A to the top. What are the forces per unit length on each of the wires?

65. (II) Two wires shown in Fig. 29–44 have identical currents flowing. Use the superposition principle and symmetry to obtain as much information as you can about the magnetic field at point P.



▲ **FIGURE 29–44** Problem 65.

66. (II) Calculate the force per unit area between two metal sheets that carry identical currents in the same direction. The sheets carry a current of linear density h A/m as in Problem 12.

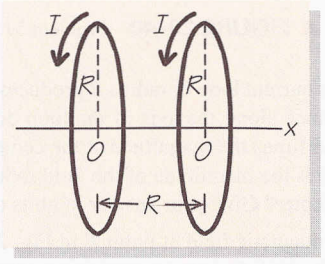
67. (II) Equal but opposite currents I travel in the inner and outer wires of a coaxial cable. As a function of the distance from the central axis, find the magnetic field (a) inside the inner wire; (b) in the region between the wires; (c) in the outer (tubular) wire; (d) outside the outer wire.

68. (II) A hydrogen atom may be described as consisting of an electron that moves in a circular orbit around a proton. The force that gives rise to the motion is the Coulomb attraction between the proton and the electron, which have charges $\pm e$, respectively, where $e = 1.6 \times 10^{-19}$ C. The motion is further constrained by the requirement that the angular momentum has the value $nh/2\pi$, where n is an integer and $h = 6.63 \times 10^{-34}$ J · s, Planck's constant. Calculate the magnitude and direction of the magnetic field at the location of the proton. What is the magnetic moment of the current loop?

69. (II) Find the force between the long, straight wire and the rectangular wire loop shown in Fig. 29–45 for currents $I_1 = 10$ A and $I_2 = 5$ A.

▲ **FIGURE 29–45** Problem 69.

70. (II) The mechanical integrity of solenoids may present a problem that has to be anticipated in technical design. To illustrate the forces that can be present, calculate the force between two neighboring turns of a superconducting solenoid. The radius of the solenoid is 3 cm, the diameter of the wire is 0.8 mm, and the current in the solenoid is 150 A.



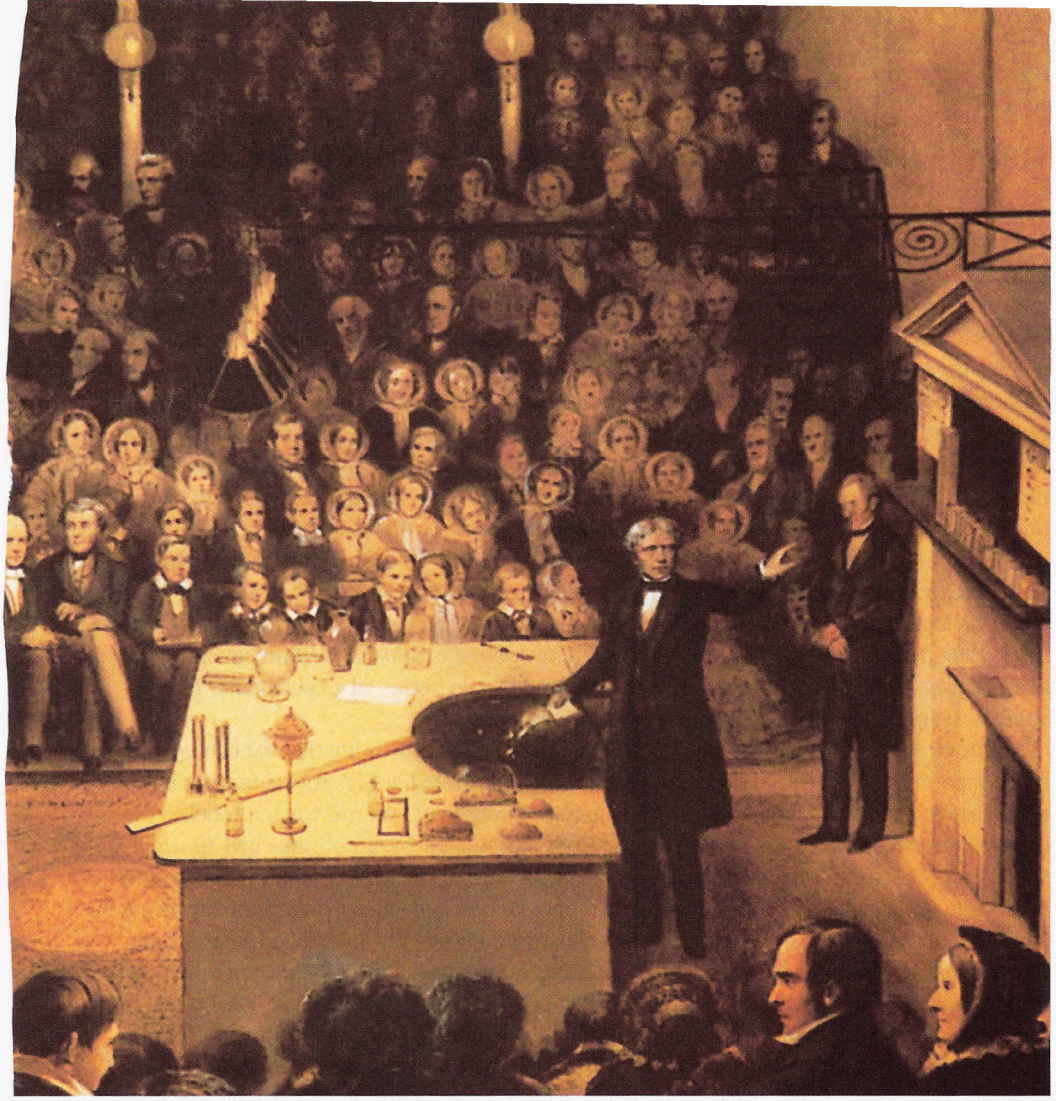
71. (II) Consider two parallel wires spaced a distance $d = 1$ cm apart, which each carry a current $I = 1$ A. (a) Compare the magnetic force between these wires to the electric force they would exert on each other if the current carriers (electrons) were not neutralized by a background of positive charges. Use 10^{21} per cm as the linear density of charge carriers in the wire. (b) What excess of electrons per unit length over the positive background would make the electric force equal the magnetic force between the wires? (c) What fraction of the total number of charge carriers is the excess calculated in part (b)?

72. (II) A long wire carries a current I_1. A segment of a second wire, which carries a current I_2, is oriented radially away from the first wire. The segment has length L, and its closest end is a distance d from the first wire. Calculate the torque, direction and magnitude, on the wire segment about the axis defined by the long wire.

73. (II) In Example 29–8, we found the magnetic field due to a circular wire of radius R, carrying a current I, at a point a distance x away from the center of the ring but along the axis to be

$$B = \frac{\mu_0 I}{2} \frac{R^2}{(R^2 + x^2)^{3/2}}.$$

A pair of such coils placed coaxially a distance R apart makes up a *Helmholtz coil*, for which the magnetic field everywhere inside is fairly constant (Fig. 29–46). (a) Determine the magnetic field on the axis as a function of x, with $x = 0$ marking the location of the left-hand coil. Evaluate the field at $x = 0$, $x = R/4$, and $x = R/2$. (b) Show that $dB_x/dx = 0$ and $d^2B_x/dx^2 = 0$ at $x = R/2$.



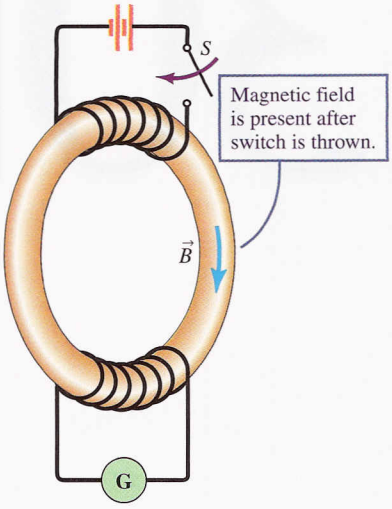
▲ **FIGURE 29–46** Problem 73.

74. (II) A sensitive experiment has to be performed in zero magnetic field. To achieve this, a Helmholtz coil of radius $R = 50$ cm with 50 turns is used to compensate for Earth's magnetic field of 5×10^{-5} T. (A Helmholtz coil is a current loop that sets up a magnetic field to cancel an external field, such as that due to Earth.) (a) What should be the current in the coil? (b) *Estimate* the residual field if the sensitive component of the equipment is confined to a thin cylindrical volume 10 cm long.

75. (III) A demonstration apparatus consists of a large glass bulb containing a small electron gun. The bulb is filled with rarified inert gas, which makes the trajectory of the electron visible. By placing the equipment in the magnetic field of a Helmholtz coil, the experiment described in Example 28–3 can be performed, and the ratio e/m for an electron can be determined. Design the equipment and select appropriate parameters for this demonstration.

76. (III) A certain electric current distribution produces a magnetic field of the form $\vec{B} = \beta(y\hat{i} - x\hat{j})$ near the origin of a coordinate system. Find the current distribution responsible.

Chapter 30



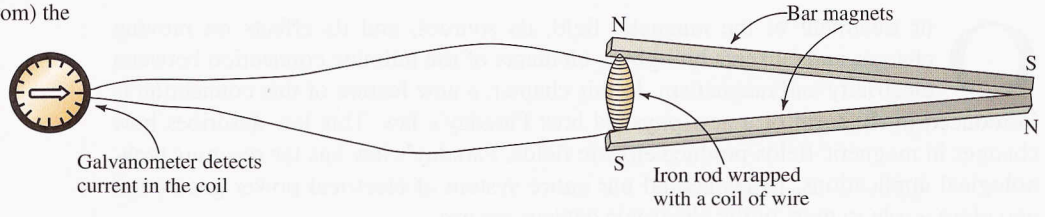
◀ Michael Faraday delivering one of his famous public lectures in 1856. These lectures earned him great popular success.

Faraday's Law

Our treatment of the magnetic field, its sources, and its effects on moving charges and currents brought in elements of the intimate connection between electricity and magnetism. In this chapter, a new feature of this connection is introduced in the form of a new physical law: Faraday's law. This law describes how changes in magnetic fields produce electric fields. Faraday's law has far-reaching technological applications. It lies behind our entire system of electrical power generation and plays a role in most of the electronic devices we use.

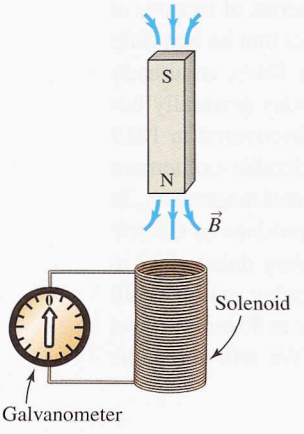
Before we look further at Faraday's law, we should acknowledge Faraday the man. Apprenticed as a bookbinder at age 13, he was inspired at age 22 by a series of lectures at the Royal Institution in London to become a scientist. In spite of the fact that he had little mathematical training, in 1813 he became an assistant to Sir Humphry Davy, an already famous scientist. Davy soon recognized Faraday's qualities, and Faraday gradually became more independent in his experimental inquiries. After Oersted discovered in 1819 that an electrical current in a wire deflected a magnetic compass, considerable excitement developed around the possible connections between electrical currents and magnetism. In particular, the inverse question presented itself: Could magnetic fields produce an electric current? Faraday pursued this sort of question for several years—an entry dated 1822 in his notebooks sets the goal "Convert magnetism into electricity." Faraday exhibited all the qualities of a great scientist in the discovery of what we now know as Faraday's law, which states that *changing magnetic fields generate electric fields*. We will study the details of his discovery and some of its ramifications in this chapter.

▲ **FIGURE 30–1** Faraday's ring. A changing magnetic flux in the iron ring induces a current in the galvanometer coil at the bottom; the changing flux is due to the opening or closing of a switch connected to the battery of the coil on the top.



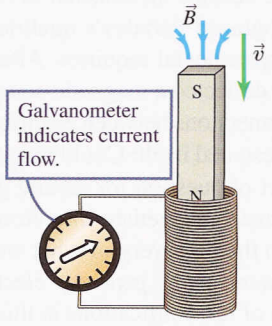
30–1 Faraday's Discovery and the Law of Induction

A great experimentalist such as Michael Faraday recognizes the significance of an odd or unexpected measurement. He or she realizes that a small effect is not always experimental error, and pursues the effect systematically, checks its reality, and considers its ramifications from as many points of view as possible. In 1831, Faraday carried out the experiment shown schematically in Fig. 30–1. The battery sends a current through the coil on the top side of an iron ring, which acts as a solenoid. The galvanometer is used to indicate any current in the coil on the bottom side of the ring. The only unfamiliar element is the iron ring, which does two things: It carries the magnetic field set up by the upper coil within the torus, and hence through the bottom coil (recall that magnetic field lines are closed), and—as we shall discuss in Chapter 31—it *magnifies* the size of the field set up in the upper coil. We say that the iron ring *links* the two coils.



To Faraday's disappointment, he observed no effect on the galvanometer when a *steady* current passed through the upper coil, but Faraday's intuition served him well when he noticed a very small twitch of the galvanometer *when the switch that controlled the flow of current in the upper coil was opened or closed*. Within several days of his observations of this small effect, he completed a series of experiments that revealed essentially all the aspects of magnetic induction.

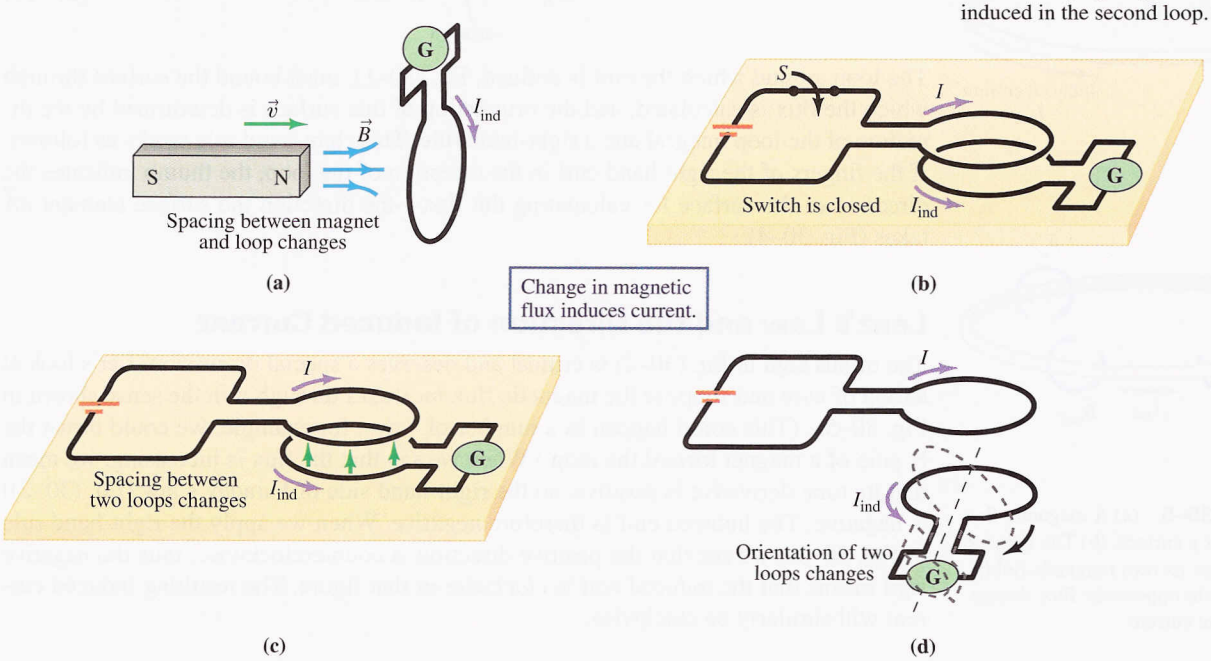
One of the first things Faraday did was to eliminate the possibility that the battery was itself important to the effect. In a second experiment, illustrated in Fig. 30–2a, two bar magnets make a V shape. A large magnetic flux passes through an iron rod when it touches the ends of the two magnets as shown. This rod is surrounded by a coil attached to a galvanometer. The galvanometer deflects—indicating a current in the coil—both when the rod is brought into contact with the ends of the two bar magnets and when the rod is pulled away. A more modern version of this experiment is illustrated in Fig. 30–2b, c; when a bar magnet remains stationary in the presence of a coil, there is no effect (Fig. 30–2b), but when the magnet moves toward the coil, a current is observed (Fig. 30–2c). The critical observation is that it is the *change* in the magnetic flux through the coil that leads to the creation of the current. The general result, which we will describe in detail below, is that the *change* of the magnetic flux through any surface bounded by a closed line causes an emf around that line. If this closed line is a circuit, then this emf can induce a current in the circuit. Faraday referred to the emf as an **induced emf** and called the current produced by a changing magnetic flux an **induced current**; he called the general phenomenon **magnetic induction**.



▼ **FIGURE 30–2** (a) A figure from one of Faraday's lectures. The movement described in the text creates a changing magnetic flux and induces a current even when no battery is present. Adapted from Faraday's book *Experimental Researches in Electricity* in 1839; the labeling is our own. (b), (c) A more modern version of Faraday's experiment. There is a current produced in the coil only when the bar magnet moves toward (or away from) the coil.

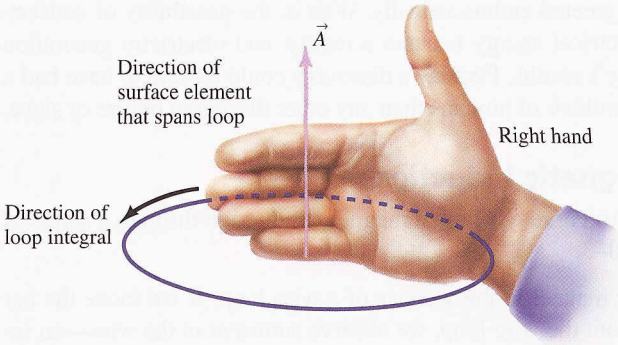
(a)

(b)



(c)

Faraday's discovery was greeted enthusiastically. With it, the possibility of converting mechanical energy to electrical energy became a reality, and electricity generation worldwide is based on Faraday's results. Faraday's discovery could be said to have had a greater effect on the material welfare of humans than any other discovery before or since.



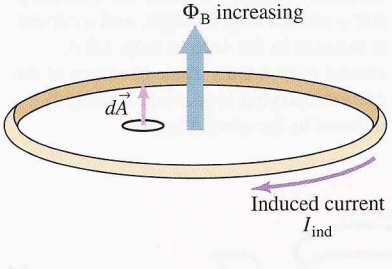
Faraday's Law of Magnetic Induction

We can clarify and add detail to Faraday's law of magnetic induction through a series of experiments, shown in Fig. 30–3.

1. Figure 30–3a shows a bar magnet in the vicinity of a wire loop. If we move the bar magnet toward or away from the wire loop, we observe a current in the wire—an induced current. In Section 29–2 we discussed the magnetic flux, which is associated with the number of magnetic field lines passing through a surface. We have such a flux here, and when the magnet moves as described, the flux through the loop made by the wire changes. Current flows *only* when the magnetic flux through the loop changes. A faster movement—a more rapidly changing flux—results in a larger current than does a slower movement. If the magnet's motion is reversed, then the current reverses.
2. Figure 30–3b shows that as a switch closes in the circuit of a first loop, an induced current momentarily appears in the second loop. Current flow in the first loop produces a magnetic field. When the switch closes, this magnetic field changes as the current in the first loop builds up from zero to its steady value. In turn, this results in a changing magnetic flux through the second loop, and a changing flux through the second loop creates an emf and hence an induced current within it.
3. In Figure 30–3c, there is a constant current in the first (upper) loop, and therefore the magnetic field it generates is constant. But if we move the second loop up or down, the flux through that loop due to the field from the first loop changes. We find that once again an induced current flows in the second loop while it is in motion within the magnetic field of the first loop, and the size of the induced current depends on how fast we move the second loop up or down.
4. Figure 30–3d shows an experiment similar to the third, except that in this case the magnetic flux through the second loop due to the magnetic field of the first loop changes because we change the orientation of the two loops. Again a current flows in the second loop.
5. A last experiment is revealing. We can take the lower coil in Fig. 30–3c and simply squeeze it, thereby changing its area. The flux through it accordingly changes, and once again we observe an induced current, and the size of the current depends on how fast we change the area of the second loop.

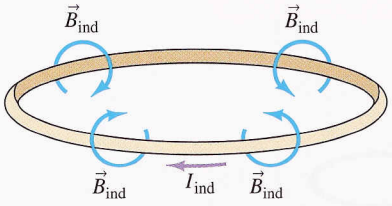
▼ **FIGURE 30–3** Ways to make a magnetic flux through a loop change and thereby induce a current I_{ind}. (a) The distance between a wire loop and a bar magnet changes, and a current is induced in the loop. (b) A switch is closed to start a current in one loop, and a current is induced in a second, nearby loop. (c) The distance between a current-carrying loop and a second loop changes, and a current is induced in the second loop. (d) A second loop rotates in the presence of the current-carrying loop, and a current is induced in the second loop.

▶ **FIGURE 30–4** When the direction around a loop is given, the orientation of the surface that spans the loop is specified by a right-hand rule. Here we show a single vector $\vec{A}$ for the entire surface, which is flat. For a curved surface, the directions of infinitesimal areas $d\vec{A}$ vary from point to point.



The common feature to all these experiments is that a changing magnetic flux through a loop induces an emf around that loop—if the loop is formed by a wire, then the induced emf leads to an induced current. How fast the flux through the loop changes determines how large the emf is. Faraday's law summarizes these observations, and also the sign: The negative of the *time rate of change* of the magnetic flux through a surface, Φ_B, equals an emf around the closed loop that bounds the surface. The negative sign dictates the direction of the induced emf, as we will discuss in the next subsection. We know from Chapter 28 that an emf $\mathcal{E}$ is the line integral of an electric field. In this case we are interested in the line integral around a *closed* loop:

$$\mathcal{E} = \oint \vec{E} \cdot d\vec{s}. \tag{30–1}$$



The precise statement of **Faraday's law of induction** is

$$\mathcal{E} = \oint \vec{E} \cdot d\vec{s} = -\frac{d\Phi_B}{dt}. \tag{30–2}$$

FARADAY'S LAW OF MAGNETIC INDUCTION

(a)

(b)

▲ **FIGURE 30–5** (a) A magnetic flux change induces a current. (b) The induced current produces its own magnetic field; that field tends to oppose the flux change that induced the current.

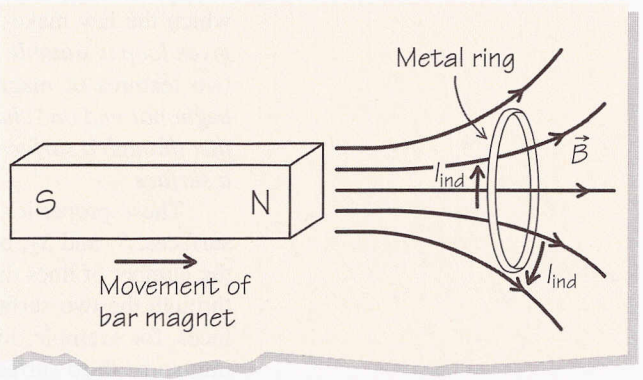
Here Φ_B is the magnetic flux through the surface S that spans the loop, a quantity defined in Chapter 29:

$$\Phi_B = \int_{\text{surface } S} \vec{B} \cdot d\vec{A}. \tag{29–11}$$

The loop around which the emf is defined, Eq. (30–1), must bound the surface through which the flux is calculated, and the orientation of that surface is determined by the direction of the loop integral and a right-hand rule. This right-hand rule works as follows: If the fingers of the right hand curl in the direction of the loop, the thumb indicates the direction of the surface for calculating the flux—the direction the surface element $d\vec{A}$ takes (Fig. 30–4).

Lenz's Law and the Direction of Induced Current

The minus sign in Eq. (30–2) is critical and deserves a special discussion. Let's look at a loop of wire and suppose the magnetic flux *increases* through it in the sense shown in Fig. 30–5a. (This could happen in a number of ways; for example, we could thrust the N pole of a magnet toward the loop.) When we say that the flux is increasing, we mean that its time derivative is positive, so the right-hand side of Faraday's law [Eq. (30–2)] is negative. The induced emf is therefore *negative*. When we apply the right-hand rule to Fig. 30–5a, we see that the positive direction is counterclockwise; thus the negative sign means that the induced emf is *clockwise* in that figure. The resulting induced current will similarly be clockwise.



We know that currents produce magnetic fields, and the induced current is no exception. By using the right-hand rule, we can see that the magnetic field produced by the induced current is directed down through the loop (Fig. 30–5b). The direction of this field is such that it tends to *decrease* the magnetic flux through the loop. Because the original flux change that induced the current in the first place was positive, we conclude that the induced current has acted to oppose the flux change that caused it. Further analysis shows that the induced current always opposes the *change* in flux and therefore tends to keep the flux from changing. This way of thinking about Faraday's law is due to Heinrich Emil Lenz, and it is called **Lenz's law**:

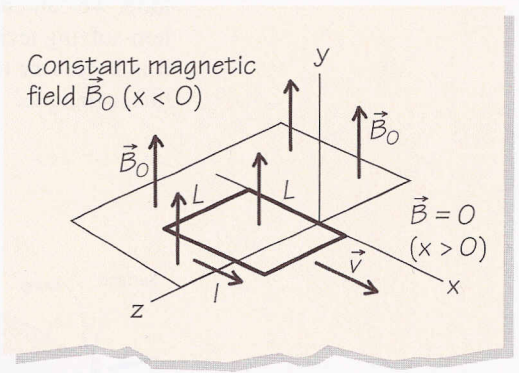
> **Induced currents produce magnetic fields that tend to oppose the flux changes that induce those currents.**

Lenz's law is useful in determining the *direction* of an induced current.

CONCEPTUAL EXAMPLE 30–1 The north pole of a bar magnet is thrust toward the face of a fixed metal ring (Fig. 30–6). Use Lenz's law to determine the direction of any induced current in the ring.

Answer As the north pole of the magnet approaches the ring, the magnetic field lines near the ring become denser. Hence the magnetic flux through the surface of the ring, which is perpendicular to the magnet, *increases*. Lenz's law states that the induced current will *oppose* the change of magnetic flux that passes through the ring. The induced current must therefore produce a field that serves to decrease the magnetic flux (and magnetic field) through the ring. This induced magnetic field will be directed to the left. If we use the right-hand rule, the current in the ring that will produce this field is oriented clockwise as seen by an observer looking toward the north pole of the magnet.

▲ **FIGURE 30–6** When the bar magnet approaches the ring, a current is induced in the ring.



EXAMPLE 30–2 A constant magnetic field has only a y-component B_0 in a large region for which $x < 0$, and is zero for $x > 0$ (Fig. 30–7). A square metal loop with sides of length L is oriented in the xz-plane and pulled through the field in the $+x$-direction with steady velocity $\vec{v} = v\hat{i}$. The total resistance of the loop is R. Find the magnitude and direction of any induced current in the wire as a function of time, assuming that the front edge of the square crosses the line $x = 0$ at $t = 0$. Evaluate your result for $B_0 = 1.0$ T, $L = 0.10$ m, $R = 0.065\ \Omega$, and $v = 10.0$ cm/s.

Strategy Starting at $t = 0$, the wire loop passes out of the region where there is magnetic field ($x < 0$). As it does so, the magnetic flux upward through the loop decreases, and an emf is induced in the loop. We find the magnetic flux through the planar surface of the loop and in particular its time dependence. We can then use Faraday's law, Eq. (30–2), to determine the emf and subsequently the induced current in the wire loop. The loop integral as seen from above is arbitrarily chosen to be counterclockwise. With this orientation for the surface element, the infinitesimal surface elements $d\vec{A}$ that make up the integral are oriented upward, in the same direction as $\vec{B}$, and $\vec{B} \cdot d\vec{A} = B_0\, dA$. The constant B_0 can then be removed from the integral.

Working It Out For $t < 0$, the flux through the loop has a constant value,

$$\Phi_B = \int_{\text{surface } S} \vec{B} \cdot d\vec{A} = B_0 \int_{\text{surface } S} dA = B_0 L^2,$$

so there is no induced emf and no current.

▲ **FIGURE 30–7**

In the time period $t = 0$ to $t = L/v$, the loop is in the process of leaving the region of the magnetic field, and the magnetic flux through it changes. The portion of the loop in the field runs from $x = 0$ to the back of the loop, which is at $x = -(L - vt)$. In other words, only an area $(L - vt)L$ remains in the field, and

$$\Phi_B = B_0(L - vt)L.$$

This flux is not constant, and for this time period

$$\frac{d\Phi_B}{dt} = -B_0 vL.$$

(continues on next page)

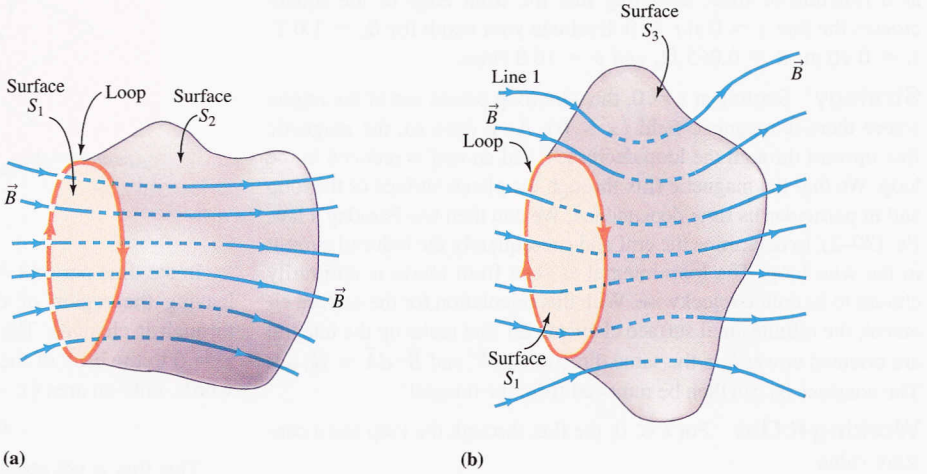
The emf counterclockwise around the loop equals the *negative* of this value: $\mathcal{E} = +B_0vL$. A counterclockwise current is induced in the loop during the time interval $t = 0$ to $t = L/v$:

$$I = \frac{\mathcal{E}}{R} = \frac{B_0vL}{R}. \tag{30–3}$$

The numerical value of this induced current is

$$I = \frac{(1.0\text{ T})(10.0 \times 10^{-2}\text{ m/s})(0.10\text{ m})}{0.065\ \Omega} = 0.15\text{ A}.$$

Finally, for $t > L/v$, the loop has moved out of the region of constant field, so the flux takes on a constant value (zero), and there is neither an induced emf nor a current.



What Do You Think? What happens if the loop is pushed back into the region of magnetic field? (a) nothing, (b) the induced current is in the same direction as before, (c) the induced current is in the opposite direction as before. *Answers to* ***What Do You Think?*** *questions are given in the back of the book.*

What Sets the Surface Used in Faraday's Law?

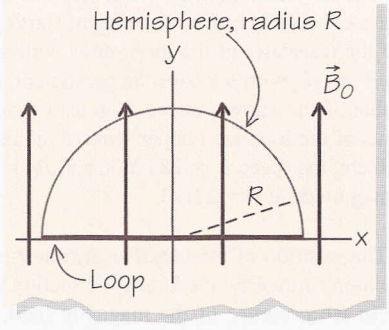
In our statement of Faraday's law, we did not specify the surface formed by the loop to which the law makes reference. We shall now show that *any surface bounded by the given loop is suitable because the flux is the same through any such surface*. Let's recall two features of magnetic flux. *All magnetic field lines are continuous; they neither begin nor end on "charges"*; indeed, there are no magnetic charges. Also, *the magnetic flux through a surface is proportional to the net number of field lines that pass through a surface*.

These properties of magnetic field lines have some consequences: Consider two surfaces, S_1 and S_2, bounded by a loop (Fig. 30–8a). Because the lines are continuous, the number of lines that pass through the two surfaces must be the same; hence the flux through the two surfaces must be the same. Some lines may not pass through all surfaces, for example, line 1 in Fig. 30–8b does not pass through S_1, but if a line passes into some third surface S_3 and not into surface S_1, then the line must also pass out of surface S_3 and therefore does not contribute to the net flux through S_3.

From this analysis we can conclude that *the magnetic flux through one surface bounded by a closed loop is the same as the magnetic flux through any other surface bounded by the same loop. Both surfaces must be oriented by the right-hand rule*. This is a very helpful result because it shows that, within the constraint of a given bounding loop, we can choose any surface we like to calculate the magnetic flux. A good problem-solving technique is to find a surface over which the flux is easily calculated when it is necessary to compute the flux, as it is in Faraday's law. Example 30–3 illustrates this technique.

▲ **FIGURE 30–8** (a) The same net number of magnetic field lines pass through any two surfaces S_1 and S_2 bounded by a closed loop. (b) Surfaces S_1 and S_3 are both bounded by a loop. If magnetic field line 1 passes through surface S_3 but not through surface S_1, it must pass through surface S_3 again and hence does not contribute to the net magnetic flux through surface S_3.

EXAMPLE 30–3 Suppose that a certain region has a constant magnetic field of magnitude B_0. Find the magnetic flux upward through a hemisphere of radius R whose base is perpendicular to the field.



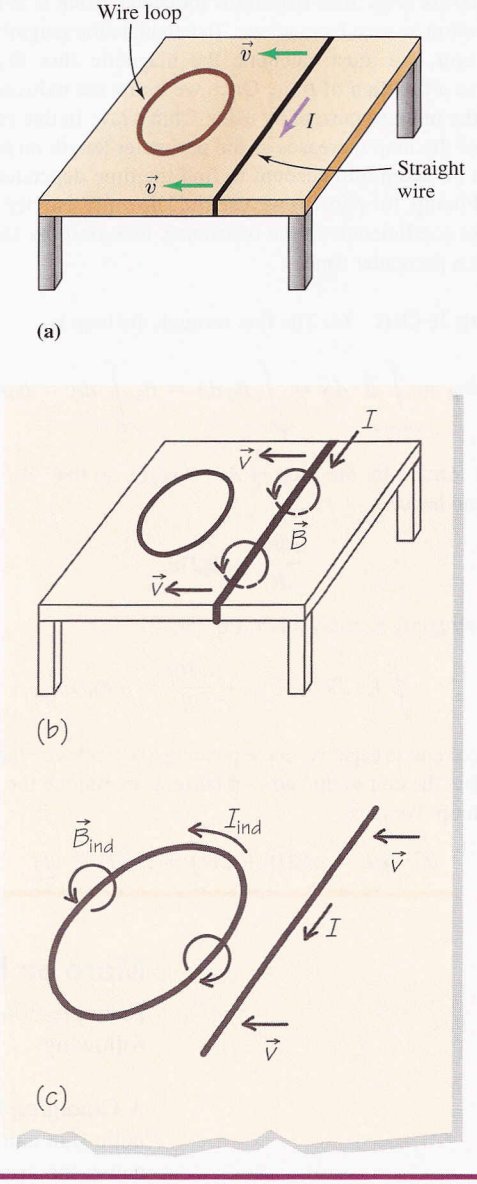
Setting It Up In Fig. 30–9 we sketch the situation, including making a choice of axes: We choose the field in the y-direction, $\vec{B} = B_0\hat{j}$, so that the base of the hemisphere forms a circle on the xz-plane.

Strategy We can find the flux through the hemisphere by finding the flux through any other surface bounded by the hemisphere's bounding perimeter, namely the circle of radius R in the xz-plane. The simplest surface that spans this perimeter is the planar disk in the xz-plane. For the disk, $\vec{B}$ is parallel to $d\vec{A}$.

Working It Out Mathematically, the equality of the flux through the hemisphere and through the planar disk can be written as

$$\Phi_{B\text{ hemisphere}} = \int_{\text{planar disk}} \vec{B}\cdot d\vec{A} = B_0 \int_{\text{planar disk}} dA = B_0\pi R^2.$$

Although the direct calculation of the flux through the hemisphere would be complicated, the calculation becomes trivial when the flat surface is used.



▲ **FIGURE 30–9**

CONCEPTUAL EXAMPLE 30–4 A loop of wire and a straight wire each lie on a tabletop (Fig. 30–10a). The straight wire, which is connected to a battery and carries a current in the direction shown, is moved toward the loop. Is a current induced in the loop? If so, what is its direction?

Answer First, does the movement of the straight wire lead to an induced emf in the loop? In Fig. 30–10b, we have drawn some of the magnetic field lines for the constant current in the straight wire. This field is stronger near the wire, so as the wire moves toward the loop, there is an increase in the flux down through the loop into the table. Because there is a changing flux through the loop, there is indeed an induced emf around it. What is its direction (which will also be the direction of the induced current)? We can use Lenz's law to answer a question about the sign of the induced emf. If we look down on the table, the current is induced in the counterclockwise direction, and the magnetic field associated with this current will come up through the center of the loop, creating a flux that opposes the flux change from the movement of the straight wire (Fig. 30–10c). Thus the direction of the induced current is counterclockwise.

What Do You Think? Will there still be a current induced in the loop if instead of the straight wire with the battery moving toward the loop, the loop moved toward the straight wire?

▶ **FIGURE 30–10** (a), (b) The field associated with the current in the wire. (c) The current induced in the loop produces a magnetic field of its own.

EXAMPLE 30–5 A closed loop is constructed of a fixed wire shaped as a square-ended U (Fig. 30–11a) and a conducting crossbar that is free to move in the x-direction and makes electrical contact with the U-shaped section. The loop lies in the xz-plane with the square base of the U-shaped section at $x = 0$. A constant magnetic field is oriented in the y-direction, $\vec{B} = B_0\vec{j}$. (a) The movable crossbar is pulled at a constant speed v to the right, starting from $x = 0$ when $t = 0$. If the resistance of the loop varies with the total length L according to $R = \alpha L$, with α a constant coefficient, what is the direction and value of the current in the loop as a function of time? (b) All segments of the loop are copper wire of radius 0.25 cm, the length $D = 7.0$ cm, the speed $v = 28$ cm/s, and $B_0 = 0.18$ T. What is the current magnitude at $t = 2.0$ s?

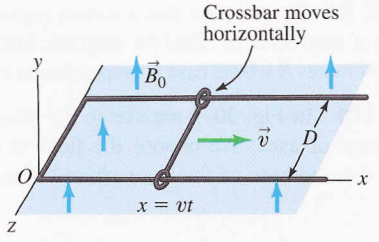
Strategy The position of the crossbar at time t is $x = vt$, and the area of the loop formed by the U-shaped section and the crossbar increases. In the presence of the magnetic field, and with the area of the loop oriented upward, parallel to the magnetic field, that means that the flux through the loop also increases, and Faraday's law of induction applies. Lenz's law states that the magnetic field due to the induced current must be directed down in order to decrease the flux (Fig. 30–11b), so the induced current is in the clockwise direction as seen from above. To calculate the magnitude of the induced emf, we must calculate the magnetic flux Φ_B through the loop as a function of time. Once we know the induced emf, we can find the induced current by using Ohm's law. In this case the resistance of the loop increases as the perimeter length increases, and that must be taken into account to find the time dependence of the current. Finally, for part (b) we use the known resistivity of copper to find the coefficient α in the resistance, then find the value of the current at a particular time.

Working It Out (a) The flux through the loop is

$$\Phi_B = \int_{\text{surface}} \vec{B}\cdot d\vec{A} = \int_{\text{surface}} B_0\, dA = B_0 \int_{\text{surface}} dA = B_0 A.$$

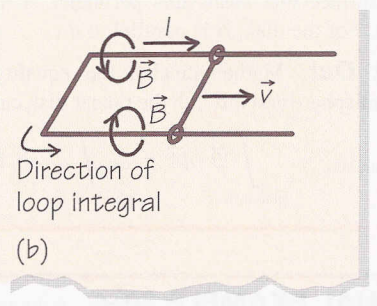
The area formed by the loop is $A = (vt)D$, so that $\Phi_B = B_0 A = B_0 Dvt$, and hence

$$\frac{d\Phi_B}{dt} = B_0 Dv.$$



We now apply Faraday's law, Eq. (30–2):

$$\oint \vec{E}\cdot d\vec{s} = \mathcal{E} = -\frac{d\Phi_B}{dt} = -B_0 Dv.$$



The induced emf is negative, corresponding to a clockwise induced emf.

To relate the emf to the induced current, we require the resistance R of the loop. We have

$$R = \alpha L = \alpha(2D + 2vt) = 2\alpha(D + vt).$$

(a)

(b)

▲ **FIGURE 30–11** (a), (b) Lenz's law shows that the current induced in the circuit that contains the moving crossbar will be in the direction shown.

The induced current is therefore

$$I_{\text{ind}} = \frac{\mathcal{E}}{R} = -\frac{B_0 Dv}{2\alpha(D + vt)}.$$

Try checking the dimensions of this current.

(b) To find α, note that the resistivity of copper is $\rho = 1.72 \times 10^{-8}\ \Omega\cdot\text{m}$ and that, according to Eq. (27–14), the resistance of a wire of length L and cross-section A is $R = \rho(L/A)$. By comparing the form $R = \alpha L$, we see that

$$\alpha = \frac{\rho}{A} = \frac{1.72 \times 10^{-8}\ \Omega\cdot\text{m}}{\pi(0.25 \times 10^{-2}\ \text{m})^2} = 8.8 \times 10^{-4}\ \Omega/\text{m}.$$

At this point, all quantities in the equation for the current are known and, at $t = 2$ s, the magnitude of the induced current is

$$\begin{aligned} I_{\text{ind}} &= \frac{B_0 Dv}{2\alpha(D + vt)} \\ &= \frac{(0.18\ \text{T})(0.070\ \text{m})(0.28\ \text{m/s})}{2(8.8 \times 10^{-4}\ \Omega/\text{m})[(0.070\ \text{m}) + (0.28\ \text{m/s})(2.0\ \text{s})]} \\ &= 3.2\ \text{A}. \end{aligned}$$

What Do You Think? Copper has a low resistivity. Nichrome has a much higher one. If nichrome wire is used throughout, the induced current will (a) increase, (b) decrease, (c) stay the same, (d) go to zero.

More on Magnetic Induction

Example 30–5 illustrates some important features of Faraday's law, among them the following:

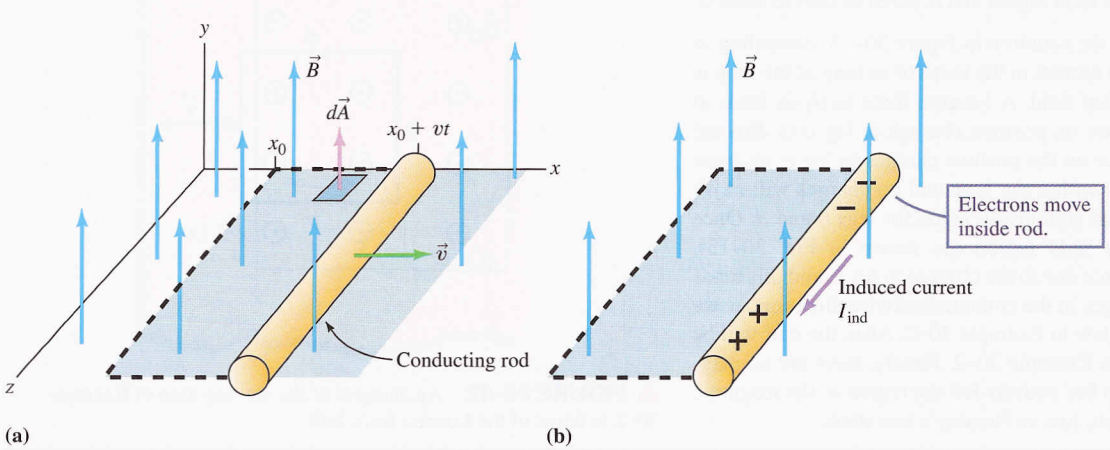
A Changing Flux Does Not Necessarily Mean a Changing Magnetic Field: The magnetic flux can change not only because the magnetic field changes with time but also because the area of the loop through which the flux is calculated may change with time.

In Example 30–5, the magnetic field is constant in some region, yet there is nevertheless an induced emf. In the next section we see some immediate applications of this fact.

Induced Electric Fields Are Nonconservative: We note that induced fields differ fundamentally from the electric fields we have previously encountered. In our earlier work, electric fields were always associated with *conservative* forces. The work done by those fields in moving a charge around a closed loop is always zero:

$$\text{conservative: } \mathcal{E} = \oint \vec{E} \cdot d\vec{s} = 0,$$

and this fact is what allows us to describe such electric forces with a potential. This is precisely what is *not* true for the fields that result from Faraday's law; the emf about a closed loop is specified by the changing flux:



$$\text{nonconservative: } \mathcal{E} = \oint \vec{E} \cdot d\vec{s} = -\frac{d\Phi_B}{dt}.$$

The induced electric field cannot be described by a potential that is a function of space.

30–2 Motional EMF

We have now developed the idea that an emf can be induced in a conductor that moves in a magnetic field, as in Example 30–5. We call this emf a **motional emf**. Figure 30–12a illustrates this in the case of a conducting rod (length L) moving with constant speed v in a constant magnetic field of magnitude B; in Fig. 30–12a, the axes are chosen so that the position of the rod along the x-axis is $x = vt$. The rod is not part of a circuit, and there is no current flowing through it, but there is an effect on the charge carriers within the rod: There is an accumulation of positive charges at the near end of the rod and negative charges at the far end. The charge accumulation leads to an emf that cancels the motional emf and allows an equilibrium to be established. This effect is described alternatively by Faraday's law or by the Lorentz force law, and here we want to see how that occurs.

Let us first look at Faraday's law applied to this situation. The rod itself does not form a loop, so you may wonder how Faraday's law applies here. But Faraday's law applies to *any* loop; we can think of the rod as forming one leg of a loop that is part real conductor and part imaginary, as indicated by the rod and the fixed dashed lines that complete the loop in Fig. 30–12a. The loop formed by the imaginary line and the rod is situated in the xz-plane with its area elements $d\vec{A}$ oriented in the $+y$-direction. Its area

▲ **FIGURE 30–12** (a) A conducting rod of length L moves with constant speed v in the $+x$-direction through a constant magnetic field directed in the y-direction. The rod is oriented in the z-direction. The dashed lines represent the imaginary closure of a loop, to which we apply Faraday's law. (b) The induced emf in the rod can be computed by Faraday's law.

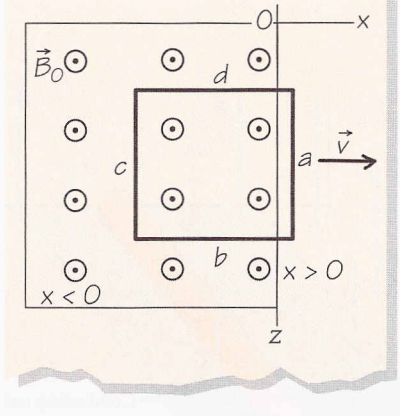
is $L(vt - x_0)$. The flux through the closed loop is therefore

$$\Phi_B = BL(vt - x_0),$$

and the rate of change of this flux is

$$\frac{d\Phi_B}{dt} = BLv. \tag{30–4}$$

The emf taken in the counterclockwise direction looking down—the direction that must be taken if we orient the loop area in the $+y$-direction—is then



$$\mathscr{E} = -BLv. \tag{30–5}$$

$\mathscr{E}$ is the *motional emf*. If the dashed line were conducting wire, this emf would drive a current clockwise (as seen from above) around the circuit. Because there is no actual closed circuit, there is movement of charge, and therefore current flow, only until sufficient positive charges accumulate toward the near end of the rod to set up an emf that cancels the motional emf (Fig. 30–12b). At that point, charge carriers no longer move within the rod. Note that the charges move in such a way that the potential will be higher at the near end of the bar.

The effect of the motional emf—the fact that positive charge moves to accumulate at the near end—is simple to understand in terms of the Lorentz force law. Each charge carrier in the rod is moving in a magnetic field and therefore feels a force that equals $q\vec{v} \times \vec{B}$. This force acts in the $+z$-direction for positive charges, just as the motional emf argument in the paragraph above indicates. The force per unit charge, or the electric field that produces this force, has magnitude vB. Because this electric field is constant along the entire length of the rod, the potential difference from one end of the rod to the other is $\Delta V = EL = BvL$. This potential is just the emf that cancels the motional emf, Eq. (30–5). *We conclude that we can view the effect of motional emf as due either to the Lorentz force law or to Faraday's law of induction.*

CONCEPTUAL EXAMPLE 30–6 In Example 30–2, we looked at how Faraday's law describes induced currents in a square loop of wire as it is pulled through a region of constant magnetic field into a region of no magnetic field. Will a Lorentz force analysis lead to the same results? Assume at $t = 0$ that the loop of wire is entirely within the magnetic field region and is about to start to leave it.

Answer We redraw the situation in Figure 30–13. According to Faraday's law, there is no current in the loop for as long as the loop is entirely within the constant field. A Lorentz force analysis leads to the same result: The force on positive charges in leg a is directed downward, as is the force on the positive charges in leg c, so these forces oppose each other within the loop and no charges will move around the loop. A similar conclusion holds for legs b and d. Once leg a passes out of the field region (as shown in Fig. 30–13), however, there is a net force due to the charges in leg c, and this tends to push the positive charges in the counterclockwise direction, as we deduced from Faraday's law in Example 30–2. Also, the emf will be B_0vL, just as we found in Example 30–2. Finally, there are no magnetic forces once the loop has entirely left the region of the magnetic field, and hence no current, just as Faraday's law states.

▲ **FIGURE 30–13** An analysis of the moving loop of Example 30–2 in terms of the Lorentz force law.

EXAMPLE 30–7 A rod of length L rotates counterclockwise with constant angular velocity ω about one end in a constant magnetic field of magnitude B_0 oriented perpendicular to the rod's plane of rotation. Find the motional emf in the rod by applying Faraday's law of induction.

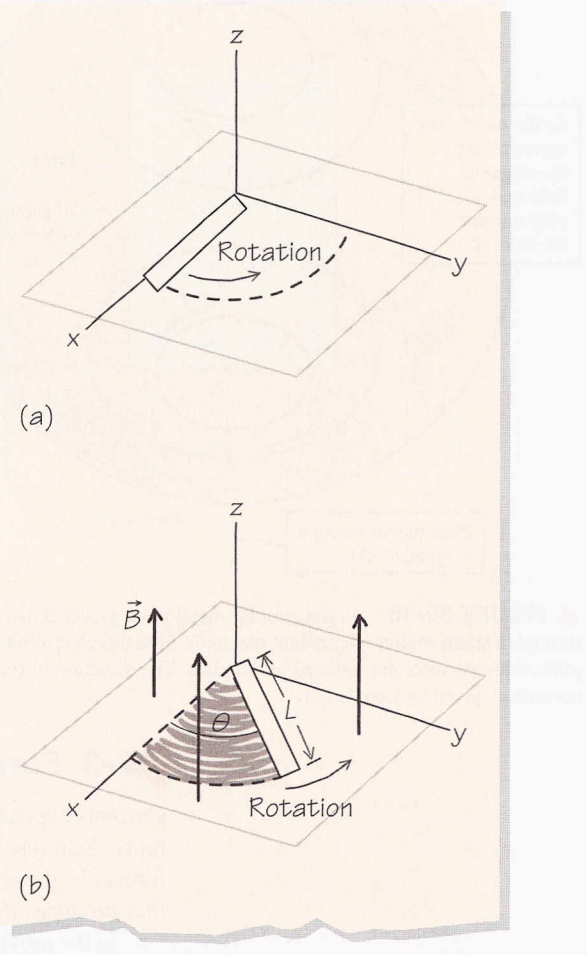
Setting It Up We illustrate this situation in Fig. 30–14a, which also includes specification of a coordinate system.

Strategy This is a case similar to the one described at the start of this section. The rod itself does not make a loop, but we construct one through the dashed line shown in Fig. 30–14b. We can then apply Faraday's law of induction by calculating the time dependence of the flux through the loop. It is simplest to orient the area elements of the loop parallel to the magnetic field. Then the flux through the loop is just the constant field times the area of the loop. We shall first find the area of our imaginary loop. This will allow us to find the magnetic flux and subsequently to find its change with time that will give us the emf.

Working It Out With the angle $\theta = \omega t$ specified in the figure, the loop area is

$$\frac{1}{2}\theta L^2 = \frac{1}{2}\omega t L^2.$$

Since the area is oriented upward, the loop integral is followed counterclockwise as seen from above. The magnetic flux through the loop is B_0 times the area; the rate of change of the flux is



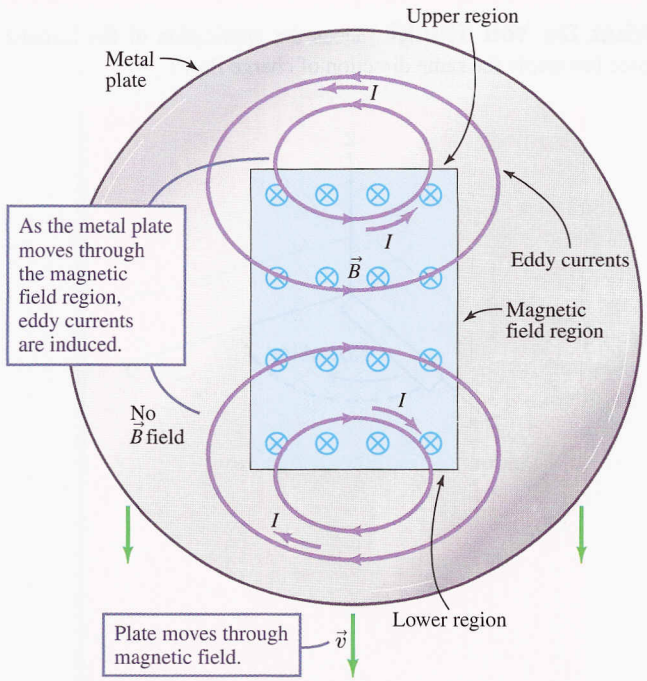
$$\frac{d\Phi_B}{dt} = \frac{d}{dt}\left(\frac{1}{2}B_0\omega t L^2\right) = \frac{1}{2}B_0\omega L^2.$$

The motional emf is then

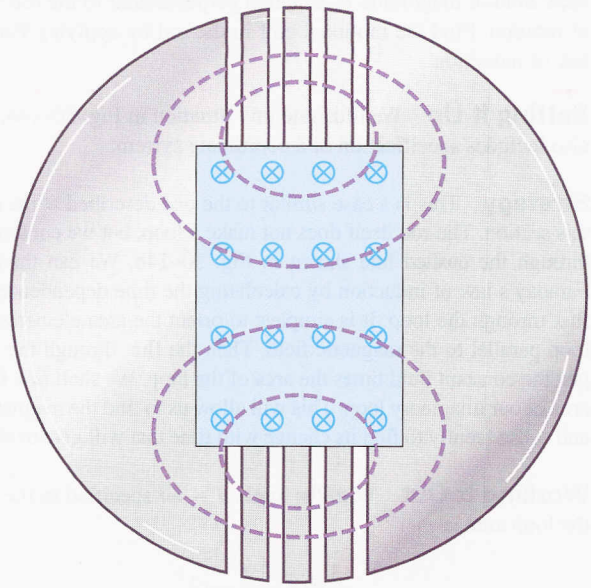
$$\mathscr{E} = -\frac{1}{2}B_0\omega L^2.$$

The sign corresponds to a clockwise emf—that is, the emf drives positive charges radially out from the origin.

What Do You Think? Does the application of the Lorentz force law imply the same direction of charge flow?



▲ **FIGURE 30–14** (b) The dashed lines represent the imaginary closure of a loop, to which we apply Faraday's law.



Eddy Currents

We have talked about induced emfs in the motion of wires and rods. But in many applications large pieces of metal move in a magnetic field, and there the effects of induced emfs can be significant, either desirable or undesirable. In large pieces the induced currents are spread through the material, and we refer to them as **eddy currents**. Figure 30–15 shows the eddy currents set up in a flat, vertically oriented plate moving downward through a region with a horizontal magnetic field.

Eddy currents are dissipated in Joule heating through the resistivity of the metal plate. The eddy currents or the related Joule heating can be a significant advantage in certain applications; eddy currents in a piece of metal that moves through a magnetic field act as brakes. Brakes of this type have practical applications that range from large electric motors to sensitive measuring devices within which oscillations or other motion would be a disadvantage. When eddy currents are undesirable, they can be reduced by eliminating paths for the current flow. This is done either by cutting slots in the metal plate (Fig. 30–16) or by laminating the metal with an insulator.

▲ **FIGURE 30–15** As the circular metal plate moves down through a small region of constant magnetic field directed into the plate, eddy currents are induced in the plate. The direction of these currents is given by Lenz's law.

▲ **FIGURE 30–16** To inhibit the development of eddy currents in the moving metal plate, slots can be cut in the plate.

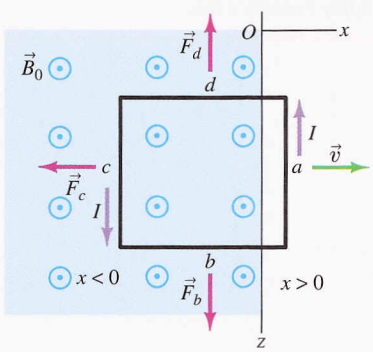
30–3 Forces and Energy in Motional EMF

Currents experience forces in magnetic fields, and this is also the case for any induced currents. As a result, wires or other materials in which currents are induced will experience forces. In general, *the magnetic force on an induced current always inhibits the motion that produces the motional emf.* As we'll now argue, this is a consequence of Lenz's law.

In the moving loop of Example 30–2 (Fig. 30–17), an induced current I appears as the loop leaves the region of magnetic field. The force on the wire is given by Eq. (28–16),

$$\vec{F}_B = I \int d\vec{\ell} \times \vec{B}, \tag{30–6}$$

where $d\vec{\ell}$ describes an element of the wire and $\vec{B}$ is the magnetic field at that wire element. Let's once again draw the loop—this time including the forces on each leg (Fig. 30–17). There is no force on those legs or portions of legs that are out of the magnetic field. Using the right-hand rule, the force on the portion of leg b that is located in the field is directed down, and it is canceled by the force on the portion of leg d located in the field. The only contribution to the net force comes from leg c. Here, application of Eq. (30–6) gives a force



$$F_c = ILB_0 \text{ to the left.} \tag{30–7}$$

Recall from Example 30–2, Eq. (30–3), that the magnitude of the current is $I = B_0 vL/R$, where R is the total resistance of the loop and v is the speed with which the loop moves. The force on the loop is thus

$$F_c = \frac{vL^2B_0^2}{R}. \tag{30–8}$$

This force acts to slow down the loop—it is the typical drag force of a viscous medium.

Because the magnetic force tends to slow the motion, the loop can move at constant velocity only if there is an external force that cancels the magnetic drag. We can imagine that we pull the loop in the direction of the velocity in Fig. 30–17. In this case, we are the external agent supplying a force $\vec{F}$ to the right. The magnitude of this force is F_c, Eq. (30–8).

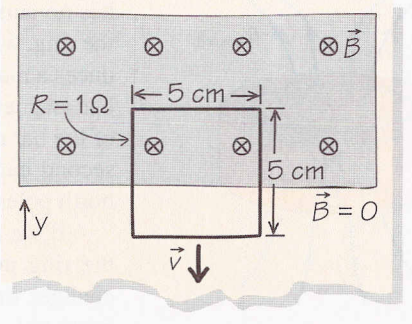
▲ **FIGURE 30–17** The magnetic forces on the loop of Example 30–2 act to slow down the loop.

By applying the external force, we are doing work, or equivalently we are supplying energy at a certain rate. In other words, there is an expenditure of power given by

$$P = \vec{F} \cdot \vec{v} = F_c v = \frac{v^2 L^2 B_0^2}{R}. \qquad (30\text{–}9)$$

CONCEPTUAL EXAMPLE 30–8 The expenditure of power by an external force in a system whose kinetic energy does not change means that there is an energy dissipation in the system. Where is the energy lost in the moving loop of Example 30–2?

Answer There is one place where we lose energy in electrical phenomena, and that is in current flow through a resistance: Joule heating. And we do indeed generate a current in this situation, the induced current which is running through a system with a resistance—the wire. Therefore we have a mechanism to account for the power supplied by the external force. An analytic calculation of the rate of Joule heating should match Eq. (30–9), and we show this below.



Let us check that the power lost in the resistive heating matches the rate at which energy must be supplied to the loop to maintain its motion at a constant speed. The power loss (or energy loss per unit time) in the resistance of the wire is

$$P = I^2 R = \left(\frac{B_0 v L}{R}\right)^2 R = \frac{v^2 L^2 B_0^2}{R}. \qquad (30\text{–}10)$$

Equations (30–9) and (30–10) are the same. *The power loss due to the current flow through the resistor is matched by the power required to keep the loop moving.* The principle of conservation of energy suggests that this result was a foregone conclusion.

The magnetic force on the loop [Eq. (30–8)] is proportional to the speed at which the loop moves and hence is a typical viscous drag (see Chapter 16). This is generally true for the forces on induced currents due to motional emf because their origin is the Lorentz force, which is also proportional to the speed.

EXAMPLE 30–9 A square loop of wire has sides of length 5.0 cm. This loop falls at speed v under the influence of gravity through a region with a constant magnetic field of magnitude 15 T (only magnets built for scientific purposes can attain such a high field), into a region with no magnetic field (Fig. 30–18). The loop is constrained to remain vertically oriented, and the field is horizontal—perpendicular to the loop and into the page. The total resistance of the loop is 1.0 Ω, and its mass is 150 g. (a) Find the terminal speed of the loop as it passes the boundary between the two fields. (b) Calculate the total energy lost to Joule heating in the loop during this period. As an approximation, assume that the loop moves at its terminal speed when it enters the magnetic field region and that this speed remains constant during the loop's passage.

▲ FIGURE 30–18

Strategy (a) There will be a drag force for the situation shown in Fig. 30–18 only when the loop of wire is either partway into or partway out of the region with magnetic field. If this is the case, we can use Eq. (30–8) for the magnetic force on the loop, which will be upward. The magnetic force, $F = vL^2B_0^2/R$, will be equal in magnitude to the force of gravity mg when the loop acceleration is zero and the loop reaches its terminal speed v_t.

Working It Out We set $v_t L^2 B_0^2/R = mg$ and solve to obtain the terminal speed v_t,

$$v_t = \frac{mgR}{L^2 B_0^2}. \qquad (30\text{–}11)$$

Numerically,

$$v_t = \frac{(0.15\ \text{kg})(9.8\ \text{m/s}^2)(1.0\ \Omega)}{(5.0 \times 10^{-2}\ \text{m})^2 (15\ \text{T})^2} = 2.6\ \text{m/s}.$$

Strategy (b) As long as the loop moves at its terminal speed, the total energy lost to Joule heating will be a constant given by the product of Joule power and the time the loop spends in the transition region. Given that the loop is moving at v_t, the time spent in the transition region is $t = L/v_t$, where $L = 0.050$ m is the length of a side.

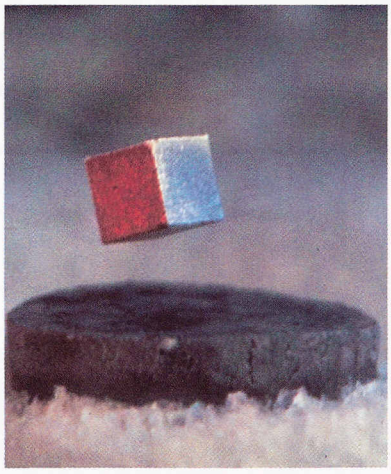
Working It Out The Joule power is, according to Eq. (30–10),

$$P = I^2 R = \frac{v_t^2 L^2 B_0^2}{R}.$$

Thus the energy loss is

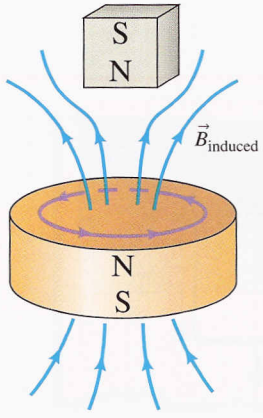
$$\Delta E = Pt = \frac{v_t^2 L^2 B_0^2}{R} \frac{L}{v_t} = \frac{v_t L^3 B_0^2}{R}.$$

(continues on next page)



Substituting for v_t from Eq. (30–11), we find that

$$\Delta E = \frac{mgR}{L^2B_0^2}\frac{L^3B_0^2}{R} = mgL.$$



This is just the change in the loop's gravitational potential energy. Numerically

$$\Delta E = (0.15\text{ kg})(9.8\text{ m/s}^2)(0.050\text{ m}) = 0.074\text{ J}.$$

What Do You Think? The calculated energy change is just the change in the gravitational potential energy of the loop as it falls through the transition region. Why?

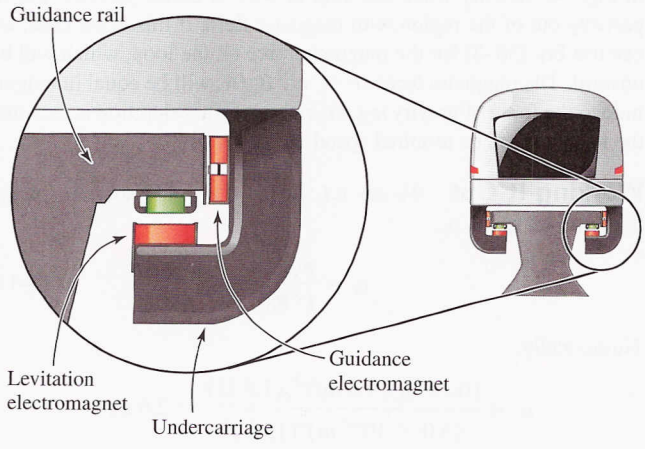
(a)

(b)

▲ **FIGURE 30–19** (a) A levitated magnet. A bar magnet moves toward the superconducting material, inducing persistent currents in the superconductor. (b) The magnetic forces between the superconductor and the magnet are repulsive and sufficiently strong to support the magnet's weight.

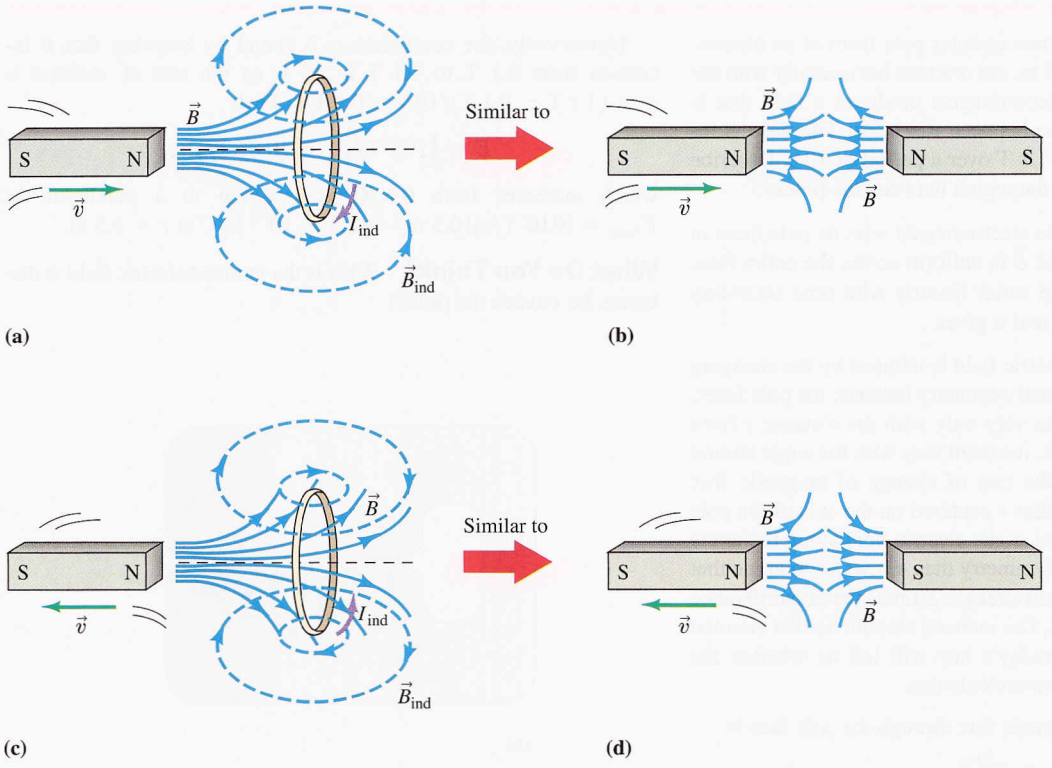
THINK ABOUT THIS. . .

HOW DOES MAGNETIC LEVITATION WORK FOR SUPERCONDUCTORS?



As we have remarked above, magnetic drag can act to slow the fall of a metal plate in a magnetic field. We can carry this to an interesting extreme by supposing that the metal plate is a superconductor, a material with no resistance and with the property that the magnetic field does not penetrate its interior. (We'll discuss superconductors and their magnetic properties further in Chapter 31.) If we drop such a piece of material into the field region, the piece is more than slowed down by its entry into the field; it is repelled and bounces back up. This bounce is perfectly elastic because there is no Joule energy loss in a material with no resistance. In this extreme thinking about drag, we are led to a system without energy losses; we have an ideal form of magnetic levitation (Fig. 30–19).

A related application is in magnetically levitated trains, with the levitation used both to hold the train off the surface and guide it along its track (Fig. 30–20). This is useful because there is no rolling friction in the operation of such a train.



Forces and Lenz's Law

Lenz's law gives us a second way to think about the forces on induced currents. The magnetic field of a current loop or solenoid is the same as that of a bar magnet. We have already seen that both magnets and current loops produce magnetic dipole fields. Suppose that the north pole of a bar magnet moves toward a conducting ring that initially has no current. The magnetic flux through the ring increases, and an emf is induced in the ring, which causes a current to flow (Fig. 30–21a). The induced current, in turn, produces a magnetic field whose flux tends to cancel the increase of flux due to the moving bar magnet, because the direction of this induced magnetic field is opposed to the field of the bar magnet. We can think of the induced magnetic field as the magnetic field of a second bar magnet, with a field as shown in Fig. 30–21b. The situation is one of two north poles meeting, and two north poles repel each other.

If we now pull the original bar magnet away from the ring, the induced current in the ring points in the opposite direction (Fig. 30–21c). The induced magnetic field changes direction, and the ring's magnetic field is like that of a bar magnet, with its south pole adjacent to the north pole of the original bar magnet (Fig. 30–21d). We know that opposite poles attract each other, so the magnet pulls the ring along with it.

▶ **FIGURE 30–20** Magnetically levitated trains use magnetic induction to hold the train above the travel track as well as to guide it within the track. Even the propulsion system is contained in the time-dependent fields of the magnets. Friction is reduced to a minimum.

▲ **FIGURE 30–21** (a) The magnetic flux through a conducting ring is increasing because the north pole of a bar magnet moves toward it. The ring is repelled. (b) The direction of the induced current in the ring gives the ring the field of a bar magnet with its north pole to the left, and two north poles repel. (c) The bar magnet is pulled away. In this case, a current is induced in the ring in the opposite direction. (d) The magnetic field of the ring is then that of a bar magnet with its south pole to the left, and it is attracted to the receding bar magnet.

30–4 Time-Varying Magnetic Fields

The magnetic flux through a loop can change in a variety of ways.

1. The loop can move or rotate in the presence of a magnetic field that is not changing with time.
2. The source of the magnetic field can move, as when a bar magnet moves.
3. The source of the magnetic field and hence the field itself can have explicit time dependence, such as when the current through a solenoid is made to change.

We have seen that for case (1) it is possible to analyze the situation using the Lorentz force law. This is not true for cases (2) and (3). Yet Faraday's law doesn't care whether it is the loop that has moved or the field that has changed. *Motional* emf can be interpreted in terms of the Lorentz force law, but a time-varying magnetic field and the emf induced by it is a truly new aspect of Faraday's law. In this section, we look more closely at this situation.

A New Way to Make an Electric Field

When a magnetic field changes with time, then an electric field is induced in space that satisfies Eq. (30–2). *If* there is sufficient symmetry in a situation, then it is possible to calculate the induced electric field in a way similar to the way in which we used Ampère's law to determine a magnetic field. This is most easily illustrated with an example.

EXAMPLE 30–10 The two circular pole faces of an electromagnet, both of radius $R = 0.5$ m, are oriented horizontally with the north pole underneath. The electromagnet produces a field that is uniform throughout the volume between the faces. The field is increased linearly from 0.1 T to 1.1 T over a period of 10 s. Describe the electric field that results in the region between the poles.

Setting It Up We show the electromagnet with its pole faces in Fig. 30–22a. The magnetic field $\vec{B}$ is uniform across the entire face, oriented upward. Its magnitude varies linearly with time according to $B = B_0 + \alpha t$, with both B_0 and α given.

Strategy The unknown electric field is induced by the changing magnetic flux. There is cylindrical symmetry between the pole faces, so the induced electric field can vary only with the distance r from the central axis of the pole faces; it cannot vary with the angle around this axis. By Faraday's law, the rate of change of magnetic flux through a horizontal disk of radius r centered on the axis of the pole faces will determine the integral of the electric field along the circle forming the edge of the disk. Symmetry then allows us to argue that this integral is the (constant) field strength E times the circumference $2\pi r$, and that will determine E. The induced electric field is oriented along this circumference—Faraday's law will tell us whether the field lines run clockwise or counterclockwise.

Working It Out The magnetic flux through the pole face is

$$\Phi_B = \pi r^2 B.$$

Using the given time dependence of B, we have

$$\frac{d\Phi_B}{dt} = \pi r^2 \frac{dB}{dt} = \pi r^2 \frac{d}{dt}(B_0 + \alpha t) = \pi r^2 \alpha.$$

Faraday's law, Eq. (30–2), then gives

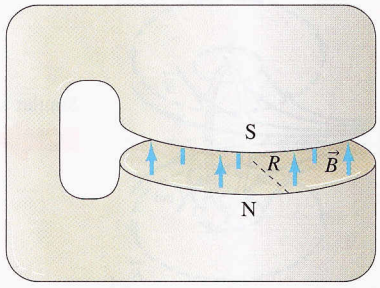
$$\oint \vec{E} \cdot d\vec{s} = -\frac{d\Phi_B}{dt} = -\pi r^2 \alpha. \qquad (30\text{–}12)$$

The direction of the loop integration is counterclockwise as we look down the north pole because the flux is oriented upward (Fig. 30–22b). With the minus sign in Eq. (30–12), the induced electric field lines run clockwise. Application of the symmetry argument gives

$$\oint \vec{E} \cdot d\vec{s} = E 2\pi r = -\pi r^2 \alpha$$

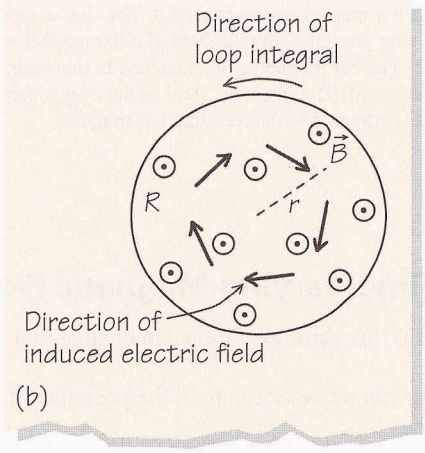
or

$$E = \frac{\pi r^2 \alpha}{2\pi r} = \frac{1}{2}\alpha r.$$



The magnitude of the induced electric field increases as we go out from the center.

Numerically, the coefficient α is found by knowing that B increases from 0.1 T to 1.1 T in 10 s, so the rate of increase is $\alpha = (1.1\text{ T} - 0.1\text{ T})/10\text{ s} = 0.1\text{ T/s}$. Then



$$E = \tfrac{1}{2}(0.1\text{ T/s})r = (0.05\text{ T/s})r,$$

which increases from 0 N/C at $r = 0$ m to a maximum of $E_{max} = (0.05\text{ T/s})(0.5\text{ m}) = 2.5 \times 10^{-2}$ N/C at $r = 0.5$ m.

What Do You Think? What is the induced electric field at distances far outside the poles?

(a)

(b)

▲ **FIGURE 30–22** (a) The current windings that produce the field are not shown. (b) A view straight down at the north pole. A changing magnetic field between the pole faces of an electromagnet induces an electric field. Symmetry allows us to specify the electric field, not just its integral around an arbitrary loop.

Is a Magnetic Field Present Where a Current Is Induced?

A changing magnetic flux induces electric fields even where the magnetic field itself is very small. This aspect of Faraday's law is not very intuitive and deserves special attention. Suppose that charged particles such as protons are moving, but they are so far away from the region of the pole faces of an electromagnet that the magnetic field in their location is very small. Would the protons accelerate when the magnetic field is changed? Is an electric field induced even in regions with no magnetic field whatsoever, as in the space outside a toroidal solenoid, or as in the situation described in Example 30–10, "What Do You Think?" Experiment confirms that the answers to our questions are affirmative. According to Faraday's law, all that counts is the change of the flux through the loop in question, regardless of the loop's location.

30–5 Generators

The generation of electric energy in our society is based largely on the Faraday induction law. The mechanical energy of the rotating blades of a steam turbine turned by steam or by rushing water is converted to the energy of moving charges—electric current—with the **alternating-current (AC) generator**.

Imagine a coil of N turns of wire that makes a circle of area A. The coil is placed in a constant magnetic field, $\vec{B}$, and rotated at angular speed ω around an axis perpendicular to the field (Fig. 30–23a). The ends of the wire that make up the coil are brought to the exterior through some sort of sliding contact with a fixed wire. As the coil rotates in the magnetic field, the magnetic flux through it changes, and an emf is induced. Figure 30–23b, which is a side view of the coil, shows that the magnetic flux through the loop is $\Phi_B = \vec{B} \cdot \vec{A} = BA \cos\theta$. If we imagine starting the rotation at $t = 0$, so that $\theta = \omega t$, the time derivative of the magnetic flux is

$$\frac{d\Phi_B}{dt} = BA\frac{d}{dt}\cos\omega t = -BA\omega \sin\omega t. \tag{30–13}$$

There are N turns of wire, and the total emf induced across the two ends of the coil is

$$\mathscr{E} = -N\frac{d\Phi_B}{dt} = NBA\omega \sin\omega t. \tag{30–14}$$

This arrangement makes up our generator, denoted in circuits by a circle enclosing a wavy line (Fig. 30–24).

If the wire of the generator coil is connected as a series element of a circuit with a resistance R, then a current is generated in the circuit:

$$I = \frac{\mathscr{E}}{R} = \frac{NAB\omega}{R}\sin\omega t. \tag{30–15}$$

This *alternating current* oscillates in sign and has a maximum magnitude of $NAB\omega/R$.

The power P delivered to this circuit is the product of the emf and the current:

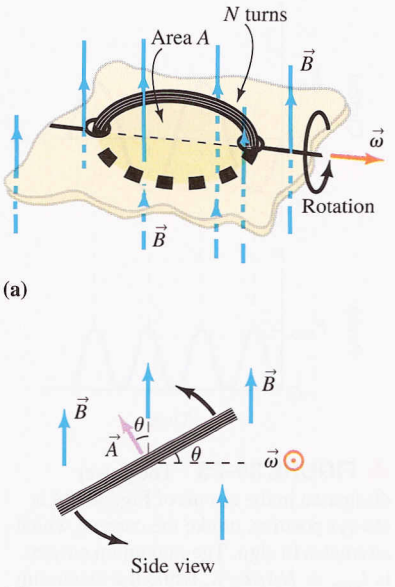
$$P = \mathscr{E}I = INAB\omega \sin\omega t. \tag{30–16}$$

The mechanical force that rotates the loop is the source of this power. We know that a loop that carries a current forms a magnetic dipole; we also know that a magnetic dipole experiences a torque that tends to align it with the direction of the magnetic field (Section 28–5). Thus the force that rotates the coil must do work against this torque. Let's compute the rate at which this work is done. The torque on a dipole of magnetic dipole moment $\vec{\mu}$ in a field $\vec{B}$ has magnitude

$$\tau = |\vec{\mu} \times \vec{B}| = \mu B \sin\theta,$$

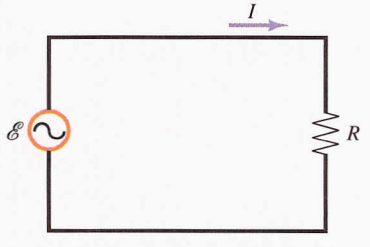
where we refer to Fig. 30–23b for θ and recall that the magnetic dipole moment is perpendicular to the current loop. The mechanical power P_{mech}, or work per unit time, that must be expended by the force that rotates the loop against this torque is

$$P_{\text{mech}} = \tau\omega = \mu B\omega \sin\theta.$$



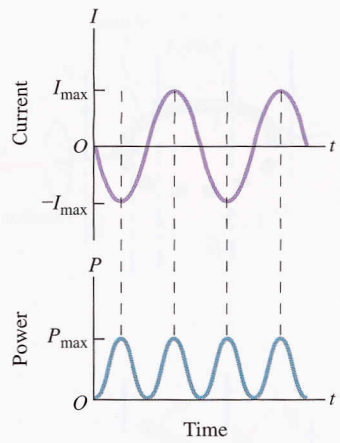
The magnetic dipole moment of a current loop with N turns is INA [Eq. (28–24)]. Thus

$$P_{\text{mech}} = INAB\omega \sin\theta. \tag{30–17}$$



This result is the same as that given by Eq. (30–16). As expected, the electric power is accounted for entirely by the mechanical power expended.

The explicit time dependence of the power is found by taking the product of the current, Eq. (30–15), and the emf, Eq. (30–14) or, more simply, by evaluating the product V^2/R. We then find



$$P = \frac{(NAB\omega)^2}{R}\sin^2\omega t. \tag{30–18}$$

▲ **FIGURE 30–23** (a) An external force rotates a coil with angular velocity $\vec{\omega}$ in a magnetic field. An emf with sinusoidal time dependence of angular frequency ω is induced in the coil. (b) Side view of the process, looking at $\vec{\omega}$.

▲ **FIGURE 30–24** When the sinusoidally varying emf that results from rotating a coil in a constant magnetic field (as in Fig. 30–22a) is part of a circuit, a sinusoidal current with the same angular frequency ω results.

▲ **FIGURE 30–25** The power dissipated in the circuit of Fig. 30–24 is always positive, unlike the current, which alternates in sign. The maximum current is $I_{max} = NAB\omega/R$, while the maximum power is $P_{max} = I_{max}^2 R$.

This quantity is always positive, as opposed to the emf or the current, both of which alternate in sign. The distinction is illustrated in Fig. 30–25, which shows a plot of the current and the power in the circuit of Fig. 30–24 as a function of time.

In practical situations it is important to consider the *time average* of the power. To do so, we note that the sine-squared function, which oscillates between 0 and 1, averages over one period to 1/2. The average power dissipated in this circuit is then

$$P_{av} = \frac{1}{2}\frac{(NAB\omega)^2}{R} = \frac{1}{2}\frac{V_{max}^2}{R}. \tag{30–19}$$

Electric power is generated by using mechanical energy to produce electric current; the current is transmitted as an alternating current (AC)—see Chapter 33. If we run a generator in reverse, we can convert electric energy into mechanical energy, and this is the basis of an *electric motor*. As we described in Chapter 28, the proper operation of a motor requires a split-ring commutator or something similar to periodically reverse the torque on a loop such that the torque is always in the same direction as the loop turns.

*30–6 The Frame Dependence of Fields

In Section 28–3 we discussed the fact that in order to maintain the relativity principle, electric and magnetic fields had to "mix," meaning that observers in different inertial frames see different combinations of electric and magnetic fields. You should recall that according to the relativity principle, there should be no way to tell which of two inertial frames—frames moving at constant velocity with respect to one another—is moving and which is not. The laws of motion should be the same in all inertial frames, so they do not provide a way to tell which frame is moving. Thus an observer O and an observer O′, who is moving with constant velocity $\vec{u}$ relative to observer O, should express the laws of motion in exactly the same way. In particular, Newton's second law,

$$\frac{d\vec{p}}{dt} = \vec{F},$$

with $\vec{p} = m\vec{v}$, must look the same to observer O, who sees a particle move with velocity $\vec{v}$, and to observer O′, who sees the same particle move with velocity $\vec{v}' = \vec{v} - \vec{u}$. This will be the case if $\vec{u}$ is constant (as it must be for inertial frames) and if the force on the particle is the same to both observers.

If the particle is charged and subject to a Lorentz force, there is an apparent difficulty because the Lorentz force depends on the velocity of the particle. The difficulty is that since the force describes the motion of the object on which the force acts, observation of the motion would represent a way to decide which of the observers is moving, and this is a violation of the principle of relativity. The problem would only be an apparent one if both observers saw the same Lorentz force. We applied this argument in Chapter 28 with the velocity selector and suggested that the problem is resolved if the fields seen by our two observers take the form

$$\vec{B}' = \vec{B}, \quad \vec{E}' = \vec{E} + \vec{u} \times \vec{B}. \tag{30–20}$$

Equation (30–20) is the correct solution to the problem of reconciling the forces when speeds are not large compared to the speed of light. *Under the transformation from one inertial frame to another, electric and magnetic fields get mixed up* (*transform among themselves*) in a very special way, as specified in Eq. (30–20).

It is interesting to think about how stationary and moving observers view the source and effect of motional emf. Suppose that an observer O is in a reference frame where there is a magnetic field but no electric field. If a conducting rod moves through this field, there is a motional emf. Its source, according to observer O, is the magnetic force on the conducting electrons in the rod (Section 30–3). Observer O′, moving with the rod, sees the rod at rest and also sees the same constant magnetic field seen by observer O, from Eq. (30–20). Therefore observer O′ sees no magnetic force. However, the same transformation equation shows that observer O′ also sees an electric field $\vec{E}'$, and this electric field has a magnitude that makes the conducting electrons in the rod

accelerate in just the way that observer O sees them accelerate. Each observer attributes the observed effects to different combinations of fields.

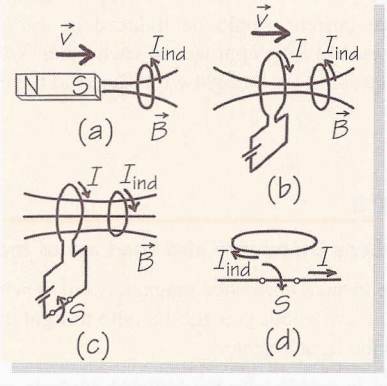
The question of the consistency of physical law for observers moving with respect to one another is a very important one; it led Albert Einstein to formulate the theory of special relativity, the subject of Chapter 39.

Summary

When the magnetic flux Φ_B through an open surface changes with time, an emf $\mathcal{E}$ is induced around the line that bounds the surface. Faraday's law states the relation:

$$\mathcal{E} = \oint \vec{E} \cdot d\vec{s} = -\frac{d\Phi_B}{dt}. \qquad (30\text{–}2)$$

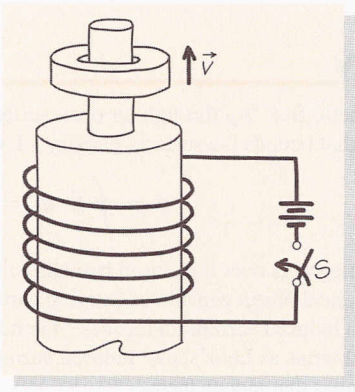
Here, the line integral is over the closed bounding line that forms the edge of the surface. When the loop is a physical object capable of carrying current, such as a loop of wire, then the induced emf results in an induced current. In this case, the minus sign in Faraday's law can be interpreted in more physical terms as Lenz's law: Induced currents produce magnetic fields that tend to cancel the flux changes that induce them.



The flux change to which Faraday's law refers can occur either because the magnetic field changes with time or because the area or orientation of the surface through which the flux is calculated changes with time. In the latter case, the induced emf is called a motional emf, and it can be derived directly from application of the Lorentz force law. Application of Lenz's law to motional emfs shows that the induced current must lead to forces that inhibit the motion of the object in which the emf is induced. The power loss due to resistive flow of induced currents is matched by the power required to keep the conductor moving. When an induced emf occurs because magnetic fields change with time, Faraday's law predicts a new type of electric field, one that cannot be described with a conventional potential and that is therefore nonconservative.

When a changing magnetic flux passes through a conducting solid, Faraday's law manifests itself by the induction of eddy currents in the material.

The AC generator, the foundation of electrical power generation, is an application of Faraday's law. When a coil rotates in a magnetic field, an emf is induced in the coil. The mechanical energy of the rotation is thus transformed into electric energy in the form of a current in circuits connected to the coil.

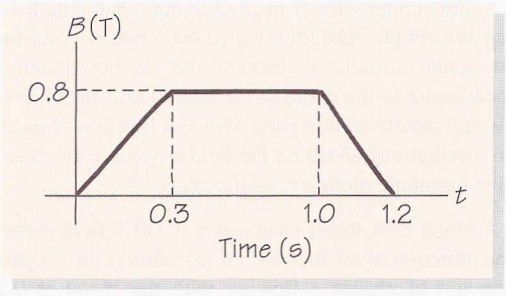


Understanding the Concepts

1. A spherical surface is placed in a changing magnetic field. Will there be an induced electric field along the equator?
2. Must there be a real conducting loop in a region with a changing magnetic flux in order for an electric field to be induced?
3. When the end of a magnet is brought to a stationary loop of wire, which of the following are true: (a) the magnetic flux through the loop decreases, (b) Lenz's law does not apply, (c) a voltage but no current are induced in the wire, (d) the induced voltage depends on the resistance in the wire, (e) the induced current depends on the resistance in the wire.
4. Electric leads (the wires that run from one part of the apparatus used for experiment to another) for sensitive experiments are almost never separated but are close together or even twisted around one another. Explain why this might be done.
5. Can the magnetic field change over some region without a change in the magnetic flux through a surface in the region? If so, give as many examples as you can.
6. A bar magnet is dropped vertically through a loop of wire, with the north pole crossing the loop first. Looking down at the loop from above, the induced current will be (a) clockwise and then counterclockwise, (b) counterclockwise and then clockwise, (c) zero, (d) only clockwise, or (e) only counterclockwise.
7. Each part of Fig. 30–26 shows a current being induced in a conducting loop by a changing magnetic flux through the loop. In each case, is the direction of the induced current correct as shown? (a) A magnet approaches a loop; (b) a current-carrying conducting loop approaches a loop at rest; (c) a switch is closed in the first loop, causing a current to flow; (d) a switch is closed in the straight wire, causing a current to flow.
8. A conducting hoop is rolled in a straight line at a constant speed in an east–west direction in the northern hemisphere through Earth's magnetic field. Will a current flow in the hoop? If so, in what direction will it circulate?

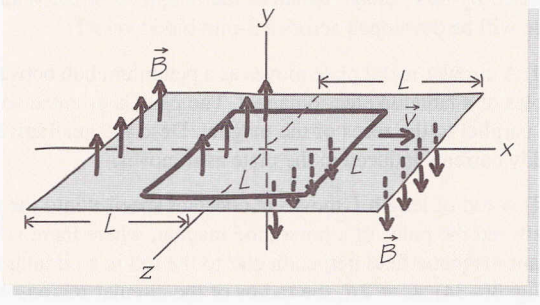
▲ **FIGURE 30–26** Question 7.

9. A rectangular loop is moving across a uniform magnetic field such that the induced emf is zero. Can you tell how the loop is oriented?
10. In Example 30–2 the induced current jumped from zero to a constant value and then dropped to zero again. Sketch, roughly, what the time-dependence of the induced current would look like if the loop were circular.
11. A sheet of metal is placed between the pole pieces of a permanent magnet, perpendicular to the direction of the field lines. Does it take positive work to pull the sheet of metal out? If so, why?
12. What would happen if you dropped a strong cylindrical magnet down inside a long vertical copper tube? Down an aluminum tube? Down a plastic tube?
13. When a bar magnet is moved toward a current loop, a current is induced in the loop. How, if at all, will physically measurable quantities change if the loop is moved toward the magnet rather than vice versa?
14. If a flat metal plate hung by a cord and oriented parallel to the pole faces of a magnet—the faces are in a vertical plane, parallel to each other—moves as a pendulum bob through the pole faces, it slows down. If the magnet is sufficiently strong, the plate comes to rest. Why? How could this phenomenon be prevented?
15. The Tennessee Valley Authority constructed several dams on the Tennessee River to produce electricity. How is water used to produce electricity?
16. When a gas is heated sufficiently, its atoms ionize into electrons and positive ions. This type of material is called a plasma. Plasma flow may be viewed as a superposition of equal and opposite currents. If the plasma is forced to flow in a channel perpendicular to a magnetic field, an electric potential builds up across the channel. The device based on this phenomenon is the *magnetohydrodynamic (MHD) generator*. Given the magnetic field strength and the potential, we can calculate the velocity of the plasma. The charge and density of the charge carriers in the plasma do not enter into the result. Why not? [*Hint*: Review the Hall effect.]
17. What happens when a bar magnet is dropped down a long, vertical copper tube?
18. In Example 30–4 we attached a battery to the straight wire and asked what current would be induced in the loop when the straight wire and loop approached each other. Would there be a current induced in the straight wire if instead the battery were on the loop?
19. In a demonstration, an aluminum ring is placed around a projection of an iron core wound with a wire and connected to a battery (Fig. 30–27). The ring jumps when the circuit is closed. Why? What happens if a gap is cut in the ring?



▲ **FIGURE 30–27** Question 19.

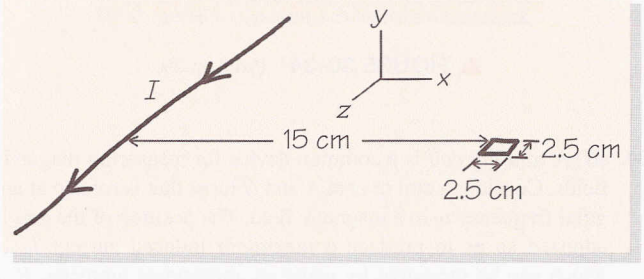
20. A cylindrical piece of iron is inserted inside a solenoid to increase the magnetic field. A voltage varying harmonically with time is placed across the solenoid leads. A copper ring is slipped down over the solenoid, so that the solenoid passes through the ring, and is held there. (a) Explain why the copper ring becomes hot even though nothing touches it. (b) What is the source of the thermal energy? (c) Explain how energy is conserved in this case.
21. In Question 20, the solenoid axis is vertical. It is possible to find a particular ring of copper that, when slipped over the solenoid and placed horizontally, remains suspended in space around the solenoid. (a) Why does this work? (b) What are the criteria for selecting the particular piece of copper?
22. Discuss how a bicycle light generator utilizing the Faraday effect might work.
23. At many traffic lights cars drive over a wire embedded in the pavement, and the traffic light soon changes from red to green. The wire forms a loop of about 1.5 m on a side. How might such a system work?
24. Describe some of the interesting things you might see if the sign of the flux change term in Faraday's law were positive.



Problems

30–1 Faraday's Discovery and the Law of Induction

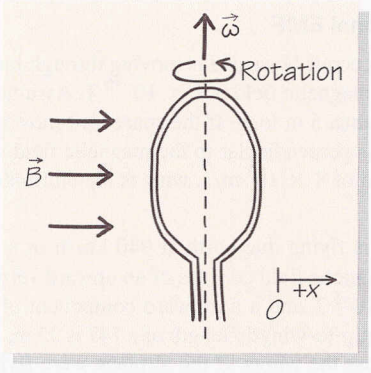
1. (I) You are given a horseshoe magnet, a coil of wire, and a flashlight bulb. How would you get the bulb to light up? How would you make the light brighter?
2. (I) Explain in words why the induced currents are as shown in each case in Figure 30–3. Describe the induced magnetic field.
3. (I) A loop of wire of area 12 cm^2 is placed between the pole pieces of an electromagnet, at right angles to the direction of the magnetic field lines. What is the emf generated around the loop if the magnetic field is changed at a uniform rate from 1.5 T to 2.0 T in 5.7 s? Assume that the magnetic field is uniform across the area of the loop.
4. (I) Suppose that the wire in Problem 3 has a resistance of 7.7 Ω. How much power will be lost to ohmic heating while the magnetic field increases?
5. (I) A magnetic field that changes with time but is uniform in space is directed along the x-axis. A conducting ring of diameter 7 cm and resistance 1.5×10^{-3} Ω is placed in the yz-plane. If the current in the ring is 2 A, how fast is the magnetic field changing?
6. (II) The magnetic field in a region is uniform. It varies with time as shown in Fig. 30–28 (see next page). Plot the current through a ring that has an area of 14 cm^2 and a resistance of 0.02 Ω, and whose plane is perpendicular to the magnetic field.
7. (II) A square wire loop of dimensions $L \times L$ oriented in the xz-plane enters a region where the magnetic field is first oriented in the $+y$- and then in the $-y$-direction (Fig. 30–29, see next page). The width of each region is L. The loop moves at speed v in the $+x$-direction. Find the emf, sign and magnitude, induced in the loop as it enters and passes through the regions with the magnetic field.



▲ **FIGURE 30–28** Problem 6.

▲ **FIGURE 30–29** Problem 7.

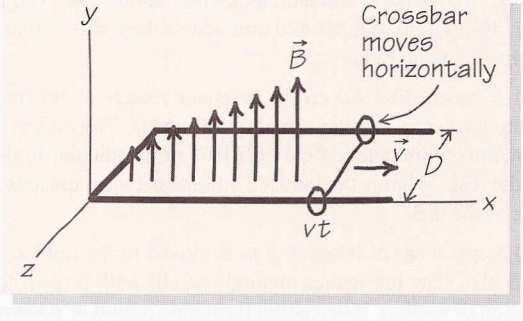
8. (II) A long, straight wire oriented in the z-direction carries a current of 120 mA. A square loop with sides of length 2.5 cm is in the xz-plane with its nearest edge 15 cm from the wire (Fig. 30–30). In a time of 0.05 s, the square loop moves uniformly 1.0 cm closer to the wire. What is the emf induced in the loop while it is moving? Ignore the variation in the wire's magnetic field *across* the loop.



▲ **FIGURE 30–30** Problem 8.

9. (II) What is the peak emf produced by a 100-turn square coil 8.0 cm on each side, rotating on a diagonal axis with a frequency of 15 Hz in a magnetic field of 0.30 T perpendicular to the axis?

10. (II) A coil with 450 turns, a radius of 2.5 cm, and a resistance of 12 Ω is rotating about a diameter in a uniform magnetic field of 0.35 T. How fast must it rotate to produce a maximum current of 3.0 A in the coil?



11. (II) There is a constant magnetic field $\vec{B} = B_0(\hat{i} + \hat{j} + \hat{k})$ in the region $x > 0$, $y > 0$, $z > 0$. A square loop of dimensions $L \times L$ whose sides are parallel to the x- and y-axes moves with constant velocity $\vec{v} = v_0(\hat{i} + \hat{j})$ in the xy-plane such that its center moves along the line $x = y$. Calculate the emf induced in the loop, given that its leading corner passes the origin at the time $t = 0$.

12. (II) A vertical loop rotates with angular velocity $\vec{\omega}$ as shown in Fig. 30–31. At time $t = 0$, it is aligned perpendicular to a constant magnetic field oriented in the x-direction. Use Lenz's law to find the direction of the emf induced in the loop at $t = 0$, $t = T/4$, $t = T/2$, and $t = 3T/4$, where T is the rotation period of the loop.

▲ **FIGURE 30–31** Problem 12.

13. (II) A closed loop is constructed of a fixed wire shaped as a squared-off U and a crossbar free to move in the x-direction, all in the xz-plane. The square base of the U-shaped segment is at $x = 0$. A magnetic field oriented in the y-direction varies with x according to $\vec{B} = Cx\hat{j}$; it is zero at $x = 0$. The situation and the relevant dimensions are as in Fig. 30–32. Suppose that the movable crossbar is pulled at a constant speed v to the right, starting at $x = 0$ when $t = 0$. Its position at any time is $x = vt$. If the resistance of the loop varies with the total length L according to $R = \alpha L$, what is the current in the loop as a function of time? Compare your answer with Example 30–5, and explain any differences.

▲ **FIGURE 30–32** Problem 13.

14. (II) Suppose the magnetic field in Example 30–5 is a constant field oriented in the z-direction, $\vec{B} = B_0\hat{k}$. Find the induced current as a function of time.

15. (II) Suppose the magnetic field in Example 30–5 varies linearly with z and is oriented in the y-direction, $\vec{B} = Cz\hat{j}$. Find the induced current as a function of time.

16. (II) A metal ring is constructed so as to expand or contract freely. In a region with a constant magnetic field $\vec{B}_0$ oriented perpendicular to it, the ring expands, with its radius growing linearly with time as $r = r_0(1 + \alpha t)$. As the ring expands and grows thinner, its resistance *per unit length* changes according to the empirical rule $R = R_0(1 + \beta t)$. Find the current induced in the ring as a function of time. Specify the direction as well as the magnitude of the current.

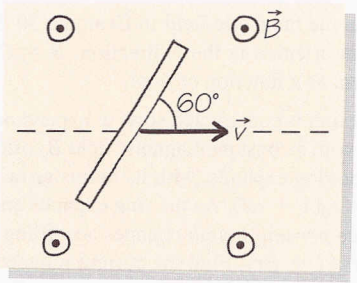
17. (II) A circular loop of area A rotates with angular frequency ω about its vertical diameter. The rotating loop is placed in a horizontal constant magnetic field, B. What is the emf induced in the loop?

18. (II) Work Example 30–3 by direct computation of the magnetic flux through the hemispherical surface.

30–2 Motional EMF

19. (I)The spacecraft *Voyager I* is moving through interstellar space, where the magnetic field is 2×10^{-10} T. Assume that *Voyager I* has an antenna 5 m long. If the spacecraft moves so that the antenna rod is perpendicular to the magnetic field when *Voyager I* has a speed of 8×10^3 m/s, what is the emf induced across the antenna?

20. (I) A 747 is flying due north at 940 km/h in a location where Earth's magnetic field consists of an upward vertical component of 2.8×10^{-5} T and a northward component of 2.5×10^{-5} T. If the wingtip-to-wingtip length of a 747 is 35 m, find the emf induced across the wings. If the airplane were flying due east instead of due north, how would your answer change?



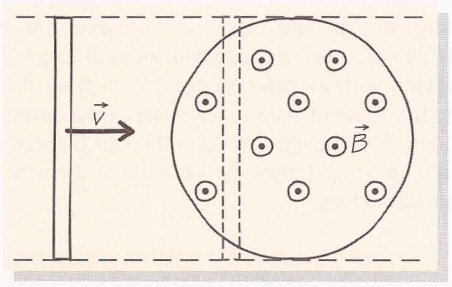
21. (I) A metal rod is pulled through a magnetic field perpendicular to it with a velocity perpendicular to both the rod and the magnetic field as in Fig. 30–12a. The rod has length 0.25 m, its speed is 1.7 cm/s, and the magnetic field has magnitude 0.069 T. What is the magnitude of the potential difference, if any, from one end of the rod to the other?

22. (I) A metal rod 6.0 cm long falls to the ground from a height of 6.0 m. It stays horizontal and oriented in an E–W direction throughout the fall. If we assume that, in the region where the metal falls, Earth's magnetic field is 1.5×10^{-4} T and points in the N–S direction, then at what rate does the potential difference between the ends of the rods increase?

23. (I) A rod 10 cm long lying in the xy-plane pivots with angular speed 100 rad/s counterclockwise about the origin (see Fig. 30–14). If the measured emf across the rod is 100 mV, what is the magnetic field?

24. (II) A metal disk 7.0 cm in diameter rotates about its axis of symmetry at an angular speed of 150 rad/s. The disk is situated in a uniform magnetic field of 0.10 T perpendicular to the plane of the disk. What is the induced voltage between the axis and the rim of the disk?

25. (II) A metal bar of length 0.7 m is moved to the right at a speed of 5 m/s. The bar makes an angle of 60° with respect to its direction of motion. It is passing through a region of uniform magnetic field of magnitude 5×10^{-3} T oriented perpendicular to the plane swept out by the bar (out of the page in Fig. 30–33). What is the potential difference between the two ends of the bar as it moves through the magnetic field?



▲ **FIGURE 30–33** Problem 25.

26. (II) A thin copper wire of negligible mass and length L is oscillating as a simple pendulum with a mass bob m. A uniform, constant magnetic field is present that is horizontal, oriented perpendicular to the plane of the pendulum's oscillations. What is the emf generated along the wire as a function of its angle θ of small oscillation? (Assume the field is weak enough so that the simple harmonic motion is unaffected.)

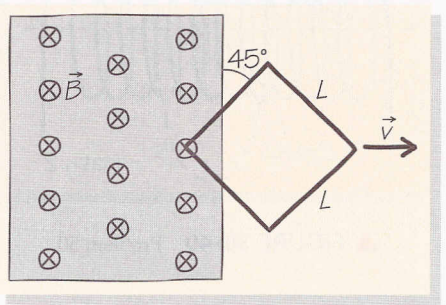
27. (II) A blood-flow meter produces a 0.030 T field perpendicular to the direction of the blood flow. (a) What is the magnetic force on an ion of charge e flowing with the blood at 0.25 m/s? (b) Positive and negative ions in the blood are forced in opposite directions, producing an electric field and a voltage across the blood vessel. The ion separation stops when the electric force caused by this voltage balances the magnetic force. What voltage will be developed across a 3-mm blood vessel?

28. (II) A circular metal plate moves as a pendulum bob between the poles of a tabletop electromagnet. The plate is oriented so that it is parallel to the faces of the magnet. Describe qualitatively the eddy currents induced in the plate as it moves.

29. (II) A rod of length L moves at constant speed v into the region between the poles of a horseshoe magnet, where there is a constant magnetic field perpendicular to the rod in a circular region (Fig. 30–34). $L = 2R$, the radius of the circular region. What is the emf induced in the rod as a function of time?

▲ **FIGURE 30–34** Problem 29.

30. (II) A *rotating coil* is a common device for measuring magnetic fields. Consider a coil of area A and N turns that is rotated at angular frequency ω in a magnetic field. The position of the coil is adjusted so as to produce a maximum induced current I_{max}, which can be measured by using an appropriate ammeter. R is the total resistance of the coil circuit. Find the relationship between the unknown magnetic field and I_{max}.

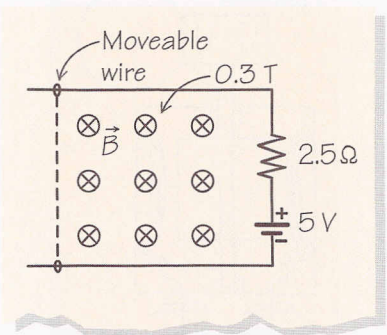


31. (II) If the rotating coil of Problem 30 is used with the split-ring commutator described in Chapter 29, DC current can be measured with a sensitive galvanometer. (a) Sketch the current as a function of time for several periods, where the period T is given by $2\pi/\omega$. (b) Calculate the average of this rectified current. (c) Find the relationship between the unknown magnetic field and the average measured DC current. [*Hint*: The average of an oscillating function with period T is $(1/T)\int_0^T f(t)\,dt$.]

32. (II) A long, straight wire carries a current of 650 mA. A thin metal rod 45 cm long is oriented perpendicular to the wire and moves with a speed of 2.2 m/s in a direction parallel to the wire. What are the size and direction of the emf induced in the rod if the nearest point of the rod is 3.5 cm away from the wire, and if the rod moves in a direction opposite to the current?

30–3 Forces and Energy in Motional EMF

33. (I) A loop of metal, total resistance $R = 25\ \Omega$, moves with speed 35 m/s through a region of magnetic field such that at time $t = 0$ the rate of change of magnetic flux through the loop is given by $17\ \text{T} \cdot \text{m}^2/\text{s}$. The magnetic field in the vicinity of the loop has instantaneous value 0.16 T at $t = 0$. Assume the shape of the loop is such that the resulting net force on the loop is due entirely to a straight section of the loop, 12 cm in length, that is perpendicular both to the magnetic field and to the direction of the loop's motion. What is the drag force on the loop at $t = 0$, and what is the instantaneous power at $t = 0$ expended by the force that must be used to keep the loop moving with constant velocity?



34. (II) A square wire loop of dimensions $L \times L$ lies in a plane perpendicular to a constant magnetic field. The field exists only in a certain region, with a sharp boundary (Fig. 30–35). The sides of the loop make a 45° angle with this boundary, and an external force moves the loop at a speed v out of the region of constant field. How much power must be supplied by the external force as a function of time?

▲ **FIGURE 30–35** Problem 34.

35. (II) A conducting bar slides frictionlessly on two parallel horizontal rails 30 cm apart. The bar and rails form a closed circuit with a resistor of resistance 0.050 Ω, assumed to be constant throughout the motion. The circuit is placed in a uniform vertical magnetic field of 0.28 T perpendicular to the circuit's plane. The bar is pulled at a constant speed of 60 cm/s along the rails. (a) What is the magnitude of the force required to pull the bar? (b) What is the rate of Joule heating in the resistor?

36. (II) A circuit with a moveable cross wire is indicated in Fig. 30–36. The resistance is 2.5 Ω, the battery voltage is 5 V, the moveable wire length is 12 cm, and there is a uniform, constant magnetic field into the plane of the circuit (the page) with magnitude 0.3 T. (a) What is the current if the moveable wire is locked into position? (b) What is the force on the moveable wire at the moment it is released from the locked position? (c) If there is an opposing force of 0.02 N on the wire, how fast will it move as a function of the time after release?

▲ **FIGURE 30–36** Problem 36.

37. (II) A horizontal wire of mass m is free to slide on vertical rails a distance L apart. These are connected at the bottom with a resistance R between them. There is a constant, uniform magnetic field B in a horizontal direction, normal to the area enclosed by the rails and sliding wire. Use the fact that the power generated by gravity is equal to the power dissipated by ohmic heating, to show that the wire ultimately moves with a constant velocity, and obtain an expression for this velocity in terms of mg, B, R and L.

38. (II) A long, straight wire carries a constant current I_0. A square loop with sides of length L and two sides parallel to the wire is pulled away at uniform speed v in a direction perpendicular to the wire. The nearest side of the loop is initially a distance D from the wire; the resistance of the loop is R. (a) Calculate the force necessary to pull the loop. (b) At what rate is work being done by the force? (c) How does your answer to part (b) compare with the Joule heating in the loop?

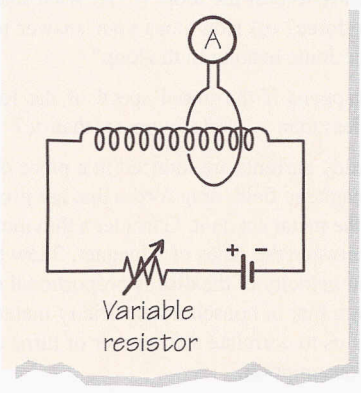
39. (II) What happens if the initial speed of the loop in Example 30–9 is (a) less than v_t, and (b) greater than v_t?

40. (II) When eddy currents are induced in a piece of metal moving through a magnetic field, drag forces that are proportional to the velocity of the metal act on it. Consider a thin metal disk rotating in a plane between the poles of a magnet. Show that the equilibrium angular velocity of the disk is proportional to the torque on the disk. Note that in household electricity meters, this arrangement allows us to correlate the number of turns of the disk with the power consumption.

30–4 Time-Varying Magnetic Fields

41. (I) Consider a length of wire looped back on itself in a magnetic field B. The shape of the loop is not given, but it lies in a plane. The wire has negligible resistance, but there is a resistor R at one end. A cross bar, which rests on opposite legs of the loop, is pulled along so that the flux enclosed by the wire and crossbar varies with time as $\Phi_B(t)$. What is the instantaneous power needed to pull the crossbar?

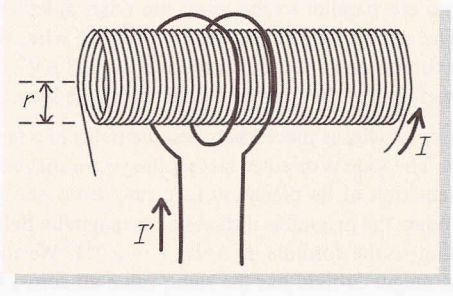
42. (I) A long, straight wire carries a current $I = I_0 \cos(220\pi t)$, where t is time. Two sides of a fixed rectangular loop are 9.0 cm long and are parallel to the wire; the other sides are 0.80 cm long. The nearest long side is 2.0 cm from the wire. What is I_0 if the maximum emf induced in the loop is 1.3 μV? (Ignore the small variation of the magnetic field across the loop.)



43. (I) A loop of wire is placed between the poles of a large electromagnet. The loop is oriented so that the vector that characterizes the orientation of its planar surface runs from one pole to the other. When the magnet is turned on, its magnetic field builds up according to the formula $B = B_0(1 - e^{-at})$. We may assume that the magnetic field has the same value all across the surface of its poles and runs from one pole to another. (This formula gives $B = 0$ at $t = 0$ and $B = B_0$ at $t = \infty$.) What is the magnitude of the emf around the loop?

44. (I) A metal ring of diameter 3.0 cm is left between the pole tips of an electromagnet, such that the plane of the loop is perpendicular to the magnetic field. The electromagnet is turned on and reaches its full magnetic field of 2.7 T in 50 ms at a linear rate. If the ring has resistance 0.15 Ω, how much current passes through the ring during the 50 ms?

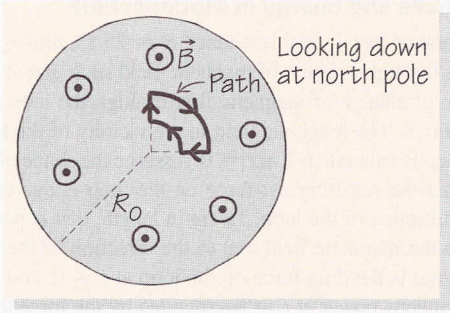
45. (II) A solenoid of radius r wound with n turns per unit length carries a current given by $I = I_0 \cos(\omega t)$, where t is the time. What are the magnitude and direction of the induced electric field just outside the solenoid?



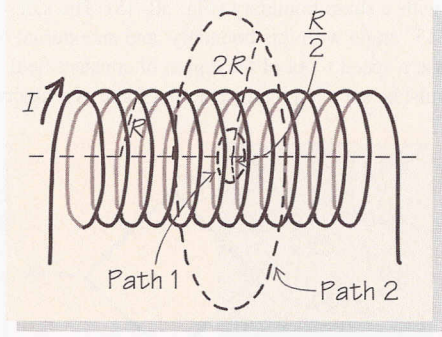
46. (II) A wire of 5.5 Ω resistance and 20 m length is wound into a coil of radius 4.3 cm. A magnetic field of 2.4 T is perpendicular to the plane of the coil. (a) If the current that forms the magnetic field is switched to the opposite direction, what is the total charge that passes through the wire coil? Assume the current switching takes place in 85 ms. (b) What is the average current and emf induced in the coil over that period?

47. (II) A single-turn circular loop of radius 0.08 m and resistance 6 Ω is coaxial with a solenoid of length 90 cm and a radius of 0.04 m, with 1800 turns. A variable resistor, as indicated in Fig. 30–37, is varied in such a way that the solenoid current falls linearly from 5 A to 1.2 A in 0.3 sec. (a) What is the induced current in the loop? (b) In what direction does the induced current flow?

▲ FIGURE 30–37 Problem 47.



48. (II) A very long cylindrical solenoid of radius r made from n turns of wire per unit length carries a current with the time dependence $I = I_0 e^{-t/t_0}$. Coaxial with and surrounding the solenoid are two turns of wire that make a circular loop slightly larger than the circular cross section of the solenoid (Fig. 30–38). The loop with two turns is far from the ends of the solenoid and has a resistance R. Find the current in the loop with two turns, I', as a function of time.

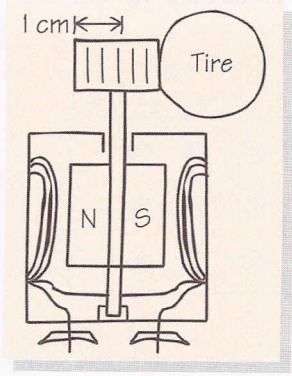


▲ FIGURE 30–38 Problem 48.

49. (II) The uniform magnetic field of the electromagnet of Example 30–10, with circular pole faces of radius $R_0 = 0.08$ m, decreases linearly from 1.5 T to 0.7 T in 25 ms. What is the emf induced around the path drawn in Fig. 30–39 that consists of quarter arcs at radial distances $R_0/4$ and $R_0/2$, connected by radial lines? The path is clockwise.

50. (II) A long solenoid of radius R and n turns per unit length carries an alternating current $I = I_0 \sin(\omega t)$ (Fig. 30–40). What are the electric fields induced within the solenoid at a distance $R/2$ and outside the solenoid at a distance $2R$? [*Hint*: Apply Faraday's law to the two paths shown, and use symmetry.]

▲ FIGURE 30–39 Problem 49.



▲ FIGURE 30–40 Problem 50.

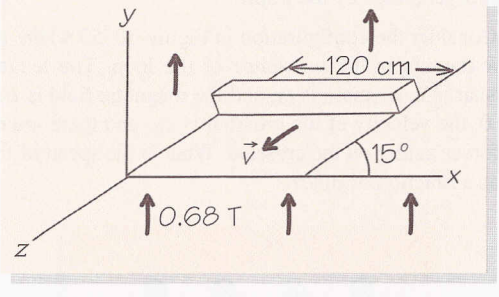
30–5 Generators

51. (I) A coil of area 6.0 cm^2 with 180 turns of wire is connected to a resistor of resistance 3 Ω. It is rotated by hand at a frequency of 0.6 rev/s in a magnetic field of 0.40 T. (a) What is the maximum amount of current produced? (b) the average power produced?

52. (II) You have 18 m of wire, a constant magnetic field of 0.45 T, and a device that can rotate a coil at a fixed frequency of 300 Hz. What size circular coil will produce an AC emf of maximum voltage 120 V?

53. (II) The headlight of a bicycle is powered by a small generator that is driven by a wheel of the bicycle. The generator contains two coils fixed at the sides of the generator and connected in series with appropriate polarity (Fig. 30–41). Each coil consists of 70 turns and has an area of 8 cm^2. A small permanent magnet is rotated in front of the coils, so that the magnitude of the magnetic field in the coils varies between 0.1 T and zero. At what speed of the bicycle will the maximum emf be 6.4 V, given that the radius of the friction wheel is 1 cm?

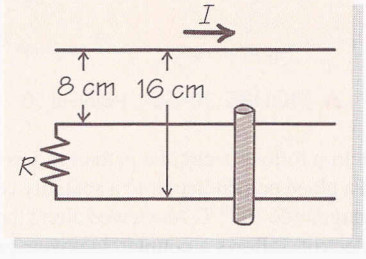
▲ FIGURE 30–41 Problem 53.



54. (II) A bicycle wheel of radius $R = 33$ cm rotates at angular speed 53 rad/s in a plane perpendicular to a constant magnetic field of magnitude 0.55 T. What is the emf generated between the center of the wheel and its rim? When one end of a wire is attached to the center and the other end to a circular track in contact with the rim, a direct current is generated in the wire. Such a device is called a *homopolar generator*.

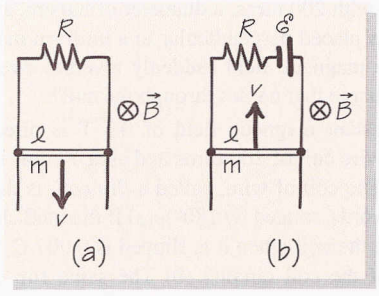
*30–6 The Frame Dependence of Fields

55. (II) Suppose that observer O sees an electric field $\vec{E} = E\hat{i}$ and a magnetic field $\vec{B} = B\hat{k}$. In what direction and at what (constant) speed u should a second observer move so as to see no electric field whatsoever? Use the nonrelativistic relation Eq. (30–20). If $E = 10^3$ V/m, for what range of values of B is the nonrelativistic approximation appropriate?



General Problems

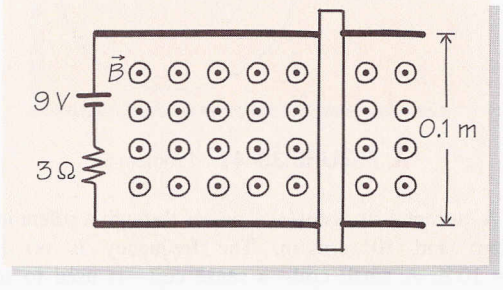
56. (II) A 120-cm-long wire of square cross section with a mass of 65 g and a resistance of 2.0 Ω slides without friction down parallel conducting rails of negligible resistance (Fig. 30–42). The rails are connected to each other at the bottom by a resistanceless rail parallel to the wire so that the wire and rail form a closed rectangular conducting loop. The plane of the rails makes an angle of 15° with the horizontal, and a uniform vertical magnetic field of 0.68 T, pointing upward, exists throughout the region. What is the steady speed of the wire?



▲ FIGURE 30–42 Problem 56.

57. (II) A straight wire carries a current $I = 150$ A near a rod that moves across two conducting wires (Fig. 30–43). The resistor has $R = 0.20\ \Omega$, and the rod moves at speed 45 cm/s. (a) What is the emf induced in the rod? (b) What is the current in the circuit? (c) How much work is done to move the rod 100 cm to the right? What force does this work?

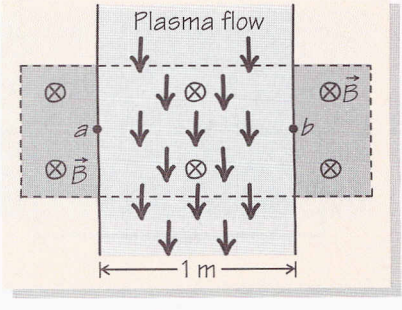
▲ FIGURE 30–43 Problem 57.



58. (II) A conducting crossbar bracketing two vertical conducting wires slides down the wires. The wires are connected with a resistor R to form a closed circuit (Fig. 30–44a). (a) If there is a horizontal magnetic field B perpendicular to the plane of the loop, how fast does the bar fall after the initial accelerating period? (b) A battery is added to the circuit (Fig. 30–44b). What polarity and emf of the battery are needed to lift the bar with the same velocity?

▲ FIGURE 30–44 Problem 58.

59. (II) A large, circular coil of N turns and radius R carries a steady current I and is rotated at a constant angular speed ω about a horizontal diameter. At the center of this coil is a small, fixed, horizontal circular ring of radius r. (a) What is the emf induced in the small ring? (b) What is the angle between the plane of the coil and that of the ring when this emf is a maximum?

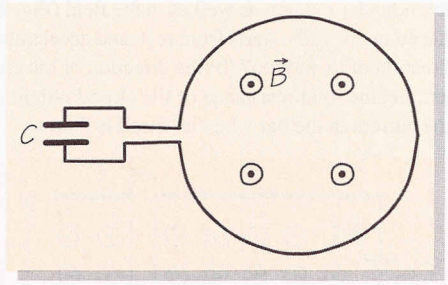


60. (II) Consider a 9-V battery attached to two conducting, frictionless rails 0.1 m apart. There is a magnetic field $\vec{B}$ of magnitude 0.5 T perpendicular to the rails, and a conducting bar can slide over the rails perpendicular to them as well as to the field (Fig. 30–45). The bar is placed on the rails, starts from rest, and accelerates. (a) What is the direction of its motion? (b) the direction of the emf induced? (c) Given that the total resistance of the closed circuit is 3 Ω, calculate the current in the bar when its speed is 3 m/s.

▲ FIGURE 30–45 Problem 60.

61. (II) A wire carrying a current I is oriented in a horizontal direction. To its side, a wire loop is oriented so that it and the straight wire lie in the same horizontal plane. The straight wire is moved toward the loop. If a current is induced in the loop, what is its direction, and what is the direction of the force on the loop?

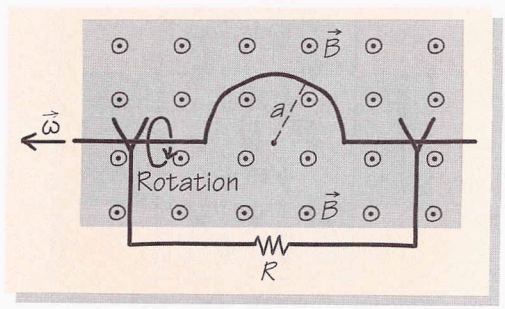
62. (II) If the plasma in a magnetohydrodynamic generator (see Question 16) is forced to flow in a channel perpendicular to a magnetic field, an electric potential builds up between points a and b, which are 1 m apart (Fig. 30–46). If the magnetic field has a strength 2.5 T, what must the speed of the plasma be in order that the potential be 1000 V?



▲ FIGURE 30–46 Problem 62.

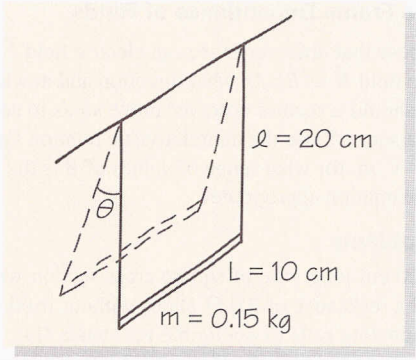
63. (II) A coil with 200 turns, a diameter of 8.0 cm, and a resistance of 5.6 Ω is placed perpendicular to a uniform magnetic field of 1.4 T. The magnetic field suddenly reverses direction. What is the total charge that passes through the coil?

64. (II) A constant magnetic field of 0.5 T is directed along the x-axis. A wire coil of 200 turns and area 12 cm^2 is placed in the yz-plane. The coil of wire, called a *flip coil*, is then turned over (in other words, rotated by 180°). (a) If the total charge that passes through the coil when it is flipped is 0.007 C, what is the resistance of the coil circuit? (b) The same flip coil is used to measure an unknown magnetic field. The coil is flipped in several directions until it attains its maximum charge of 0.02 C, when the coil is flipped with its face in the xy-plane. What is the magnitude of the magnetic field? (c) What is the direction of the magnetic field in part (b)?



65. (II) A circular ring of area 100 cm^2 is connected to a 15-μF capacitor. The circuit has a resistance of 2 Ω. A uniform time-dependent magnetic field of magnitude $B = (0.03\ T/s)t$ is perpendicular to the ring (Fig. 30–47). Calculate the current in the ring and the charge on the capacitor. Give the direction of the current and the polarity of the charge.

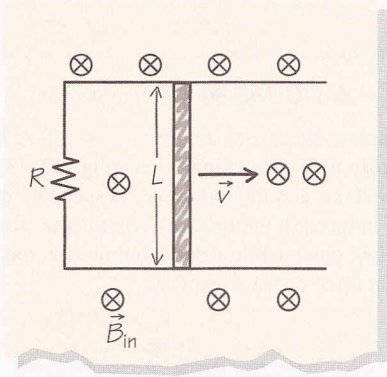
▲ **FIGURE 30–47** Problem 65.



66. (II) A current $I = I_0 \cos(\omega t)$ passes through a solenoid of area 10 cm^2 and 10^5 turns/m. The frequency is 60 Hz, and $I_0 = 10$ A. A small coil—a sense coil—is used to sense the changing flux. This sense coil has an area of 20 cm^2 with 10 turns and is placed across the solenoid so that the face of the coil is perpendicular to the solenoid axis; the two coils are concentric. (a) What is the emf induced in the sense coil? (b) If the resistance of the sense coil circuit is 5 Ω, what is the current?

67. (II) A wire that is bent into a semicircle is rotated with angular velocity ω about its diameter, as shown in Fig. 30–48. The bent wire and its supports are placed in a uniform magnetic field perpendicular to the plane of the supports. What is the emf induced in the circuit shown? If the resistance of the closed loop is R, what is the average power dissipated?

▲ **FIGURE 30–48** Problem 67.



68. (II) A pendulum consists of a metal bar suspended from two thin wires attached to a fixed conducting bar (Fig. 30–49). The resistance of this closed circuit is 0.030 Ω. The pendulum is placed in a vertical magnetic field of magnitude 0.12 T. The pendulum is displaced by a small angle from the equilibrium position and allowed to oscillate. What is the ratio of the power dissipated to the energy of the oscillator?

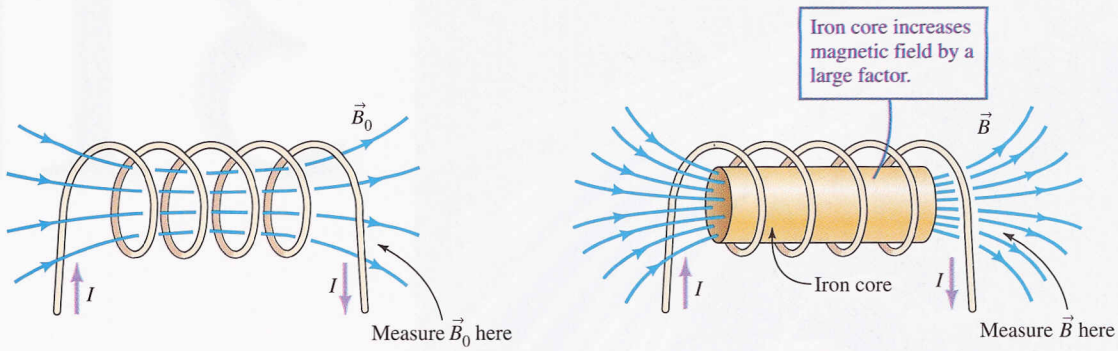
▲ **FIGURE 30–49** Problem 68.

69. (II) A train travels in the northerly direction at 60 mph on tracks that are 1.5 m apart. In the region, Earth's magnetic field is 0.7×10^{-4} T making an angle of 30° with the vertical. What is the emf generated by the train?

70. (II) Consider the configuration in Figure 30–50 where the resistor R dominates the resistance of the loop. The length of the crossbar is L, its mass is m, and the magnetic field is B. At time $t = 0$, the velocity of the crossbar is v_0, and there are no external forces acting on the crossbar. What is the speed of the crossbar as a function of time?

▲ **FIGURE 30–50** Problem 70.

71. (III) An electron follows a circular path of radius $R = 1$ m while traveling in a plane perpendicular to a spatially constant magnetic field of magnitude 10^{-6} T. As viewed along the magnetic field lines, the electron follows a counterclockwise path. (a) What is the speed of the electron? (b) Assuming that the motion of the electron is nonrelativistic, what is the energy E of the electron? (c) The magnitude of the magnetic field is reduced smoothly by a certain percentage during an interval Δt. Show that the fractional energy change of the electron, $\Delta E/E$, is independent of the radius of the electron's orbit as well as of the electron's speed. (This effect is the basis for low-energy operation of a particle accelerator called the *betatron*.) (d) If the magnetic field is reduced in time $\Delta t = 5$ s by 10 percent, estimate $\Delta E/E$.



Chapter 31

◀ As part of the manufacturing process for high-temperature superconductor wire, technicians at American Superconductor operate capstans that pull the wire through a metal die, reducing its diameter and increasing its length. The successful production of high-capacity wire made of a high-temperature superconductor would revolutionize many aspects of our power distribution system.

Magnetism and Matter

While we have made frequent use of bar magnets in the previous chapters, we have not asked questions as to why the materials that make up such magnets behave the way they do. Is there something in such materials that is like the electric currents that produce magnetic fields according to the laws we have developed? How do we explain the fact that magnets pick up needles but not pieces of paper? Why is it possible to make a slab of iron act like a bar magnet at some times but not at other times? Why can't the same be said for a piece of aluminum? What explains the magnetic properties of superconductors? In other words, what lies behind the magnetic properties of matter? The answers to these types of questions lie in the microscopic structure of matter, all the way down to the subatomic level. We utilize the magnetic properties of material when we construct computer disk drives, electric motors, generators, transformers, particle accelerators, and medical scanners, so that understanding the magnetic properties at a fundamental level is essential. When we considered the electric properties of materials, we saw that the dielectric properties of materials depend on the polarizability of atoms and molecules. In the same way, the magnetic properties of materials depend on the magnetic properties of atoms and molecules and their constituents. This chapter is concerned with the origins of these properties.

▲ **FIGURE 31–1** (a) A solenoid that carries a current has a magnetic field. (b) The cylindrical volume of the solenoid is filled with an iron core.

31–1 The Magnetic Properties of Bulk Matter

We begin with a description of the different kinds of behavior that are observed on an everyday scale. We can explore the magnetic properties of various materials using a solenoid. We measure the magnetic field $\vec{B}_0$ produced by, and near one end of, a current-carrying solenoid (Fig. 31–1a) and ask how the presence of various materials affect the magnetic field. (Throughout this chapter $\vec{B}_0$ represents any field, not necessarily constant, that is present before we introduce materials.) If we insert a wooden or copper core into the solenoid and repeat the measurement, it would take a very sensitive instrument to reveal that the field has been changed by one part in 10^6. But if we place an iron core in the solenoid (Fig. 31–1b), the measured field is increased by a factor many times that of the original field of the hollow solenoid. If we now remove it, the iron core will act like a bar magnet, even if it showed no such properties before insertion. The solenoid somehow magnetizes the iron core; the wooden or copper cores show no such effect. Magnetic properties depend on the material!

The magnetic behavior of bulk materials—gases, liquids, and solids—is characterized by the **magnetization**, $\vec{M}$, which we define as the *magnetic dipole moment per unit volume* of material. The field outside a material with a net magnetization is that of a magnetic dipole, the same as that of a bar magnet. A magnetic moment has dimensions of current times area [see, for example, Eq. (29–27)], so magnetization has dimensions of current times area divided by volume, or current per length. The SI units of $\vec{M}$ are amperes per meter (A/m). Our aim here is to find a connection between an applied field $\vec{B}_0$ and the magnetization.

The net magnetic field of a solenoid S_1 with a core of some material in it is the vector sum of contributions from the original magnetic field of the solenoid, $\vec{B}_0$, and the contribution of the magnetization of the core. The core can be viewed as a second solenoid S_2 as any magnetic dipole has a magnetic field with the same general form as that of a solenoid. Suppose that S_2 can be treated as a solenoid of area A, length L, and N loops that carry current I. From Eq. (29–15), the magnetic field of S_2 is

$$B_2 = \frac{\mu_0 NI}{L} = \frac{\mu_0 NIA}{LA} = \mu_0 \frac{m_2}{V},$$

where[†] m_2 is the magnetic moment of S_2, $m_2 = NIA$, and μ_0 is the permeability of free space. The factor m_2/V is the magnetic moment per unit volume—the magnetization size $|\vec{M}|$. Thus *the contribution of the core to the total magnetic field is* $\mu_0\vec{M}$, and the total field of the solenoid with the core present is

$$\vec{B} = \vec{B}_0 + \mu_0\vec{M}. \tag{31–1}$$

[†]To avoid confusion with the magnetic permeability μ to be introduced shortly, we use the notation m for the magnetic dipole moment throughout this chapter. Don't confuse it with a mass!

Equation (31–1) applies whatever the source of the original field $\vec{B}_0$ in which the bulk material is placed, and it need not be the field due to a solenoid. This situation is similar to that of dielectrics, where an electric field within a material has contributions from an original electric field due to free charges and from an internal, induced distribution of charge. We saw in Chapter 25 that we can separate the effect of these types of charges through the introduction of a dielectric constant and a generalized permittivity. Similarly, we want to separate the effects of the internal magnetization, which has contributions from what must be the equivalent of internal currents, from the magnetic fields due to ordinary currents. We refer to the latter as *free*, or *real*, currents. The effects of free currents are isolated by defining the **magnetic intensity** $\vec{H}$, a quantity for which the effect of the magnetization of the material is subtracted out:

$$\vec{H} \equiv \frac{\vec{B}}{\mu_0} - \vec{M}. \tag{31–2}$$

Notice that the dimensions of $\vec{H}$ are those of $\vec{M}$, *not* of $\vec{B}$. By replacing $\vec{B}$ in Eq. (31–2) with $\vec{B}_0 + \mu_0\vec{M}$ according to Eq. (31–1), we find

$$\vec{B}_0 = \mu_0\vec{H}. \tag{31–3}$$

Equation (31–3) shows that *the magnetic intensity measures the magnetic field due to free currents*. Another form for the relation among $\vec{B}$, $\vec{H}$, and $\vec{M}$ is found by combining Eq. (31–1) and (31–3):

$$\vec{B} = \mu_0\vec{H} + \mu_0\vec{M}. \tag{31–4}$$

Most materials have no magnetization unless they are in the presence of an external magnetic field $\vec{B}_0$ that induces magnetization. The important exceptions to this are iron and some other materials that we will refer to below as ferromagnetic—these are the materials that make permanent magnets. We know by experiment that over a large range of conditions, *the size of the magnetization of nonferromagnetic materials varies linearly with the external magnetic field*. For these materials, $\vec{M}$ depends linearly on $\vec{B}_0$, and hence on $\vec{H}$. The **magnetic susceptibility** χ_m is defined as the coefficient of the linear relation between the magnetization and the magnetic intensity:

$$\vec{M} \equiv \chi_m\vec{H}. \tag{31–5}$$

The direction of the magnetization is more complicated: The original field $\vec{B}_0$ and the field $\mu_0\vec{M}$ due to the magnetization are parallel for one class of materials but antiparallel for a second class. If the susceptibility of a material is positive, its magnetization is aligned along the external field; if the susceptibility is negative, the magnetization is aligned opposite to the external field. Because $\vec{M}$ and $\vec{H}$ have the same dimensions, χ_m is dimensionless. Table 31–1 gives a range of susceptibilities found in nature. Examination of the table reveals the three general classes of materials: those with small negative susceptibility (**diamagnetic materials**), those with small positive susceptibility (**paramagnetic materials**), and iron and its cousins (**ferromagnetic materials**), which have a large positive susceptibility and can have a magnetization even with no external field present. The nature and properties of these classes of materials is the major topic of this chapter.

With our definition of magnetic susceptibility χ_m, we can express the relation between the magnetic field in a material and the magnetic intensity. From Eq. (31–1),

$$\vec{B} = \vec{B}_0 + \mu_0\vec{M} = \mu_0\vec{H} + \mu_0\chi_m\vec{H} = \mu_0(1 + \chi_m)\vec{H}. \tag{31–6}$$

We define the coefficient of $\vec{H}$ in this equation as the **permeability**, μ, of the material:

$$\mu = \mu_0(1 + \chi_m). \tag{31–7}$$

TABLE 31–1 • Some Magnetic Susceptibilities (at 20°C unless indicated otherwise)

Material	Susceptibility, χ_m
Diamagnetic	
Water	-13×10^{-6}
Copper	-5.5×10^{-6}
Silver	-2.0×10^{-5}
Carbon (diamond form)	-5.9×10^{-6}
Bismuth	-2.4×10^{-4}
Paramagnetic	
Sodium	1.6×10^{-6}
Cupric oxide (CuO)	2.6×10^{-4}
Aluminum	1.7×10^{-5}
Liquid oxygen (90 K)	8.7×10^{-3}
Oxygen gas	3.5×10^{-3}
Ferromagnetic	
Iron (annealed)	5.5×10^{3}
Permalloy (55% Fe, 45% Ni)	2.5×10^{4}
Mu-metal (77% Ni, 16% Fe, 5% Cu, 2% Cr)	1×10^{5}

The relation between the total magnetic field in a material and the magnetic intensity, which is a measure of the effect of free currents, is then

$$\vec{B} = \mu\vec{H}. \tag{31–8}$$

Just as when materials are present, the electric permittivity ε replaces the permittivity of free space ε_0 in expressions for electric fields that contain only the free charge, so too when materials are present, μ replaces μ_0 in expressions for magnetic fields that contain only the free current. Equation (31–3) shows that when there is a magnetic field in a vacuum, that field is related to the intensity by a relation like that of Eq. (31–8), but with μ_0 appearing in the place of μ; thus μ_0 is the permeability of the vacuum. From Table 31–1 we can see that μ is very close to μ_0 for nonferromagnetic materials.

The various quantities we have defined are all useful in characterizing the bulk magnetic behavior of materials. In Table 31–2, we summarize these quantities and their relations.

TABLE 31–2 • Magnetic Bulk Properties and Their Relations

Symbol	Property
$\vec{B}_0$	Applied magnetic field, produced independently of type of material by a nearby magnet or currents
$\vec{H}$	Magnetic intensity, proportional to the applied magnetic field
$\vec{M}$	Magnetization, the magnetic dipole moment per unit volume of a material
$\vec{B}$	Net magnetic field, the sum of the applied magnetic field and a term proportional to the magnetization
μ_0	Permeability of free space
χ_m	Magnetic susceptibility of a material
μ	Permeability of a material, $\mu = \mu_0(1 + \chi_m)$.

Some Relations

	$\vec{B}_0$	$\vec{H}$	$\vec{M}$	$\vec{B}$
$\vec{H} =$	$\vec{B}_0/\mu_0$	—	$\vec{M}/\chi_m$	$\vec{B}/\mu$
$\vec{M} =$	$\chi_m\vec{B}_0/\mu_0$	$\chi_m\vec{H}$	—	Not used
$\vec{B} =$	$(1 + \chi_m)\vec{B}_0$	$\mu_0(1 + \chi_m)\vec{H}$	$\dfrac{\mu_0(1 + \chi_m)}{\chi_m}\vec{M}$	—

EXAMPLE 31–1 A straight solenoid of diameter 5 cm and length 25 cm is wrapped with 200 turns of wire that carries a current of 5 A. The solenoid is filled with iron, magnetic susceptibility $\chi_m = 5.5 \times 10^3$. Find (a) the magnetic intensity within the solenoid and (b) the magnetic field within the solenoid. (c) By what factor is the magnetic field changed due to the presence of the material?

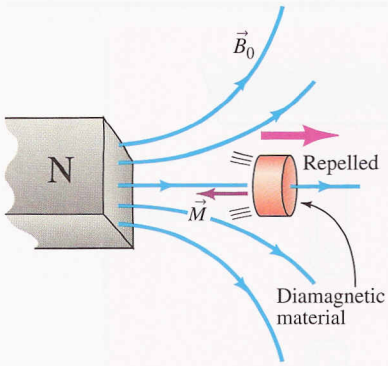
Setting It Up We assign labels of the known and unknown quantities: The current is I, the number of turns of wire per unit length is n, the magnetic intensity has magnitude H, and the magnetic field has magnitude B.

Strategy The first step is to calculate the magnetic intensity $H = B_0/\mu_0$, where B_0 is the magnetic field associated with the free currents in the solenoid. This is given by $B_0 = \mu_0 nI$, so that $H = nI$. We can then calculate $B = \mu H$, using, for example, Eqs. (31–8) and (31–7), and hence the factor by which the field changes due to the material in the solenoid. The diameter of the solenoid does not enter here, except to confirm that the solenoid is long compared to its width, so that our formulas for ideal solenoids apply.

Working It Out (a) With $n = (200 \text{ turns})/(25 \text{ cm}) = 800 \text{ turns/m}$, and $I = 5$ A,

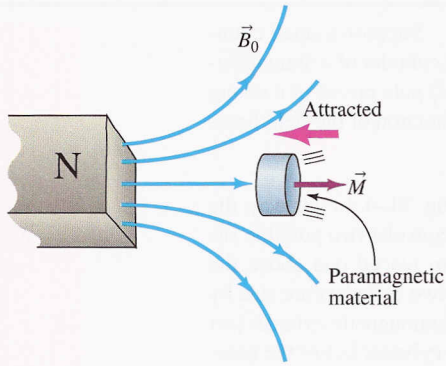
$$H = nI = (800 \text{ turns/m})(5 \text{ A}) = 4000 \text{ A/m}.$$

(b) The magnetic field includes the effect of the field due to the iron that fills the solenoid. We have



$$B = \mu H = \mu_0(1 + \chi_m)H \cong \mu_0\chi_m H$$
$$= (4\pi \times 10^{-7} \text{ T} \cdot \text{m/A})(5.5 \times 10^3)(4000 \text{ A/m}) = 28 \text{ T}.$$

(c) The factor by which the field changes is



$$\frac{B}{B_0} = 1 + \chi_m \cong \chi_m.$$

For a ferromagnetic material such as iron, this is a large factor, and very substantial enhancements of magnetic fields occur using these kinds of materials.

What Do You Think? Do you expect B inside to be (a) larger, (b) smaller, or (c) unchanged if copper were used in the core? *Answers to **What Do You Think?** questions are given in the back of the book.*

▲ **FIGURE 31–2** Diamagnetic substances are repelled by one pole of a nearby bar magnet.

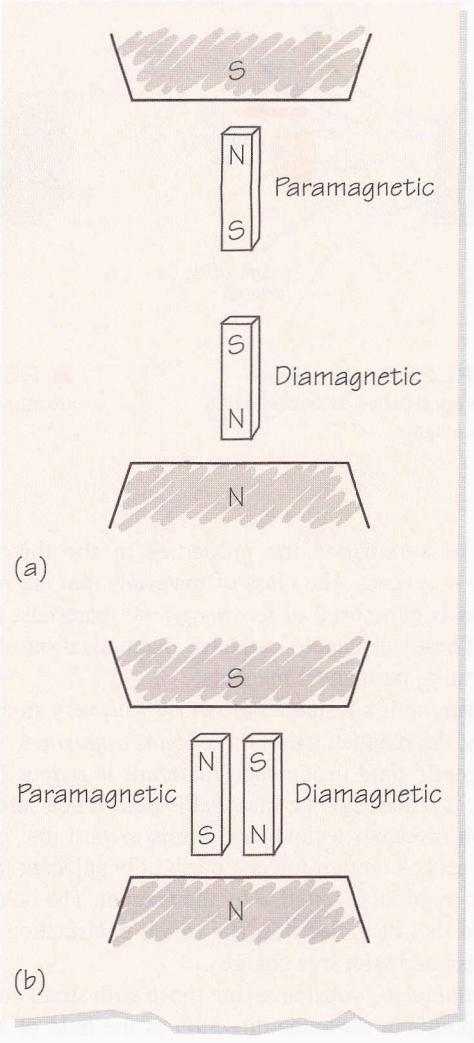
▲ **FIGURE 31–3** Paramagnetic substances are attracted to one pole of a nearby bar magnet.

Let us summarize the properties of the three broad classes of materials that Table 31–1 reveals. The class of materials that are most often used for their magnetic properties is composed of *ferromagnetic* materials, those with large positive susceptibilities. These substances can have magnetization without the presence of an external field, forming permanent magnets.

Diamagnetic substances are those with very small negative susceptibilities. In such materials, the magnetization direction is *opposite* to the direction of the inducing field. The magnetic field inside such materials is *reduced* a little from its value outside the material. If a diamagnetic material is placed near the north pole of a magnet, the magnetization produces a field that points toward that pole (Fig. 31–2). The diamagnetic material acts as though it has a north pole adjacent to the external north pole: The diamagnetic material is *repelled* by the magnet. The behavior of diamagnetic substances is similar to that of dielectrics, for which polarization effects tend to cancel the electric field associated with free charges.

Paramagnetic substances are those with small positive susceptibilities. The magnetization points in the same direction as the field of an external magnet (Fig. 31–3), as though the paramagnetic substance has a south pole oriented toward the magnet's north pole: The piece of paramagnetic material is *attracted* to the magnet.

Table 31–3 gives the forces acting on some samples near a sizable (3.0 T) electromagnet. Only the relative scale of the numbers matters in the table, since we are providing no details about the geometry of the magnet. The force is expressed in units of the weight of each sample. The minus sign reflects repulsion (diamagnetism); the plus sign reflects attraction (paramagnetism and ferromagnetism). Note the differences in the sizes of these forces for the different classes of materials.



We'll discuss the underlying atomic origins of ferromagnetism, diamagnetism, and paramagnetism in Sections 31–3 and 31–4.

TABLE 31–3 • Magnetic Forces on Materials near a Large Electromagnet

Material	Material Class	Force (in units of sample weight)
Copper (pure)	Diamagnetic	-1.3×10^{-3}
Lead	Diamagnetic	-19×10^{-3}
Graphite	Diamagnetic	-56×10^{-3}
Sodium	Paramagnetic	$+10.2 \times 10^{-3}$
Copper chloride	Paramagnetic	$+143 \times 10^{-3}$
Iron	Ferromagnetic	+20
Magnetite	Ferromagnetic	+61

CONCEPTUAL EXAMPLE 31–2 Suppose a small cylinder of a paramagnetic substance and a small cylinder of a diamagnetic substance are placed between the (parallel) pole pieces of a strong magnet, so that they are aligned along the direction of the field lines. Will they attract or repel each other?

Answer We visualize the situation in Fig. 31–4. In this way, the magnetic field lines point upward. We now consider two possible situations, one in which the two cylinders are placed one above the other (Fig. 31–4a) and another in which the two cylinders are side by side (Fig. 31–4b). For case a, we place the paramagnetic cylinder just below the S pole piece and the diamagnetic cylinder below the paramagnetic cylinder. (You can verify that the order does not matter.) The external magnetic field induces magnetism in the paramagnetic substance so that the cylinder acts like a very weak magnet lined up in such a way that the field points up. Thus the top of the paramagnetic cylinder acts like a N pole of a magnet, and the bottom like the S pole of a magnet. The situation with a diamagnetic cylinder is just the opposite. The top of the diamagnetic cylinder acts like the S pole, and the bottom like a N pole. Thus the two S poles of the materials are adjacent, and they repel each other. Figure 31–4b shows that when the two cylinders are placed side by side, they attract.

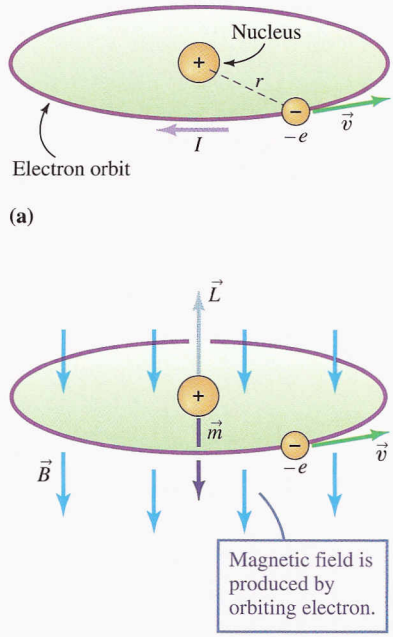
▶ **FIGURE 31–4** In (a) the samples are one above the other; in (b) they are side by side.

31–2 Atoms as Magnets

The magnetic field of a solenoid is the same as that of a bar magnet. How can two such apparently dissimilar systems have the same magnetic field? The answer lies in the magnetic properties of atoms. To understand these properties qualitatively, we start with a classical planetary model for atoms, in which electrons orbit a nucleus, and add some necessary quantum mechanical features. The orbiting electrons form ring currents like those of a solenoid, and the atoms then act as magnetic dipoles, complete with magnetic dipole moments. In most situations, the magnetic moments of a large assembly of atoms point in random directions, so that the net magnetic moment of a macroscopic material adds to zero. The exception occurs in ferromagnetic materials, in which forces between atoms act to line up atomic magnetic moments with their neighbors, giving rise to a net magnetization.

The magnetic properties of individual atoms are affected by a (quantum-mechanical) tendency of their electrons to pair off such that the magnetic moment due to an individual electron's current points in the opposite direction from that of its partner. The net result is that a pair of electrons has no magnetic moment. In a classical picture of the atom as a collection of electrons orbiting about a nucleus, this effect would be interpreted as the cancellation of moments due to clockwise-moving electrons with the moments due to counterclockwise-moving electrons. This suggests that in many cases, atoms with an even number of electrons will have no magnetic dipole moment, whereas only a last unpaired electron makes a difference in atoms with an odd number of electrons.

The Magnetic Dipole Moment of Atoms



Consider the simplest possible *classical* planetary model of an atom, in which a single electron of charge $-e$ moves at speed v in a circular orbit of radius r around a heavy nucleus—as in Fig. 31–5a. The orbital period is $T = 2\pi r/v$. Because electric current is charge per unit time, the current around the nearly stationary nucleus is

$$I = \frac{-e}{T} = -\frac{ev}{2\pi r}. \tag{31–9}$$

The minus sign indicates that the current is in a direction opposite to that of the motion of the electron. The current loop has an area of πr^2; following Eq. (29–27), the magnitude of the *orbital magnetic dipole moment* is therefore given by

$$m_{\text{orbital}} = |I|\pi r^2 = \frac{ev}{2\pi r}\pi r^2 = \frac{1}{2}evr. \tag{31–10}$$

The direction of the magnetic moment vector $\vec{m}$ is determined by a right-hand rule (Fig. 31–5b).

▶ **FIGURE 31–5** (a) An electron in a circular orbit around a nucleus. Over numerous orbits, the effect is the same as a continuous current ring about the nucleus. (b) The circulating electron forms a magnetic dipole with magnetic moment $\vec{m}$ ($\vec{m}_{\text{orbital}}$) oriented downward, opposite to the angular momentum $\vec{L}$.

EXAMPLE 31–3 Estimate an atomic orbital magnetic moment by taking the radius of the electron orbit to be of roughly atomic size, 10^{-10} m, and the kinetic energy to be a typical atomic energy of 1 eV. Compare this to the magnetic moment of a macroscopic loop of area 1 cm^2 that carries a current of 1 mA.

Strategy To use Eq. (31–10) for the magnetic moment, we must first calculate the speed. With the kinetic energy $K = m_e v^2/2$, where m_e is the electron mass, we get $v = \sqrt{2K/m_e}$. Thus

$$m_{\text{orbital}} = \frac{1}{2}er\sqrt{\frac{2K}{m_e}}.$$

The moment of the specified current loop is IA, where A is the area of the loop.

Working It Out If we convert to SI units, our energy estimate of 1 eV is 1.6×10^{-19} J. Thus

$$v = \sqrt{\frac{2(1.6 \times 10^{-19}\text{ J})}{m_e}} \cong \sqrt{\frac{3.2 \times 10^{-19}\text{ J}}{10^{-30}\text{ kg}}} \cong 6 \times 10^5\text{ m/s},$$

where we have used (to the same accuracy as the orbit radius) $m_e \cong 10^{-30}$ kg. Equation (31–10) then gives the magnetic moment

$$m_{\text{orbital}} = \tfrac{1}{2}(1.6 \times 10^{-19}\text{ C})(6 \times 10^5\text{ m/s})(10^{-10}\text{ m}) \cong 5 \times 10^{-24}\text{ A}\cdot\text{m}^2.$$

For comparison, the magnetic moment of the macroscopic loop is

$$m = (10^{-3}\text{ A})(10^{-4}\text{ m}^2) = 10^{-7}\text{ A}\cdot\text{m}^2,$$

which is some 2×10^{16} times larger than the magnetic moment of the single atom.

What Do You Think? We learned in mechanics that in planetary motion, both the light particle (the electron here) and the heavy particle (here, the positively charged nucleus) rotate about the center of mass of the system. Do we need to worry about this complication?

In Example 31–3, we can think of a magnetic dipole moment as due to a circulating charge, with the magnetic moment proportional to the angular momentum of the circulating charge. It is useful to express magnetic moments in terms of angular momentum because angular momentum is a fundamental physical quantity. For an electron in an atom, the orbital magnetic dipole moment [Eq. (31–10)] has the magnitude

$$m_{\text{orbital}} = \frac{1}{2}evr = \frac{e}{2m_e}m_e vr = \frac{e}{2m_e}L, \tag{31–11}$$

where m_e is the electron's mass and $L = m_e vr$ is the angular momentum of the electron in its circular orbit. If we include the vectorial properties of both the angular momentum and the magnetic moment, then Eq. (31–11) becomes

$$\vec{m}_{\text{orbital}} \equiv g_L\vec{L}. \tag{31–12}$$

The coefficient g_L connecting the magnetic moment and the angular momentum is known as the **gyromagnetic ratio**. For the orbital motion, we have just seen that

$$g_L = -\frac{e}{2m_e}. \tag{31–13}$$

The minus sign is present because $\vec{m}_{\text{orbital}}$ and $\vec{L}$ point in opposite directions (Fig. 31–5b).

At this point, we make a necessary leap to a nonclassical atom. According to classical mechanics, the magnitude of the orbital angular momentum depends on the size of the orbit and the velocity of the electron, but in fact atoms cannot be described in this way. Quantum mechanics shows that orbital angular momentum cannot take on a continuous range of values; rather, the magnitude of the orbital angular momentum is limited to the values $\ell\hbar$, where $\hbar = 1.05 \times 10^{-34}\ \text{J}\cdot\text{s}$ is a constant that appears in all aspects of atomic physics and ℓ is a positive integer (or zero).[†] When we use this restriction in Eq. (31–12), we find that this also places restrictions on the possible values of the magnetic moment:

$$m_{\text{orbital}} = \left(\frac{e\hbar}{2m_e}\right)\ell \equiv m_B\ell. \tag{31–14}$$

The quantity m_B is the **Bohr magneton**, after Niels Bohr, one of the founders of quantum mechanics. Its numerical value is

$$m_B = \frac{e}{2m_e}\hbar = 9.27 \times 10^{-24}\ \text{A}\cdot\text{m}^2. \tag{31–15}$$

This is a value that is characteristic of all magnetic moments on the atomic scale.

In addition to a magnetic moment associated with orbital motion, experiments show that electrons also carry an *internal* magnetic moment that cannot be identified with any real current. *The electron itself behaves as a tiny magnet!* This is another quantum phenomenon, one with no analog in classical physics. As a consequence, we must add the contribution of the electron's *intrinsic magnetic moment*, $m_{\text{intrinsic}}$, to the orbital magnetic moment. The value of $m_{\text{intrinsic}}$ turns out to be approximately m_B to an accuracy of 0.1%.

Bulk Effects Are Due to the Alignment of Atomic Magnetic Dipoles

The magnetic field of an individual atom is tiny compared to the magnetic field of a bar magnet. But there are so many atoms that if all the atomic magnetic moments were perfectly aligned in a material, we would have a truly huge effect. As Example 31–4 shows, the alignment of the atomic magnetic moments need be only very slight to produce noticeable bulk effects.

EXAMPLE 31–4 Consider 1 mol of atoms with individual magnetic moments $m_0 = 10^{-23}\ \text{A}\cdot\text{m}^2$. Assume that the magnetic moments can point only in the $+z$- and $-z$-directions, with a fraction f pointing "up" and a fraction $1 - f$ pointing "down." What value of f gives the same magnetic moment as a 1-cm^2 wire loop that carries a current of 10 mA?

Strategy The total magnetic moment is the vectorial sum of individual magnetic moments $m_0 = 10^{-23}\ \text{A}\cdot\text{m}^2$. In this case the vectors that represent the individual moments take only the two directions *up* and *down*. Thus with altogether N_A atoms in a mole, where N_A is Avogadro's number 6×10^{23}, the total magnetic moment is the algebraic sum of fN_A moments with a plus sign (pointing up) and $(1 - f)N_A$ identical moments with a minus sign (pointing down). This must match the magnetic moment IA of the wire loop, where A is the area of the loop and I is the current running through it. We can then solve this equation for f.

Working It Out The relation above reads

$$m_{\text{tot}} = N_A f m_0 - N_A(1 - f)m_0 = N_A m_0(2f - 1) = IA.$$

Solving this relation for f, we find

$$f = \frac{1}{2}\left(1 + \frac{IA}{N_A m_0}\right).$$

Numerical evaluation gives

$$f = \frac{1}{2} + \frac{(10^{-2}\ \text{A})(10^{-4}\ \text{m}^2)}{2(6 \times 10^{23}\ \text{atoms})(10^{-23}\ \text{A}\cdot\text{m}^2/\text{atom})}$$
$$= \frac{1}{2} + (8 \times 10^{-8}).$$

In other words, a departure from complete randomness ($f = \frac{1}{2}$) of only one part in 10 million leads to macroscopic effects.

What Do You Think? Suppose we place the atoms between the poles of a magnet. The magnetic field will to some degree line up the magnetic moments so that they tend to point in the direction of the magnetic field. Why don't we expect f to be 1 in this case?

[†]We would have to refine this further to be in accord with the full predictions of quantum mechanics; for now this is a sufficiently good description of the situation.

CONCEPTUAL EXAMPLE 31–5 Take a bar magnet 30 cm long and cut it into two 15- cm pieces. On the basis of our understanding of the magnetism of materials, would you predict that the magnetization of the two pieces is (a) larger, (b) smaller, or (c) comparable to the magnetization of the original magnet?

Answer If we use the simple model of a magnet treated in Example 31–4, we see that net magnetism is a consequence of a small imbalance between atomic magnetic moments pointing *up* and *down*. There is no reason to believe that this imbalance is in any way distributed inhomogeneously throughout the sample, so that the fraction f discussed in Example 31–4 should be the same across different parts of the sample. Since the magnetization is the magnetic moment per unit volume, the size of any pieces is not relevant—magnetization is an intensive quantity. We thus expect the magnetization of the two pieces to be the same as that of the single larger piece from which they came.

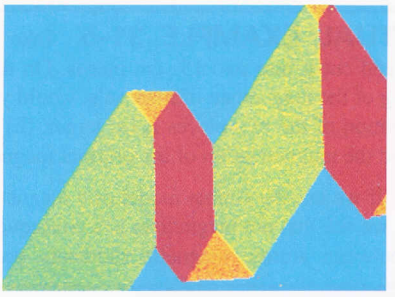
THINK ABOUT THIS. . .

WHY AREN'T MOST MATERIALS MAGNETIC?

We saw in Example 31–4 that only a small deviation from randomness leads to significant bulk effects provided that individual atoms or molecules have *some* magnetic moment (as indeed they do). Some random fluctuation of this size might then produce macroscopic effects. But in fact the "small" deviation in the example is not so small. In statistics, $\sqrt{N}$ is a typical fluctuation from the mean when N objects or events are involved. Thus in a sample of 10^{24} atoms, statistical fluctuations away from an average magnetic moment of zero will lead, on average, to an excess of only 10^{12} atoms pointing, say, up. This translates to a fraction $f = 10^{12}/10^{24} = 10^{-12}$ of atoms pointing up, and this corresponds to a net magnetic moment much smaller than the one we saw in Example 31–4. It is only when there are forces between atoms that cause neighboring atoms to line up with each other that we form permanent magnets. ■

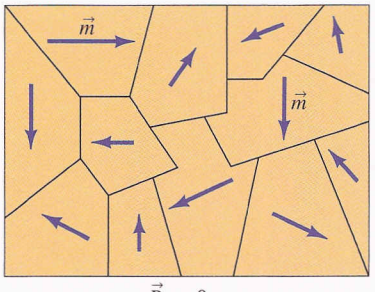
The Connection Between Microscopic and Macroscopic Quantities

We have seen that a piece of material will have significant magnetization if the directions of the magnetic dipole moments of its many component atoms or molecules are not completely random. In that case, the vector sum of the atomic magnetic moments will not be zero. If we divide the vector sum of the magnetic moments by the number of atoms, we get an *average* magnetic moment $\vec{m}_0$ per constituent (atom or molecule). The magnetization is then



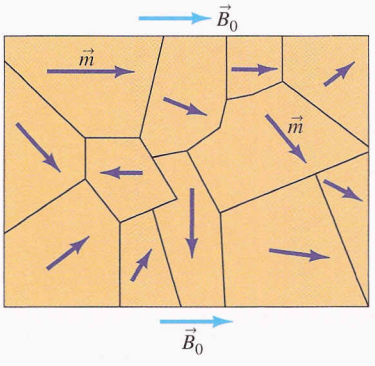
$$\vec{M} = n\vec{m}_0, \tag{31–16}$$

where n is the number of constituents per unit volume. Once we have determined $\vec{M}$, we can determine the other bulk magnetic properties from the discussion in Section 31–1.



31–3 Ferromagnetism

Ferromagnetic materials, which include the elements iron, cobalt, nickel, gadolinium, and dysprosium, together with their alloys, can have large permanent magnetizations, and the direction and size of the magnetization can be set by an external magnetic field. These materials and their properties come into play every time you use computer memory or a credit card, as well as throughout the electrical transmission network.



In ferromagnetic materials, the intrinsic magnetic dipole moments of the electrons in atoms align themselves to some degree and lead to large magnetic effects. The explanation for the alignment of the intrinsic magnetic moments, which was suggested in 1928 by Werner Heisenberg, is purely quantum mechanical—there is no classical mechanism that results in a sufficiently strong alignment. As a consequence of the quantum-mechanical exclusion principle (see Chapter 26), electrons with parallel *intrinsic* magnetic moments arrange themselves in ferromagnetic materials in orbits that tend to maximize the distance between them. This reduces the potential energy of Coulomb repulsion between them and makes a state with parallel magnetic moments a state of lower energy. As a result, there is a preference based on energy for the intrinsic magnetic moments of electrons to line up parallel with one another. This argument shows that the forces that tend to keep the magnetic moments parallel are electrostatic forces rather than the much weaker magnetic forces, and this explains why ferromagnetic materials must be heated to hundreds of degrees Kelvin before they become demagnetized.

▶ **FIGURE 31–6** Photomicrograph of magnetic domains in a sample of iron with 3 percent silicon. A strong net magnetic field is associated with each domain. Domains with different orientations appear in different colors.

(a)

(b)

▲ **FIGURE 31–7** (a) Domain formation in ferromagnetic materials in the absence of an external magnetic field. The arrows indicate the magnetic moments of individual domains. (b) The presence of an external magnetic field influences the domains, making some larger and realigning others.

The intrinsic magnetic moments of the unpaired electrons of different atoms—for example, each iron atom has two such electrons—do not ordinarily become aligned *throughout* a piece of ferromagnetic material. Rather, the alignment takes place between adjacent atoms in regions called *magnetic domains*, which may contain 10^{17} to 10^{21} atoms and occupy a volume on the order of 10^{-12} to $10^{-8}\ \text{m}^3$ (volumes from 0.1 mm to 1 mm on a side). The magnetic field within these domains is quite large, but a piece of ferromagnetic material may be made of thousands of such domains, and because each domain will have its magnetization aligned differently, the magnetization of the entire material will average to zero. Figure 31–6, a photograph of iron, clearly shows the boundaries (*domain walls*) between domains. Figure 31–7a is a schematic diagram of the domains showing their individual magnetic moments.

Given the description above, how does a piece of iron gain and maintain a significant magnetization? An external magnetic field $\vec{B}_0$ provides the mechanism that can align the magnetizations of different domains. This field acts in two ways. First, the size of domains with their magnetic moments already aligned with $\vec{B}_0$ may enlarge at the expense of neighboring domains. Second, the magnetic moments of some of the domains may rotate to the direction of $\vec{B}_0$ through an overall realignment of their constituents (Fig. 31–7b). Both of these mechanisms work because a state with a magnetic moment aligned along $\vec{B}_0$ is a state of lower energy.

The process we have described is a little like that of a marching band whose members face in random directions. The band leader orders them to face the same direction but fails to say *which* direction. Influenced by immediate neighbors, small groups of the band may align themselves together, but these groups may not be aligned with each other. If the band leader adds an instruction as to a precise direction, the groups will realign along that direction and there will be uniformity across the entire band.

When a magnet made of ferromagnetic material—we'll refer to this more simply as a ferromagnet—is heated, the increased movement of the atoms leads to a randomization of their orientation and thus to a decrease in the alignment. At the *Curie temperature*, T_c (after Pierre Curie), the randomization is complete, and the material loses its magnetization—it is no longer a ferromagnet. The value of T_c varies from material to material; in iron, $T_c = 1043\text{K}$, in gadolinium, $T_c = 292\text{K}$. Now we drop the temperature again. As T drops below T_c, ferromagnetism appears through a phase change, just as water forms the ordered lattice we know as ice below 273K. The ordering occurs in domains, as described by our marching-band analogy. Thus when the material cools below T_c, it will not act as a permanent magnet, because the domains are randomly oriented. Water supplies another physical example of this behavior. When a lake surface freezes, the freezing takes place in domains rather than as one huge ice crystal.

EXAMPLE 31–6 Estimate the maximum possible magnetization in a piece of iron.

Setting It Up To solve this problem, we require some knowledge about iron: We may know the intrinsic magnetic moment of a single electron, but we also need the knowledge that there are *two* unpaired electrons per iron atom, and both will contribute to the total magnetic dipole moment. In addition, to find the number of electrons per unit volume we also need the number of iron atoms per cubic meter; this is information that can come from the mass density of iron and the atomic weight of iron.

Strategy The maximum possible magnetization corresponds to having *all* the magnetic moments of the contributing electrons lined up—only one domain, with perfect alignment within the domain. The magnetization is then the number of contributing electron magnetic moments in a unit volume, times the individual electron magnetic

moment $m_B = 9.3 \times 10^{-24}\ \text{A} \cdot \text{m}^2$ [Eq. (31–15)]. The number of iron atoms in a cubic meter of iron is

$$n_{Fe} = \frac{N_A \text{ atoms}}{1 \text{ mol}} \frac{1 \text{ mol}}{\text{mass of iron in 1 mol}} \times \text{mass of iron per unit volume},$$

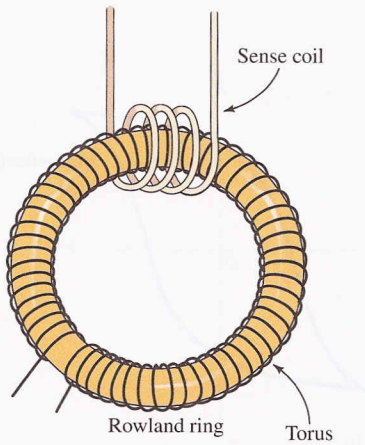
the number of unpaired electrons per atom is twice this value.

Working It Out The mass of iron in 1 mol is 56 g, and the mass density of iron—the third factor on the right in the expression for n_{Fe}—is 7.8 g per $\text{cm}^3 = 7.8 \times 10^6$ g per m^3. Using $N_A = 6.02 \times 10^{23}$, we then find $n_{Fe} = 0.84 \times 10^{29}$ atoms per m^3, hence n = the number of unpaired electrons per $\text{m}^3 = 1.7 \times 10^{29}$. This has to be multiplied by the magnetic moment per unpaired electron to get the maximum magnetization:

$$M_{\max} = nm_B = (1.7 \times 10^{29}\ \text{electrons/m}^3)$$
$$(9.3 \times 10^{-24}\ \text{A} \cdot \text{m}^2 \text{ per electron}) = 1.6 \times 10^6\ \text{A/m}.$$

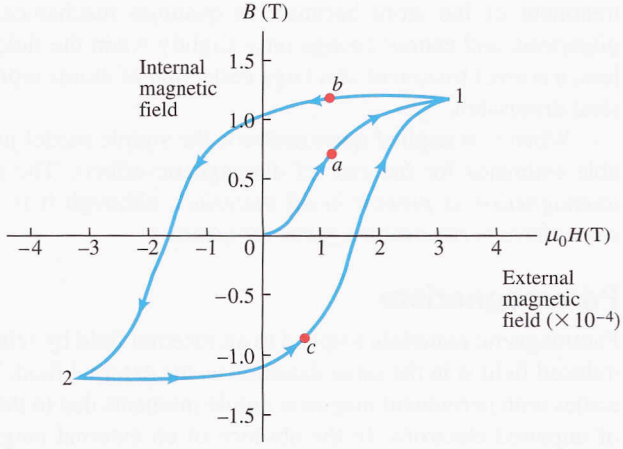
Compare this value to the magnetic dipole moment of the macroscopic loop in Example 31–3—the value found here is quite large by comparison.

What Do You Think? An experimental value of $M_{\max}$ for iron in a particular device is 1.7×10^4 A/m. What does this say about our calculation or about the piece of iron?



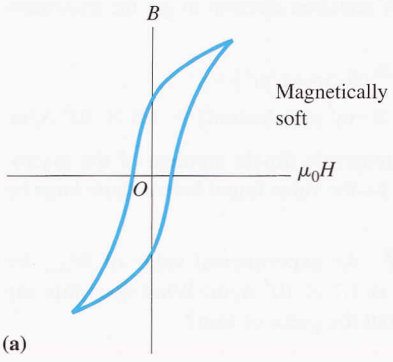
Hysteresis

The relation between the magnetic field B and the magnetic intensity H is more complicated in ferromagnets than in other materials. In order to measure the relation between B and H in a ferromagnetic material, that material is first demagnetized by heating. It is then cooled, shaped into a ring, and wound with a wire that carries a current I. This experimental arrangement is called a *Rowland ring* (Fig. 31–8). Without the ferromagnetic material, the magnetic field inside the ring, or toroidal solenoid, has the nearly constant value

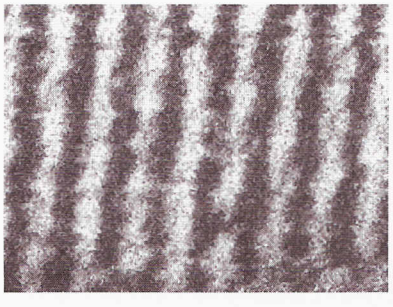


$$B_0 = \mu_0 H = \mu_0 nI, \tag{31–17}$$

provided that the torus is "thin," like a bicycle tire. Here n is the number of windings per unit length. As we know, when the ferromagnetic material is inserted into the torus, the magnetic field increases tremendously to a new value B. We measure B by using a sense coil outside the torus (Fig. 31–8). The sense coil measures an induced emf proportional to the time rate of change of the magnetic field. As we raise the current in the toroidal coil at a given rate, we know the magnetic intensity $H = nI$, and the sense coil measures B. Figure 31–9 shows one example of a measured relation between H and B; a plot of H versus B is called a *magnetization curve*. Knowing H and B, we can determine the magnetization from the relation $B = \mu_0 H + \mu_0 M$.



For ferromagnetic materials, we observe a magnetization curve like that shown in Fig. 31–9; this curve is known as a **hysteresis loop**, and it indicates the phenomenon of **hysteresis**. The presence of hysteresis demonstrates an irreversibility in the magnetization process. When the current I in the solenoid is slightly changed and then changed back again, the original magnetization is generally not recovered. For example, if we start on curve c in Fig. 31–9 at a value of 10^{-4} T for $\mu_0 H$, B in the ferromagnetic material is negative. If $\mu_0 H$ is increased to 3×10^{-4} T and then brought back to 10^{-4} T, B is now positive, following curve b. Hysteresis results from the fact that the magnetic domains do not return to their original zero-external-field status when the current decreases. They "remember" the rise in field and do not automatically revert to their original alignments.



▲ **FIGURE 31–8** A Rowland ring is a wound core (solenoid) of material that may be used to measure the relation between $\vec{B}$ and $\vec{H}$ of that material. A sense coil measures changes in $\vec{B}$.

◀ **FIGURE 31–9** A magnetization curve illustrates the phenomenon of hysteresis in ferromagnetic materials. The material starts at the origin with zero magnetization. When a magnetic intensity H is applied, the material responds by becoming magnetic and is magnetic even when H is again zero.

▲ **FIGURE 31–10** Hysteresis loops for materials that are (a) magnetically soft and (b) magnetically hard.

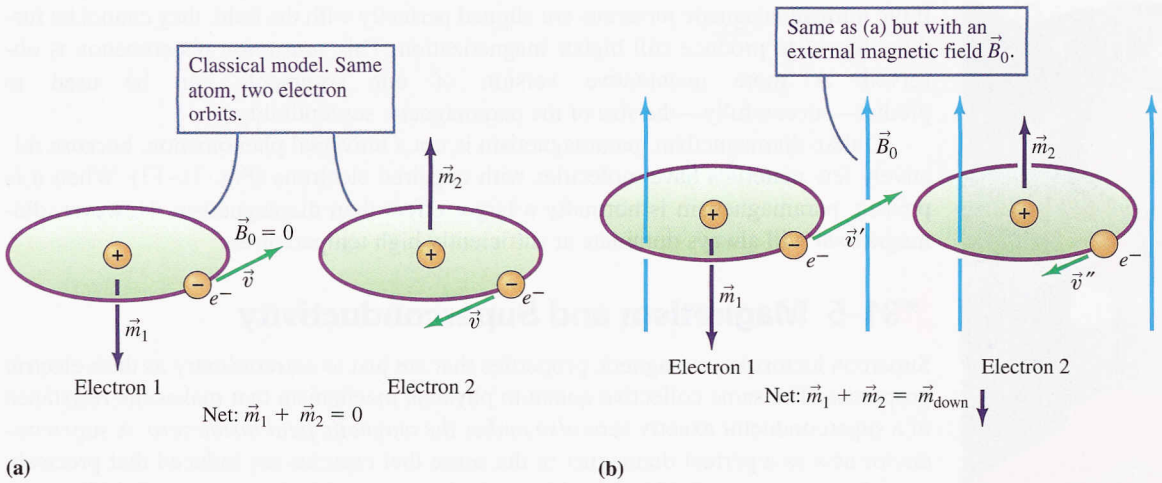
▲ **FIGURE 31–11** Closeup view of the magnetic structure of recording media, here a hard disk. These consist of a series of magnetized regions laid out along grooves. Here the grooves are some 3 nm wide, and the storage density on this still-experimental medium would be 1.7 Gbit/in^2.

Some materials have narrow hysteresis loops, meaning that the alignment of the domains follows the external field rather closely (Fig. 31–10a). This is the type of curve that materials considered *magnetically soft*, such as properly prepared iron, will follow. Such materials are often used in transformer cores. (Transformers are devices that transform AC currents—or voltages—from one value to another.) Other materials have broad hysteresis loops, meaning that their domains respond only to large external fields (Fig. 31–10b). Such materials, including alloys of iron with carbon or tungsten, are said to be *magnetically hard*. They are difficult to magnetize but, once magnetized, they retain much of the magnetization and make good permanent magnets because they are equally difficult to demagnetize. Magnetically hard materials are especially important for making magnetic tapes or memory disks because such materials are stable against changes due to nearby magnetic fields (Fig. 31–11). Which materials are magnetically hard and which are magnetically soft is a complex question whose understanding demands a detailed understanding of atomic and solid state structure.

*31–4 Diamagnetism and Paramagnetism

In this section we'll examine the origin of the phenomena of *diamagnetism* and *paramagnetism*, both generally small but nevertheless significant manifestations of the way materials respond to external magnetic fields.

Diamagnetism



Diamagnetic materials respond to an external magnetic field $\vec{B}_0$ by reducing it slightly; the induced field is *opposite* to $\vec{B}_0$. The resulting net magnetic field is *less* than $\vec{B}_0$. Diamagnetism, as distinguished from ferromagnetism and paramagnetism, occurs as a primary effect in materials whose atoms have no permanent magnetic dipole moments, either orbital or intrinsic, and is also a secondary effect in any material. A classical model helps us to understand the phenomenon qualitatively. Let's consider two electrons with identical orbits, except that the motion is counterclockwise in one and clockwise in the other (Fig. 31–12a). With no external magnetic field, the orbital magnetic moments of the two electrons cancel ($\vec{m}_1 + \vec{m}_2 = 0$), and there is no magnetization.

Now suppose that an applied magnetic field $\vec{B}_0$ perpendicular to the orbits of the electrons is turned on (Fig. 31–12b). For the electron on the left of the figure, the flux through its orbit increases as the external field increases; by Lenz's law, the electron responds to counter the increasing flux. Accordingly, the negatively charged electron speeds up, increasing its angular momentum as well as the magnitude of its orbital magnetic moment $\vec{m}_1$, which points downward. When the external field levels off, angular momentum conservation ensures that the new value of $\vec{m}_1$ persists. Similarly, the electron on the right slows down to oppose the increase in flux through its orbit, so the magnitude of its magnetic moment $\vec{m}_2$, which points upward, is reduced. The result is that $\vec{m}_1 + \vec{m}_2$ now has a net value that points downward, and a magnetic field is produced that opposes the increasing external field. This is the origin of the negative magnetic susceptibility. The classical model must be revised for a proper quantum mechanical treatment of the atom because, in quantum mechanics, the angular momentum is *quantized*, and cannot change only slightly when the field changes slightly. Nevertheless, a correct treatment of a large collection of atoms reproduces the effect of the classical discussion.

When it is applied quantitatively, the simple model just described leads to reasonable estimates for the size of diamagnetic effects. The model correctly implies that *diamagnetism is present in all materials*, although it is masked for materials whose atoms have permanent magnetic moments.

Paramagnetism

Paramagnetic materials respond to an external field by reinforcing the field slightly; the induced field is in the same direction as the external field. These materials contain molecules with permanent magnetic dipole moments due to the intrinsic magnetic moments of unpaired electrons. In the absence of an external magnetic field, these dipoles are

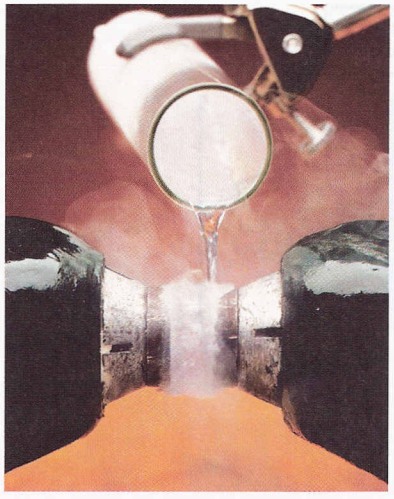
▲ **FIGURE 31–12** (a) A two-electron atom with a net orbital magnetic moment of zero in the absence of an applied magnetic field. (b) In the presence of an applied magnetic field, the orbital magnetic moment associated with each electron is changed, and there is a net magnetic moment that points down, opposite to the external field.

randomly oriented due to thermal motion, and the net magnetization of the materials is zero. Recall from Chapter 28 that the energy of a magnetic dipole moment $\vec{m}$ in a magnetic field $\vec{B}$ is, by Eq. (28–26), $U = -\vec{m} \cdot \vec{B}$. The lowest energy occurs when $\vec{m}$ and $\vec{B}$ are *parallel*. Thus an external magnetic field $\vec{B}$ tends to align the atomic magnetic moments along $\vec{B}$ and produces a positive magnetic susceptibility.

Two effects determine the extent to which the permanent magnetic dipoles become aligned. The first is the external field, which by the energy argument above encourages alignment, and the second is the thermal motion, which randomizes the alignment. The relative importance of these two factors is measured by the relative size of the magnetic energy factor mB and the thermal energy factor kT, where T is temperature. If T is so large that $kT \gg mB$, the average alignment over a large number of electrons will be weak. Conversely, if T is so low that $kT \ll mB$, the average alignment will be strong. For intermediate temperatures and fields, the average alignment is proportional to the ratio of these energies, i.e. to $(mB)/(kT)$. At room temperature, the intrinsic magnetic moments of most paramagnetic materials are only very slightly aligned, but as we already saw in Example 31–4, large bulk effects can come from very small alignments. In 1895, Pierre Curie observed the linear relation that we now call *Curie's law*:

$$\vec{M} = C\frac{\vec{B}}{T}, \tag{31–18}$$

where C is *Curie's constant*, a quantity that varies from one material to another. This law, which holds best for small values of mB/kT, is often expressed in terms of magnetic susceptibility, defined according to Eq. (31–5) as $\vec{M} = \chi_m \vec{H}$. If we anticipate that the susceptibility will be small, as it is for paramagnetic materials, then we can replace $\vec{B}$ in Eq. (31–18) by $\mu_0 \vec{H}$:



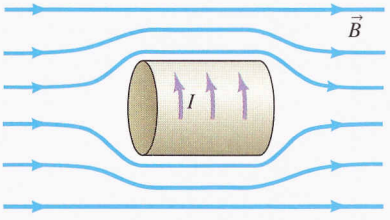
$$\vec{M} = C\frac{\mu_0 \vec{H}}{T},$$

or

$$\chi_m = \frac{\mu_0 C}{T}. \tag{31–19}$$

The value of C depends on the material. The susceptibility is positive, which is characteristic of paramagnetism.

The temperature dependence in Eq. (31–18) is the same as that of the analogous phenomenon for dielectrics [see Eq. (25–30)]. There, too, this dependence is called *Curie's law*. We expect the law to fail at sufficiently low temperatures and/or large fields.



▲ **FIGURE 31–13** Oxygen is paramagnetic and is therefore attracted by the poles of a magnet. Here, liquid oxygen poured between two poles is held in place by the forces between it and the permanent magnet.

If the intrinsic magnetic moments are aligned perfectly with the field, they cannot be further aligned to produce still higher magnetization. This *saturation* phenomenon is observed. A more quantitative version of our arguments can be used to predict—successfully—the size of the paramagnetic susceptibility.

Unlike diamagnetism, paramagnetism is not a universal phenomenon, because relatively few materials have molecules with unpaired electrons (Fig. 31–13). When it is present, paramagnetism is normally a larger effect than diamagnetism. However, diamagnetism will always dominate at sufficiently high temperatures.

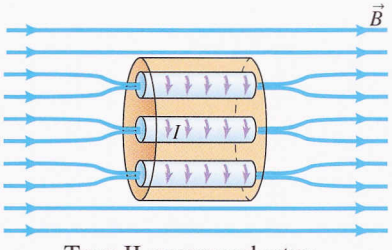
*31–5 Magnetism and Superconductivity

Superconductors have magnetic properties that are just as extraordinary as their electric properties. The same collective quantum physical mechanism that makes the resistance of a superconductor exactly zero *also makes the magnetic field inside zero*. A superconductor acts as a perfect diamagnet in the sense that currents are induced that precisely cancel any magnetic field inside. Alternatively, we say that the magnetic field lines are *expelled* from the superconductor—a phenomenon known as the *Meissner effect*. In fact, superconductors come in two types according to just how the field is expelled: In Type I superconductors, the field is expelled entirely (Fig. 31–14). In Type II superconductors, the field is isolated in nonsuperconducting filamentary structures within the material (Fig. 31–15). Currents circulate on the surfaces of these filaments, shielding the rest of the material from the magnetic field within the filaments. Quantum physics sets a minimum amount of magnetic flux within each filament, and the flux found within any given filament is an integer multiple of this minimum amount. This is yet another example of how physical quantities are quantized in a quantum-mechanical world.

Type I superconductor

▲ **FIGURE 31–14** A Type I superconductor expels magnetic field from its interior by acting as a perfect diamagnet: Surface currents that just cancel the applied field inside are established.

The expulsion of magnetic fields from the interior of a superconductor, whether Type I or II, translates into a statement about its magnetic susceptibility. Equation (31–6) expresses the internal field in terms of the magnetic intensity $\vec{H}$, and this internal field must be zero:



$$\vec{B} = \mu_0(1 + \chi_m)\vec{H} = 0.$$

The magnetic intensity is due to the free currents and is not zero. Thus $1 + \chi_m = 0$, or

$$\chi_m = -1.$$

If there is no magnetic field inside a superconductor, then there can be no currents inside. To see this, imagine that some internal region of a superconductor carries current. Then we can draw a loop around this region and apply Ampère's law. If there were a current through the loop, there would be a magnetic field, but there is no such field. We conclude that *all current carried by superconductors must be carried on their surfaces* (any boundary between superconducting and nonsuperconducting phases). For example, current can be carried on the walls of the filaments in Fig. 31–15.

In the presence of a large enough magnetic field (a *critical field*), a material in a superconducting phase jumps back to the normal (nonsuperconducting) phase even at a fixed temperature, a phenomenon that can cause serious practical problems. For example, many large electromagnets are made from superconductors because they do not undergo Joule heating in spite of the large currents in them. However, the large magnetic field may itself destroy the superconductivity, and one is left with a lot of current in nonsuperconducting wires and a potential meltdown from Joule heating. To overcome this problem, Type II superconductors are generally a better choice for superconducting wires in the electromagnets, because they channel the magnetic field into filaments, providing a way to make superconductors with much higher critical fields.

Type II superconductor

▲ **FIGURE 31–15** In Type II superconductors, the magnetic field is confined to filamentary structures. Inside the filaments, the material is not in its superconducting phase.

*31–6 Nuclear Magnetic Resonance

Atomic nuclei consist of protons and neutrons, far more massive than electrons. Because it is so massive, the orbital motion of the nucleus itself about the atomic center of mass is negligible, and the small size of the nucleus allows us to ignore orbital motions of the protons and neutrons within the nucleus. However, protons and neutrons, like

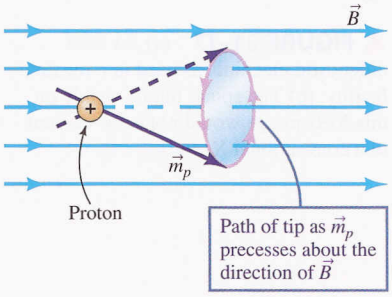
electrons, have intrinsic magnetic dipole moments. These magnetic moments are some 2000 times smaller than that of the electron because protons and neutrons are some 2000 times more massive than electrons [see Eq. (31–15)]. They arise from an intrinsic angular momentum called the *spin* and labeled $\vec{S}$. Unlike the orbital angular momentum, which according to quantum mechanics can occur only in integer multiples of $\hbar$ (Planck's constant, h, divided by 2π), the electron or proton spin has the value $\frac{1}{2}\hbar$. If the proton magnetic moment is labeled $\vec{m}_p$, then as for the orbital angular momentum [see Eq. (31–12)], there is a gyromagnetic ratio g_p that gives the relation between the spin and the magnetic moment,

$$\vec{m}_p \equiv g_p \vec{S}. \tag{31–20}$$

What is the effect of an external magnetic field $\vec{B}$ on the proton? Consider the torque on it due to such a field, given by $\vec{\tau} = \vec{m}_p \times \vec{B}$. Now, the torque on the proton is the rate of change of its internal angular momentum, $d\vec{S}/dt$, so with $\vec{S} = \vec{m}_p/g_p$ we have

$$\frac{1}{g_p}\frac{d\vec{m}_p}{dt} = \vec{m}_p \times \vec{B}. \tag{31–21}$$

This is an equation that gives the rate of change of the magnetic moment of a proton in a magnetic field. As the analysis of this equation in Chapter 10 showed, the magnitude of $\vec{m}_p$ cannot change, but its direction can, and Eq. (31–21) describes the *precessional* motion of $\vec{m}_p$ about the direction of $\vec{B}$ (Fig. 31–16). This precession, called *Larmor precession*, is analogous to the precession of a spinning top under the influence of gravity (see Section 10–8). In a classical picture of Larmor precession, the direction of $\vec{m}_p$ traces a cone around the direction of $\vec{B}$, as in Fig. 31–16. However, quantum mechanics tells us that the analog of only two such cones are allowed: one with spin "up" and one with spin "down." In Problem 41, we find the angular speed of classical precession,

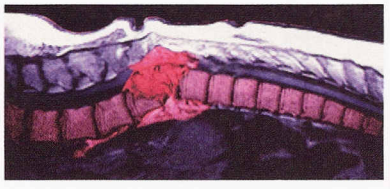


$$\omega_0 = g_p B. \tag{31–22}$$

Finally, let's recall one other feature of this motion: There is a potential energy associated with a magnetic moment $\vec{m}$ in an external field, given by $U = -\vec{m} \cdot \vec{B}$, and the motion with the "up" cone has lower energy than does the motion with the "down" cone.

Now consider exposing the atom to an oscillating magnetic field. (Such a field occurs in electromagnetic waves; see Chapter 34.) This field would normally not have much effect, but when the angular frequency ω of the oscillating field *exactly matches* the angular frequency ω_0 of the precession (a condition known as *resonance* and described in Section 13–8), the direction of the magnetic moment can flip. In this case, the oscillating magnetic field either supplies *just the precise amount of energy*—$2\vec{m}_p \cdot \vec{B}$—necessary to flip the spin of the proton from up to down, or absorbs exactly this amount of energy to flip the spin from down to up.

This effect is called **nuclear magnetic resonance** (**NMR**). When the spin flips due to a transfer of energy between the oscillating field and the proton, there is a detectable signal. Thus, by tuning the frequency of the oscillating magnetic field, we can measure the frequency $\omega_0 = g_p B$ with very high precision.



If the external magnetic field is known, the NMR method may be used to measure the gyromagnetic ratio, g_p. It is in this way that the gyromagnetic ratios for protons and neutrons are known to contain the coefficients 2.79 and -1.91, respectively, multiplying an expression like Eq. (31–13) (but with the proton or neutron mass in place of the electron mass). These coefficients suggest that the internal structures of protons and neutrons are more complicated than that of electrons. NMR measurements can also be extended to nuclei, where they are used to study nuclear structure and the forces that give rise to it. For example, the deuterium nucleus—which may be described as a bound state of a proton and neutron structured in such a way that the intrinsic spins, and therefore the intrinsic magnetic moments, are parallel to each other—is expected to have a magnetic moment that is the sum of the moments of the proton and the neutron. NMR measurements give a slightly smaller result than this sum. It is possible to conclude from this that the deuteron is slightly cigar-shaped, and this gives us information about the forces that bind it.

▲ **FIGURE 31–16** The magnetic moment of a proton, $\vec{m}_p$, precesses about the direction of an external magnetic field with an angular speed ω_0.

(a)

(b)

▲ **FIGURE 31–17** (a) An MRI diagnostic machine, as used in a medical facility. (b) The spinal tumor visible on this MRI image would not be as evident in a conventional X-ray.

THINK ABOUT THIS. . .

WHAT IS MAGNETIC RESONANCE IMAGING?

NMR has important applications in the study of materials and in medical diagnostics, where the procedure is called *magnetic resonance imaging* (MRI). (The word "nuclear" was dropped due to patients' fears that nuclear radiation was being used. In fact, whatever it is called, it is an especially safe procedure.) One knows the value g_p associated with the nucleus of hydrogen, and by placing a complex combination of materials such as a human body within a field whose values vary with position, one can tell by setting up the conditions for spin flip and hence absorption of energy from the field just where there are large numbers of hydrogen atoms—only at locations where the B-field has just the right value will the spin flip occur. In this way MRI locates concentrations of hydrogen atoms in patients. Fat, which has a high concentration of hydrogen, can be distinguished from muscle, which has a much lower hydrogen concentration, and tumors can be distinguished from nerve tissue. Bones have little hydrogen and are hardly seen at all (Fig. 31–17). Before MRI it was difficult to image soft tissues, which don't show in X-rays.

Summary

The magnetic properties of bulk matter are summarized in the magnetization, $\vec{M}$, the magnetic dipole moment per unit volume. In the presence of an external **magnetic field** $\vec{B}_0$, there is a total magnetic field in a material given by

$$\vec{B} = \vec{B}_0 + \mu_0 \vec{M}. \tag{31–1}$$

The effect of free (real) currents (as opposed to the induced atomic effects) is contained in the magnetic intensity, $\vec{H} = \vec{B}_0/\mu_0$:

$$\vec{H} \equiv \frac{\vec{B}}{\mu_0} - \vec{M}. \tag{31–2}$$

The magnetic susceptibility χ_m describes the response of a material to a magnetic field of external origin:

$$\vec{M} \equiv \chi_m \vec{H}. \tag{31–5}$$

The net magnetic field is given in terms of χ_m by

$$\vec{B} = \mu_0(1 + \chi_m)\vec{H} = \mu\vec{H}. \tag{31–6, 31–8}$$

Here, μ is the permeability of the material:

$$\mu = \mu_0(1 + \chi_m). \tag{31–7}$$

Magnetism in matter is due ultimately to the magnetism of its atomic constituents and particularly to the unpaired electrons of atoms. An orbiting electron produces an atomic orbital magnetic moment

$$\vec{m}_{\text{orbital}} = g_L \vec{L}, \tag{31–12}$$

where g_L is the gyromagnetic ratio. Quantum mechanics implies that these magnetic moments take the value

$$m_{\text{orbital}} = \left(\frac{e\hbar}{2m_e}\right)\ell \equiv m_B \ell, \tag{31–14}$$

where the factor m_B is the Bohr magneton and ℓ is an integer. In addition, electrons have intrinsic magnetic moments equal in magnitude to m_B. Even a very slight alignment of atomic magnetic moments leads to large magnetic effects in bulk matter.

Ferromagnetic materials have large permeabilities. The atomic dipole moments are lined up in small regions called domains due to forces of quantum mechanical origin. The imposition of an external field leads to the dipole moments of the domains lining up together and produces permanent magnets. The fact that a ferromagnetic material "remembers" the orientation of the external field that magnetizes it leads to the phenomenon of hysteresis, in which the magnetization curve depends on how the magnetization was produced.

Diamagnetic materials have small negative susceptibilities that are ultimately due to Faraday's law. Diamagnetism is always present but may be masked by paramagnetic or ferromagnetic effects. Paramagnetic materials have small positive susceptibilities due to the intrinsic magnetic moments of

unpaired electrons, which find it energetically favorable to line up with an external field. Paramagnetism is strongly temperature dependent. As well as having no measurable resistance, superconductors also have some remarkable magnetic properties; namely, they completely expel magnetic field from their superconducting regions.

In nuclear magnetic resonance (NMR), the intrinsic magnetic moments of nuclei and nuclear constituents precess about an applied magnetic field. This precession is detected by the response of a material to the imposition of an electromagnetic wave of just the right frequency—a frequency that is characteristic of the material.

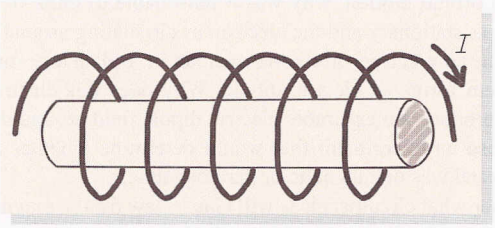
Understanding the Concepts

1. When we calculated the magnetic dipole moment associated with orbital motion, why was it reasonable to think of the nucleus as stationary and the electron as circulating around it?
2. When an electron orbits the nucleus in a planetary model, the system forms an electric dipole. Why does this electric dipole not produce a measurable electric dipole field around the atom?
3. Devise an experiment that would determine whether a certain material was diamagnetic or paramagnetic.
4. Under what circumstances will Gauss' law for the magnetic field also hold for the magnetic intensity?
5. In a Rowland ring measurement of the magnetic field inside a piece of magnetic material, is it helpful to wrap the sense coil around the material many times?
6. Why would speaker coils and computer disks use magnetically hard material, while transformers and computer read/write heads use magnetically soft material?
7. Does iron exhibit diamagnetic properties? How could you determine them?
8. Aluminum is separated in junk yards by using large magnets. How is this possible?
9. Should the magnetic latch on a refrigerator door be made from magnetically hard or soft material?
10. Why should computer floppy disks not be made from magnetically soft material?
11. Why does diamagnetism dominate over paramagnetism in most materials at sufficiently high temperatures?
12. Explain how a permanent bar magnet attracts an unmagnetized iron needle.
13. Will a paramagnetic sample be attracted or repelled from a region of increasing magnetic field?
14. You are given two identical iron rods—one magnetized, the other not. How can you determine which is the magnet, without using a third magnet (for example, Earth)?
15. Suppose that an electron in a circular orbit around a nucleus is placed in an external magnetic field. Will the angular momentum of the electron change if the field is aligned perpendicular to the plane of motion? Parallel to the plane of motion?
16. Is it possible to arrange for a classical current loop to have a magnetic moment but no angular momentum? Assume first that you have both positive and negative charge carriers to work with, and then that you have only negative ones.
17. What is the value of $\vec{H}$ in an isolated permanent magnet?
18. It takes an external field to establish a macroscopic magnetization inside a permanent magnet cooled below its Curie temperature. What could have done this for lodestones, which are permanent magnets found in nature?
19. In a uniform magnetic field, a magnetic dipole experiences no net force, only a torque. How do two bar magnets repel or attract each other?
20. Suppose you are given the magnetic moment due to a single charge orbiting in a circle about a center. Describe qualitatively how you would calculate the magnetic moment of (a) a uniformly charged ring rotating with angular momentum perpendicular to its plane; (b) a uniformly charged disk rotating with angular momentum perpendicular to its plane; and (c) a uniformly charged sphere rotating about an axis through its center.

Problems

31–1 The Magnetic Properties of Bulk Matter

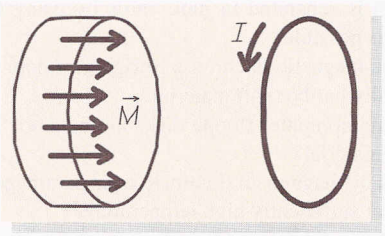
1. (I) A cylindrical rod of palladium (magnetic susceptibility $\chi_m = 8 \times 10^{-4}$), of radius 1 cm and length 5 cm, is placed in and aligned with a uniform magnetic field of 1.0 T. What is the magnetic dipole moment of the rod?
2. (I) A thin, toroidal coil of total length 34 cm is wound with 1600 turns of wire. A current of 0.62 A flows through the wire. What is the magnitude of $\vec{B}$ inside the torus if the core consists of a ferromagnetic material of magnetic susceptibility $\chi_m = 2.8 \times 10^3$? What is the magnitude of $\vec{H}$?
3. (I) The coil of a solenoid wound with a turn density of 3400 turns/m is filled with a material of unknown magnetic susceptibility χ_m. When the wire carries 0.450 A, the magnetic field within is 1.907×10^{-4} T. What is χ_m?
4. (I) A solenoid magnet wound with a turn density of 1300 turns/m, with permalloy inserted inside the windings, has a magnetic field of 3.5 T inside. How much current flows in the windings?
5. (I) A permalloy magnet is 5 cm in diameter, 30 cm long, and has magnetic intensity $\vec{H} = 30$ A/m at its pole. How many turns/m must an empty solenoid of the same dimensions have to give rise to the same intensity if it carries a current of 6 A?
6. (I) What is the magnetic moment of the equivalent solenoid in Problem 5?
7. (I) Earth's magnetic moment is about 10^{23} A · m^2. If the core, which is responsible for the magnetic moment, is about 20% of Earth's volume, what would be the core's magnetization? Assume the core is spherical.
8. (I) The core of a solenoid wound with 400 turns/m is filled with some material. When the current is $I = 3.1$ A, the magnetic field inside the core is measured to be 0.20 T. What is the magnetic susceptibility of the material placed in the core?
9. (I) A toroidal solenoid has a mean outer radius of 8.7 cm with 487 turns of wire. How much current is required to produce a magnetic field of 0.40 T if the solenoid is filled with permalloy?
10. (I) A toroid of core radius of 1.5 cm and toroidal radius of 20 cm is wound with silver wire. There are 1200 turns of wire and a current of 8 A flows through the wire. What is the magnetization per turn of wire?



11. (II) In a vacuum, a solenoid with a current I has a magnetic field B_0. (a) If silver is placed inside the solenoid, what is the change in the magnetic field? (b) What happens if cupric oxide is placed inside the solenoid?
12. (II) A 0.80-cm^3 cube of copper is placed between the poles of a magnet with a magnetic field of 0.48 T. What is the induced magnetization in the copper?
13. (II) A long solenoid filled with ferromagnetic material of permeability $\mu = 1320\mu_0$ is wound with wire so that there are 15 turns per cm. What current must flow through the wire to produce a magnetic field of 0.16 T within the solenoid?

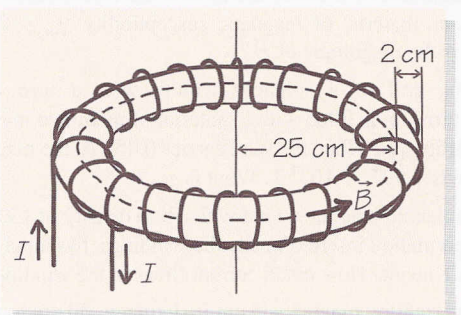
31–2 Atoms as Magnets

14. (I) Suppose that 1 mol of atoms in a material have individual magnetic moments of 1.8×10^{-23} A · m^2. In the absence of any alignment, the magnetic moments form an *average* angle of 90° with some external axis. By how much does the average angle differ from 90° if the material has the same magnetic moment as a 1-cm^2 loop of wire that carries a current of 0.3 A? (The magnetic moment of the loop is aligned with the external axis.) Assume that the components of the atomic magnetic moments add algebraically.
15. (I) The atomic number of iron is 26, its atomic weight is 55.8, and its density is 7.87 g/cm^3. (a) How many electrons are there in 10 cm^3 of iron? (b) Suppose that each electron has the magnetic moment estimated in Example 31–3 (5×10^{-24} A · m^2), and that the magnetic moments "up" and "down" make up the fractions $\frac{1}{2}(1 + 2 \times 10^{-7})$ and $\frac{1}{2}(1 - 2 \times 10^{-7})$, respectively. What is the magnetization of the iron?
16. (II) Consider an electron in a circular orbit around a single proton (a hydrogen nucleus) whose total energy is −13.5 eV. Find the value of the orbital magnetic moment.
17. (II) Consider a ring of radius R rotating about the axis through its center and perpendicular to the plane of the ring with an angular velocity ω. It carries a uniform charge, with charge density λ C/m. What is the magnetic moment of the ring?
18. (II) A disk of radius R rotates with angular velocity ω about an axis through its center, perpendicular to the surface of the disk. The disk carries a uniform charge, with charge density σ C/m^2. What is the magnetic moment of the disk?
19. (II) The electron has a *classical radius* given by $r_0 \equiv e^2/4\pi\varepsilon_0 m_e c^2 = 2.8 \times 10^{-15}$ m. This quantity is suggested by dimensional analysis: The particular combination of classical quantities is the only one that can be formed with dimensions of length. Use Eq. (31–11), with m_{orbital} equal to the Bohr magneton, m_B, to show that any charge at the distance of the classical radius will be moving faster than the speed of light. (Assume that all the charge is concentrated at a belt of radius r_0.) Treatment of the magnetic moment of an electron as a classical quantity leads to trouble!
20. (II) The current I in a circular loop of radius R is due to the flow of free electrons in the loop. Show that the gyromagnetic ratio of the loop is independent of I, R, and the density of atoms.



31–3 Ferromagnetism

21. (I) A torus is wound with 800 turns/m of wire. A current of 5 A runs through the wire. If the core of the torus is iron, the internal magnetic field in the core is 1.8 T. What is the magnetization? What is the value of μ/μ_0 for the iron core?
22. (I) An electromagnet with a ferromagnetic core, $\chi_m = 15{,}000$, produces a maximum magnetic field of 0.36 T. What is the maximum current carried by the coil if the turn density of the coils is 14 turns/cm?
23. (I) A long, tightly wound solenoid contains a magnetic field of magnitude $B = 2.4 \times 10^{-3}$ T. An iron core, with susceptibility χ_m, is inserted so that it fills the space inside. What is the new value of B?
24. (II) We may view the iron core in the previous problem as equivalent to another solenoid that is concentric with the outer one and essentially coincident with it. How could you view the situation if the iron core were quite a bit shorter than the length of the solenoid? If the radius of the iron core were smaller than that of the solenoid? Draw magnetic field lines for these cases.
25. (II) A current of 0.5 A flows through a solenoid with 400 turns/m. An iron bar, with $\mu/\mu_0 = 640$, is placed along the solenoid axis (Fig. 31–18). (a) What is the magnetic field inside the iron bar? (b) Outside the iron bar, but still within the solenoid?

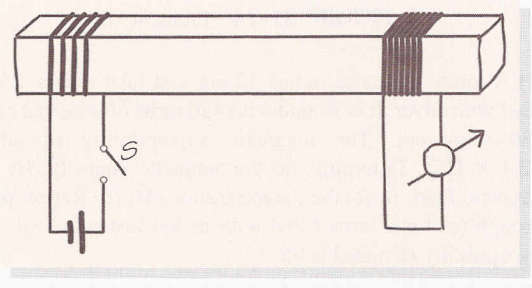


▲ **FIGURE 31–18** Problem 25.

26. (II) A disk-shaped permanent magnet has a thickness of 3 mm and a diameter of 1.5 cm. It is magnetized perpendicular to the plane of the disk, with the magnetic field on the axis near its north pole of magnitude 0.05 T. What is the current carried by a 80-turn coil of the same dimensions that gives this same value of the magnetic field on the axis (Fig. 31–19)?

▲ **FIGURE 31–19** Problem 26.

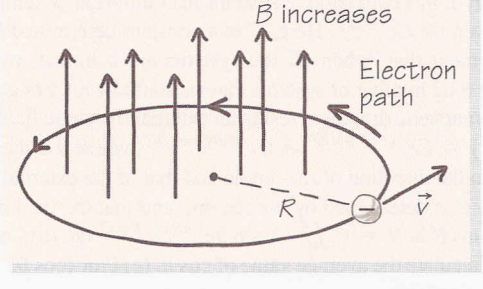
27. (II) A current of 0.16 A is carried by a 50-turn coil 5.5 cm in diameter and 1.0 cm in length. Suppose a piece of iron with susceptibility 4.8×10^3 is placed inside the coil. What is the magnetic field inside the iron? What is the magnetic intensity there?
28. (II) A torus with a central radius of 25 cm and a tube radius of 2.0 cm is filled with iron of permeability $2800\mu_0$ (Fig. 31–20). There are 1200 turns around the torus. How much current must flow in the winding coil to produce a magnetic field of 1.5 T inside the torus? Treat the torus as having a constant magnetic field equal to the field at the central radius of the torus.



▲ **FIGURE 31–20** Problem 28.

29. (II) Iron (susceptibility = 6000) is used as the core of a transformer (see Chapter 33 for a discussion of this device). If large distortions of current are to be avoided, the transformer must be designed in such a way that the proportionality between $\vec{B}$ and $\vec{H}$ applies even for the strongest field. Estimate the maximum allowable value of H, knowing that the magnetic moment of individual iron atoms is $2.2\ m_B$.

30. (II) A Rowland ring measures the charge Q that passes through a sense coil by integrating the current in the sense coil over time (see Fig. 31–8). Both the sense coil and primary coil are wrapped tightly around a material. These coils have an area A. The number of turns in the sense coil is N. The emf induced in the sense coil by a changing magnetic flux in the material (due to a switch that passes current through the primary coil when the switch closes) is $\mathscr{E}$, and the sense coil has resistance R. Obtain a relation between the change in magnetic field, ΔB, and the charge Q. [*Hint*: Remember that $I = dQ/dt$.]



31. (II) A sense coil with a resistance of 0.1 Ω is wrapped tightly in 40 turns around a magnetic material of area 0.02 m^2. When a switch is closed in the primary coil, a charge of 5 mC flows through the sense coil (Fig. 31–21). If the magnetic field was initially zero, what is the new magnetic field in the material? (See Problem 30.)

▲ **FIGURE 31–21** Problem 31.

*31–4 Diamagnetism and Paramagnetism

32. (III) An electron under the influence of some central force moves at speed v_i in a counterclockwise circular orbit of radius R. A uniform magnetic field $\vec{B}$ perpendicular to the plane of the orbit is turned on (Fig. 31–22). Suppose that the magnitude of the field changes at a given rate dB/dt. (a) What are the magnitude and direction of the electric field induced at the radius of the electron orbit? (b) The tangential force on the electron due to the induced electric field increases the electron's speed. Find the value of dv/dt. (c) Assuming that the initial orbital speed was v_i, find the final speed v_f as the magnitude of the magnetic field steadily increases from zero to a final value B_f by integrating dv/dt with respect to time. (d) Using your result for the change in speed, find the change in orbital angular momentum. (e) Use Eq. (31–11) to relate a change in the orbital magnetic moment to the change in the angular momentum.

▲ **FIGURE 31–22** Problems 32 and 33.

33. (III) Refer to Fig. 31–22, but this time assume that the electron circulates clockwise rather than counterclockwise at speed v_i. By applying the same sequence of steps, show that the change in the magnetic moment of the electron's orbit is opposite the direction of change in the external field, just as in the case in which the electron circulates counterclockwise.

34. (III) Refer to Problems 32 and 33. Suppose that there are now two electrons moving at speed v_i in circular orbits of radius R, one clockwise and one counterclockwise. (a) What is the net orbital magnetic moment when the external field is zero? (b) After the external field has reached $\vec{B}_f$? (c) Show that the magnetic susceptibility for this system is $\chi_m = -(\mu_0 e^2 R^2/4m_e)\rho_e$, where ρ_e is the electron density.

35. (III) Using the techniques of Problems 32 through 34, estimate the magnetic susceptibility of copper, which has 29 electrons per atom. Assume that all the electrons move in orbits of the same radius, and that 14 move clockwise while 15 move counterclockwise. You will need to calculate the number density of electrons in copper.

36. (II) The temperature of a sample of $FeCl_3$ (the ferric ions have an intrinsic magnetic moment) inside a magnetic field is held constant as the field is increased. Sketch the induced magnetic moment as the magnetic field is increased.

37. (II) A long, straight conducting wire is embedded within an insulating paramagnetic material of magnetic susceptibility 2.6×10^{-4} at 300K and carries a current of 10 mA. Find the value of the magnetic intensity as a function of the distance from the wire, as well as the magnetic field. What is the change in the magnetic field when the temperature is lowered to 86K?

*31–6 Nuclear Magnetic Resonance

38. (I) Find the magnetic moment of the neutron, given that its gyromagnetic ratio is $-3.82e/2m_n$.

39. (II) Assume that it is possible to align perfectly the magnetic moments of protons in 1 mol of hydrogen gas at standard temperature and pressure. What are the magnetization and magnetic field inside the gas?

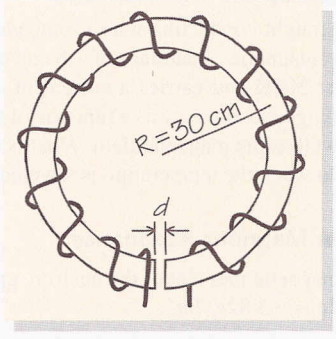
40. (II) In ^{17}O (oxygen with 17 nucleons in its nucleus) the nuclear magnetic moment is $-9.54 \times 10^{-27}\ A \cdot m^2$. The atomic electrons are lined up in such a way that they make no contribution to the magnetic moment of the atom. Suppose it were possible to align the oxygen atoms such that 50.05 percent pointed in one direction and 49.95 percent pointed in the opposite direction. What would be the magnetization of 1 mol of ^{17}O gas under those conditions at standard temperature and pressure?

41. (II) Express the equation $d\vec{m}/dt = g_p \vec{m} \times \vec{B}$ relevant to NMR in component form for the case that $\vec{B} = B\hat{k}$ and $\vec{m} = m_x\hat{i} + m_y\hat{j} + m_z\hat{k}$. (a) Show that m_z is a constant; (b) that $m_x^2 + m_y^2 + m_z^2$ is a constant; and (c) that $m_x = m_1 \cos(\omega t)$ and $m_y = -m_1 \sin(\omega t)$ satisfy the equation of motion, where ω is *the angular frequency of precession*.

42. (II) Archaeological objects are often located by detecting their minute influence on Earth's magnetic field. The equipment used for such measurements is the *proton magnetometer*, which measures the intensity of the magnetic field by measuring the angular frequency of protons in that field. Determine the angular frequency of protons in Earth's field at a typical location ($B = 80\ \mu T$) and the change in frequency caused by a change $\Delta B = 12$ nT.

43. (II) Calculate the frequency of precession (see Problem 42) for a proton's magnetic moment in a field of 10^{-1} T. This frequency is in the so-called rf (radio-frequency) range.

44. (II) Gauss' law for magnetism,



$$\int_{\text{closed surface}} \vec{B} \cdot d\vec{A} = 0,$$

remains unchanged when materials are present because materials do not give rise to magnetic monopoles. Use this law to show that the magnetic field $\vec{B}$ does not change at the interface of two materials if the interface is perpendicular to the direction of the field. [*Hint*: Recall the method used to derive the electric field due to a surface distribution of charges.]

45. (II) If magnetic matter is present, Ampere's law changes to

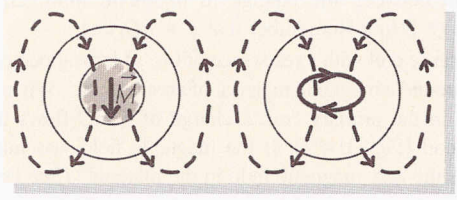
$$\oint (\vec{B}/\mu) \cdot d\vec{s} = \oint \vec{H} \cdot d\vec{s} = I_{\text{enclosed}}.$$

Use this equation to find the magnetic field in a narrow gap cut through the core of a toroidal coil (Fig. 31–23). (The purpose of such an arrangement is to allow samples to be placed within the gap.) The average radius of the torus is 30 cm, $\mu = 1200\mu_0$ for the core material, and the coil consists of 500 turns carrying a current of 8 A. Calculate B for gap widths of 1 mm and 3 cm.

▲ **FIGURE 31–23** Problem 45.

General Problems

46. (II) Estimate the diamagnetic susceptibility of the diamond form of carbon, using the formula derived in Problem 34. Take the density of diamond to be 3.5 g/cm^3; the atomic weight, 12; the atomic number, 6; and the atomic radius, 0.75×10^{-10} m. Assume that all the electrons circulate at this radius. Your estimate should be rather good. Compare this result to that found in Table 31–1.



47. (II) Large magnets typically consist of wound toruses of ferromagnetic material. There is a gap in the torus that forms a space between pole faces. Show that the magnetic field across the pole faces is the same as the magnetic field inside the ferromagnet by applying Gauss' law for magnetism to a closed surface partly in and partly out of one of the pole faces. (Gauss' law for magnetism holds independent of the presence of materials. Its validity rests on the fact that there are no magnetic monopoles, and materials introduce no such animals.)

48. (II) Two parallel conducting strips are each 3.0×10^{-3} m thick and 2.5 cm wide and are separated by a distance of 1.0 cm. The space between the strips is filled with a ferromagnetic material whose permeability is $650\mu_0$. Each strip carries a uniform current of 2.0 A, in opposite directions. Find the value of the magnetic field and magnetic intensity in the space between the strips.

49. (II) Cobalt has atomic mass number $A = 59$, and mass density of 8.7×10^3 kg/m^3. If each atom has a magnetic dipole moment of the order of 1.7 Bohr magnetons, what is the maximum magnetic moment of a cubic centimeter of Co?

50. (II) The magnetic moment of a uniformly charged sphere of radius a and total charge Q rotating with angular velocity ω is $m = Q\omega a^2/5$. A neutral spherical object has a net magnetic moment 0.45μ. If we were to model this by a sphere of charge $-Q/2$ of radius r, surrounded by a spherical shell of charge $+Q/2$ and thickness $a - r$, what is the ratio r/a?

51. (II) Earth's magnetic field is close to that of a dipole, and the strength of the field at the magnetic north pole is about 0.6×10^{-4} T. Calculate Earth's magnetic moment. If this magnetic moment is due to a magnetized iron core whose radius is half Earth's radius, what is the magnetization of the core (Fig. 31–24)? If the magnetic moment were due to a circulating belt of current at the radius of the core, what would be the magnitude of this current (Fig. 31–24)?

▲ **FIGURE 31–24** Problem 51.

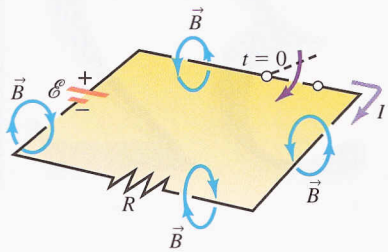
52. (II) A torus of central radius 12 cm and tube radius 1.5 cm is filled with silver. It is wound with 450 turns of wire and carries a 0.80-A current. The magnetic susceptibility of silver is -2.4×10^{-5}. Determine (a) the magnetic intensity, $\vec{H}$; (b) the magnetic field, $\vec{B}$; (c) the magnetization, $\vec{M}$. (d) Repeat parts (a) through (c) for a torus filled with nickel instead of silver. The susceptibility of nickel is 95.

53. (II) In one of two simple classical models of the electron spin, the charge circulates at the classical electron radius r_0 (see Problem 19). In the other, the total electron charge is spread uniformly over a disk whose radius is the classical radius. Calculate the ratio of magnetic moments for the case in which the overall charge occurs entirely at the classical radius versus the case in which the charge is spread over the disk.

54. (II) The neutron has an internal spin $\vec{S}$ of magnitude $\hbar/2$ and a magnetic moment related to the spin by the gyromagnetic ratio g_p, as in Eq. (31–20). The gyromagnetic ratio is $g_p = -3.82(e/2m_n)$. Suppose that a neutron consists of a heavy, positively charged particle of mass M and magnetic moment $e\hbar/2M$, with a lighter, negatively charged particle of mass m but no intrinsic magnetic moment orbiting the heavier particle with orbital angular momentum $\hbar$. What would mass m have to be to explain the observed magnetic moment of the neutron? (For simplicity, ignore the motion of the heavier particle about the center of mass.)

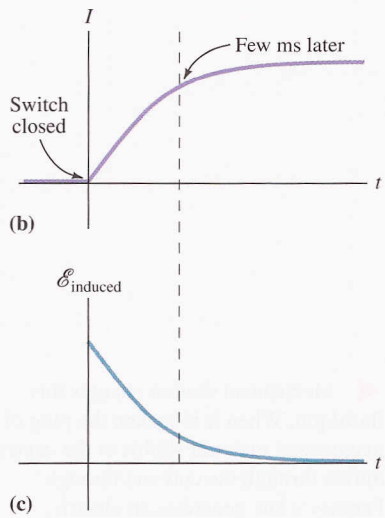
55. (III) In our discussion of kinetic theory (Chapter 19), we noted that, according to Boltzmann, the number of systems with a given energy E in a collection of systems in equilibrium at temperature T is given by $Ce^{-E/kT}$. Here, C is a constant determined by the requirement that, when all the systems are summed, we find the same total number of systems that we started with. For a collection of N magnetic dipoles at rest in an external magnetic field, we have $N(T) = Ce^{-(-\vec{m}\cdot\vec{B})/kT} = Ce^{(mB\cos\theta)/kT}$, where θ is the angle between the direction of the dipole and that of the external magnetic field. C is determined by the requirement that the total number of systems N is $N = C\int_0^{\pi} 2\pi \sin\theta e^{(mB\cos\theta)/kT}\, d\theta$. (a) Calculate C. (b) Calculate the average value of $\cos\theta$. (c) Plot $\langle\cos\theta\rangle$ as a function of mB/kT.

Chapter 32



◀ Mechanical motion charges this flashlight. When it is shaken the plug of magnetized material visible at the center moves through the coil and through Faraday's law generates an electric current. With the addition of a capacitor or small chargable battery this is a flashlight that will never run out on you.

Inductance and Circuit Oscillations



We have already seen that we can store energy in the electric field of a capacitor. Energy can also be stored in a magnetic field, using *inductors* as the circuit elements. Their operation is based on Faraday's law, which describes the phenomena that occur when magnetic fields (or more generally magnetic fluxes) change. These phenomena occur frequently in circuits because so many applications of circuits, from computers to televisions to the functioning of the power grid, involve time dependence in currents and hence in magnetic fields. For this reason, inductors are crucial to the control of time dependence in circuits. We will see that electric circuits containing inductors, capacitors, and resistors are analogous to damped harmonic oscillators, and all the features of such mechanical systems are also seen in these circuits.

32–1 Inductance and Inductors

When you are at home vacuuming the rug, you may see a spark at the wall socket if you accidentally pull the plug from it. Why? This is just Faraday's law at work, holding up the currents that were already flowing. When a circuit contains a *changing* electric current, the magnetic field associated with that current also changes, changing the magnetic flux through the circuit. According to Faraday's law, that means that the circuit's *own* changing current will induce an additional emf in the circuit. Lenz' law tells us that this additional emf will tend to maintain the existing current.

(a)

(b)

(c)

▲ **FIGURE 32–1** (a) When the current in a circuit changes, the flux through the circuit also changes. (b) The current in the circuit increases as a function of time. (c) The induced emf is proportional to the derivative of the current according to Faraday's law.

For example, Fig. 32–1a shows a circuit with a switch that closes at $t = 0$. When as a result the current increases from zero (Fig. 32–1b), the magnetic field around the wire also increases. As the magnetic field grows, the magnetic flux through the area enclosed by the loop increases—in the figure, the flux is directed downward. According to Faraday's law, as formulated by Lenz, an emf is induced in the loop and opposes this increase in flux (Fig. 32–1c). The induced emf *opposes* the emf of the battery and slows down the flow of current. The principle illustrated here is a simple one: *Changing currents in circuits lead to effects that act to reduce the rate of change of those currents.*

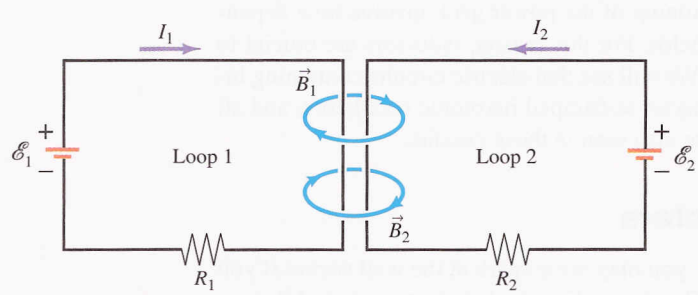
If a second circuit loop is in the general vicinity of the first, there may be a changing magnetic flux through the second circuit due to the magnetic field produced by the first circuit, and a current will be induced in the second circuit. This in turn produces a changing flux that can affect the first circuit, and so forth. In this case, the two circuits are said to be **linked**.

When the first loop induces an emf in itself, we say that there is a **self-inductance**, or **inductance** for short. When the first loop induces a current or emf in a second loop, we say that there is a **mutual inductance** between the two loops. Faraday's law is the principle that lies behind both self-inductance and mutual inductance.

Self-Inductance: When a wire carries a current I, a magnetic field is set up whose strength is proportional to I. In turn, the magnetic flux appearing through a loop of that wire is also proportional to the current. The proportionality constant is defined to be the *inductance* L. L depends on the particular geometry of the loop around which the emf is induced as well as on the number of turns of the loop, and is defined by

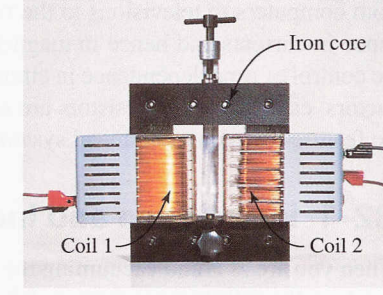
$$\Phi_B = LI. \tag{32–1}$$

If the current and therefore the flux changes, then according to Faraday's law, the emf induced in this loop, $\mathscr{E}$, is the rate of change of the flux through the loop:



$$\mathscr{E} = -\frac{d\Phi_B}{dt} = -L\frac{dI}{dt}. \tag{32–2}$$

EMF BY SELF-INDUCTANCE



The minus sign in this equation is the manifestation of Lenz' law. We will see that the presence of this induced emf can have a marked effect on how charges flow through the circuit.

Mutual Inductance: Let's now consider the two adjacent circuits shown in Fig. 32–2. If a current I_1 flows in loop 1 and a current I_2 flows in loop 2, there is a magnetic flux $\Phi_B(1)$ through the area of loop 1 given by

$$\Phi_B(1) = L_1 I_1 + M_{12} I_2. \tag{32–3}$$

(a)

(b)

▲ **FIGURE 32–2** (a) The flux through a circuit or circuit element may be due to its own current or to the current carried by an adjacent circuit or circuit element. (b) The two coils mounted on the iron core demonstrate mutual induction.

The first term is due to the current flowing in loop 1, and the constant of proportionality L_1 is the self-inductance of loop 1. The second term is due to the current flowing in loop 2 (Fig. 32–3a), and the constant M_{12} is what we define as the *mutual inductance* of loop 1 due to loop 2. Both L_1 and M_{12} are positive by definition. They depend *only* on the geometry of the loop and on the materials in its vicinity, but not on the currents themselves.

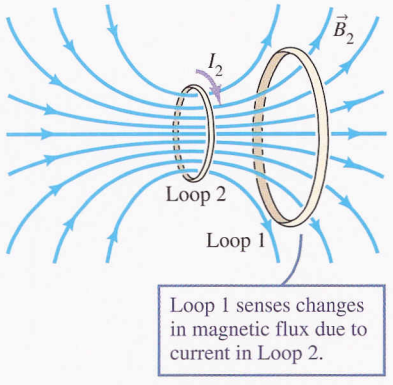
The term *mutual* implies a degree of symmetry between the two loops. The magnetic flux through loop 2 has a term proportional to its own current and also a term proportional to the current in loop 1 (Fig. 32–3b):

$$\Phi_B(2) = L_2 I_2 + M_{21} I_1. \tag{32–4}$$

The second term introduces what might appear to be a new constant, M_{21}, the mutual inductance of loop 2 due to loop 1. We will not provide the proof, which is not simple, but *the mutual inductances are equal*: $M_{12} = M_{21}$. It is customary to drop the subscripts and write $M = M_{12} = M_{21}$, the mutual inductance of two loops.

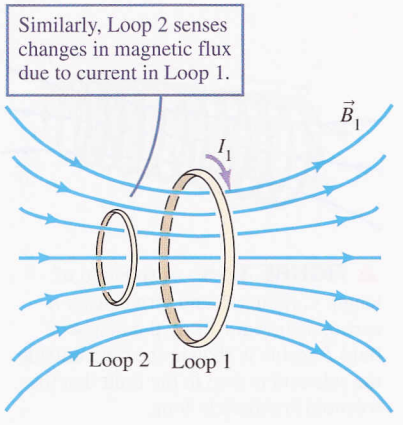
Faraday's law gives the emf induced in loop 2 due to the change in current of loop 1:

$$\mathcal{E}_{21} = -M\frac{dI_1}{dt}. \tag{32–5}$$



EMF BY MUTUAL INDUCTANCE

A similar expression gives the emf induced in loop 1 due to the current in loop 2.



The inductances L and M have SI units of magnetic flux divided by current, or webers per ampere (Wb/A). Inductance is given its own unit in the SI, the **henry** (H), named after Joseph Henry (Fig. 32–4):

$$1\ \text{H} = 1\ \text{Wb/A} = 1\ \text{T}\cdot\text{m}^2/\text{A}. \tag{32–6}$$

To give you an idea of how large a henry is, a cylindrical solenoid of area 10 cm^2, length 20 cm, and a winding density of 10 turns/cm has an inductance of 0.25 mH. An inductance of 1 H is large but not unrealizable; typical values of self- and mutual inductance range from μH to tens of mH. Self-inductance is usually the more important effect in circuits; the role of mutual inductance in linked circuits is most important in *transformers*. These are devices used to change the magnitude of time-varying voltages and are crucial elements of the electric-power distribution system. We shall encounter transformers again in Chapter 33.

(a)

(b)

▲ **FIGURE 32–3** Mutual inductance. (a) There is a magnetic flux through loop 1 due to the magnetic field from the current I_2 in loop 2. (b) There is a magnetic flux through loop 2 due to the current I_1 in loop 1.

◀ **FIGURE 32–4** Joseph Henry, as depicted in a stained-glass window in the First Presbyterian Church of Albany, New York, the site of Henry's baptism. Henry investigated many effects of induction at about the same time as did Faraday.
